Friday, September 9, 2011

Welcome

The Aerosol Society of the UK and Ireland welcomes participants to the 2011 European Aerosol Conference in Manchester, held under the auspices of the European Aerosol Assembly. Aerosol scientists make up a diverse community and meetings such as EAC serve to demonstrate this richness, whilst underlining the connectivity between different branches of the field. This Handbook describes the programme of events, and together with the conference website it should provide most of the information you need. We hope you find the meeting stimulating and valuable.

Ian Ford and Hugh Coe, co-chairs of EAC2011

Committees

Programme committee:

- Ian Ford (chair)
- Charles Clement
- Sophie Cross
- Alan Jones
- John McAughey
- Conor McGrath
- Darragh Murnane
- Simon Parker

Organising committee:

- Hugh Coe (chair)
- Miriam Byrne
- Don Clark
- Sheila Coates
- Ian Colbeck
- Mark Crooks
- Virginia Foot
- Rebecca Hopkins
- Julie Hipperson
- Jessica Perkins
- Steve Preston
- Julie Samson

The international advisory committee, responsible for much of the reviewing of abstracts, consists of the following chairs and co-chairs of the EAA working groups:

- Lucas Alados-Arboledas
- Christof Asbach
- Ari Asmi
- Andrei Bologa
- David Broday
- Jose Castillo
- Charles Clement
- Aladar Czitrovszky
- Johanna Gietl
- Martin Gysel
- Regina Hitzenberger
- Yoshi Inuma
- Martina Krämer
- Francois-Xavier Ouf
- Hanns-Rudolf Paur
- Otmar Schmid
- Olli Sippula
- Wendelin Stark
- Roberta Vecchi
- Elisabetta Vignati
- Birgit Wehner
- Sabine Wurzler
- Caner Yurteri

The European Aerosol Assembly

The European Aerosol Assembly (EAA) consists of 12 national or regional societies across Europe, though membership of these societies is not limited to European nationals. The major activity of the EAA and its working groups takes place at the European Aerosol Conference, held in three out of every four years.

The Aerosol Society

The Aerosol Society held its inaugural meeting in 1986 as a forum for the then embryonic community of aerosol scientists in the UK and Ireland. Hence 2011 is our silver jubilee and the hosting of the European Aerosol Conference is a suitable way to celebrate this 25 year history.

General Information

Venue

The European Aerosol Conference 2011 is being held at the Oxford Road campus, University of Manchester. The major sessions (in particular plenaries and exhibition) take place in the University Place Conference Centre, with parallel oral sessions also in the Schuster Building. The poster sessions will be in the marquee adjacent to the conference centre and in an area adjacent to plenary lecture theatre B.

Transport to the Conference Centre

By taxi

Mantax Taxis 0161 230 3333
Union Cars 0161 225 5566
Black Cabs 0161 227 1888

A typical taxi fare from the Conference Centre to Manchester city centre in a black cab is £4-£6.

By bus

From Piccadilly Railway Station catch the 147 bus (80p per single trip or £1.50 for day ticket) and ask for the University.

From Piccadilly Bus Station catch any of the following buses:
14, 16, 41, 42, 43, 44, 48, 111, 140, 142, 157 and 250
A bus fare costs approx 80p-£1.20 for a single journey.

From Victoria Railway Station, catch the Metro tram to Piccadilly Bus Station and catch one of above services.

From Manchester Airport take bus 43, or a train to Piccadilly or Oxford Road Railway Stations and proceed from there.

Name badges

Upon registration you will receive a name badge which should be worn at all conference events including the social functions. The double sided badge is designed for maximum visibility.

Lunch, coffee/tea and snacks

Coffee/tea points

Refreshments will be available at coffee and tea points in the University Place Conference Centre during the designated morning and afternoon breaks in proceedings. Water will also be available from coolers and from the Eats restaurant.

Lunch boxes

Sandwich lunches will be provided in boxes from the Eats restaurant area during the designated lunch breaks. A vegetarian option will be available. This will be inclusive in the registration fee.

Vending machine/Snacks

Vending machines for crisps/chocolate/drinks can be found in the Williamson Building, to the right of University Place when viewed from Oxford Road. The machines are located on the ground floor facing the

first set of double doors, and on the second floor to the right of the stairwell.
There is a Spar shop which sells snacks, baked goods, groceries, etc, located about 100 metres north along Oxford Road in the University Precinct, which also contains various other food outlets.

Cafeterias/Restaurants

Couture at the Manchester Museum (opposite University Place), from 8am-2.30pm, breakfast and lunch.

Christies Bistro (opposite University Place) from 9am-5pm, breakfast and lunch.

Potters Bar (cafe) Simon Building, Brunswick Street, from 8am-4pm, snacks, breakfast, lunch.

Kro2, 325 Oxford Road Manchester (opposite Student Union), from 8am – 10pm, breakfast, lunch, dinner.

Tai Pan, Cantonese Restaurant 81 Upper Brook Street (top of Brunswick St, turn right).

Internet

A Wi-Fi internet connection is available throughout the conference buildings. Please contact the registration and information desk for a username and password. Desktop connections will be available in George Kenyon Computer Cluster, 9-5pm Monday to Friday (see map page 5).

The conference website www.eac2011.com will carry up to date information about programme changes etc.

Sponsors and Exhibitors

The organisers wish to acknowledge the support of the many exhibitors present at EAC2011. Please visit their stands on the ground floor in the University Place Conference Centre, and consult their entries at the back of this handbook. The exhibitors are listed below:

Air Monitors Ltd	Droplet Measurement Technologies	Particle Measuring Systems
AirModus Oy	Ecotech Pty Ltd	PMT GB
Biotest UK	Enviro Technology Services plc	Surface Measurement Systems Ltd
Biral	Grimm Aerosol Technik	Sunset Laboratory Inc
Cambustion	Matter Aerosol	Topas GmbH
Comde	Meritics	TSI
Copley Scientific Ltd	NPL	URG Corporation
Dekati Ltd	Palas GmbH	Wiley
Digitel		

We are grateful for the financial and administrative support provided by Visit Manchester, the University of Manchester and University College London.

Conference Information

Registration and information desk (during the conference):

General information (outside the conference period)
Sheila Coates
The Aerosol Society
Tel: 01275 849019
Fax: 01275 844877
admin@aerosol-soc.org.uk

Main presentation sessions

The conference will open at 9:00 on Monday 5th September and close at 16:00 on Friday 9th September according to the schedule shown later in this Handbook.

Exhibition

The exhibition is situated in the University Place Conference Centre and is available 8:30 – 18:00 Monday to Thursday and 8:30 – 13:45 on Friday.

Registration and information desk

The registration and information desk will be open at the University Place Conference Centre as follows:
Sunday 4th September: 14:00 – 18:00
Monday 5th September: 08:00 – 18:00
Tuesday 6th September: 08:30 – 18:00
Wednesday 7th September: 08:30 – 13:30
Thursday 8th September: 08:30 –18:00
Friday 9th September: 08:30 –13:30

Certificate of attendance

Certificates will be available by request at the registration and information desk.

Social Programme

Sunday 4th September

Drinks Reception – The Manchester Museum & Whitworth Hall
Address: Oxford Road, Manchester M13 9PL (opposite the University Place Conference Centre)
Time: 18:00 – 20:00.
Delegates are invited to wander through the museum where drinks and canapés will be served. The museum features collections and galleries of animal life, plants, rocks and minerals, prehistoric life, an aquarium and a vivarium. This icebreaker event is included in the registration fee.

Wednesday 7th September

The afternoon is left free for you to explore Manchester. Much tourist information is to be found online, but from a science perspective, the Museum of Science and Industry is well worth a visit. Lab tours at the University of Manchester are also planned.

Thursday 8th September

Conference dinner – Palace Hotel
Address: Oxford Street, Manchester M60 7HA (next to the Oxford Road Railway Station)
Time: 19:00

Menu:

Oyster Bar

*****

Goats cheese crotin with slow roasted roma tomatoes, marinated vegetables and homemade roquette pesto

*****

Breast of chicken, sautéed spring cabbage, smoked bacon, crushed jersey royals, chanteney carrots, thyme & white wine sauce

Vegetarian Option:

Cepe, shallot & grilled asparagus tartlet, baby spinach, sautéed potatoes & salsa verde

*****

Vanilla bourbon pannacotta with peach and champagne syrup, biscotti and berries

English cheeses and oat cakes

Coffee and petit fours

Awards

Smoluchowski Prize

The award will be given by GAeF to a young researcher (as a rule under 40 years of age) who has achieved and published significant new results in aerosol science in the preceding 3 years.

Alan Cussens Memorial Award

Alan Cussens played an important role in setting up the Aerosol Society and served for many years on its committee. He also founded Biral plc, the well known distributor and developer of aerosol instrumentation based in the UK. His untimely death in 2010 is to be marked by the Aerosol Society at EAC2011 through the Alan Cussens Memorial Award, consisting of a prize of £500 and a certificate.

Best Poster Prizes

To recognise excellence in poster presentation, the EAA will award a number of Best Poster Prizes at the conference. The criteria for selection are effective design, clarity of communication and scientific quality. The Prize Committee is chaired by Dr François-Xavier Ouf.

Board meetings

- Journal of Aerosol Science Editorial Board. Monday 5th September 18:00-19:00. Room 2.217 University Place.

- GAeF Board meeting. Tuesday 6th September, 12:00-13:00. Room 2.217 University Place.

- EAA Board meeting. Wednesday 7th September, 12:45:13:45. Room 2.217 University Place.

- Workplace and Indoor Aerosols 2012, Scientific Board meeting. Wednesday 7th September, 13:00-15:00. Blackett Theatre.

- EAA Working Group chairs meeting. Friday 9th September, 12:45-13:45. Room 2.217 University Place.

- Atmospheric Environment Editorial Board. Friday 9th September, 12:00-14:00. Room 3.205 University Place.

Assemblies

GAeF General Assembly. Theatre B, Tuesday 6th September, 18:00-19:00

Aerosol Society AGM. Theatre A, Tuesday 6th September, 18:00-19:00

EAA Working Group meetings

The purpose of these meetings is to discuss general matters within the various topic areas and to help plan future events, particularly the next EAC. All delegates are welcome.

Tuesday 6th September, 17:10-18:00. The following groups meet:

Aerosol Modelling	Theatre A
Aerosol Chemistry	Rutherford Theatre
Aerosol-based Nanotechnology	Blackett Theatre
Atmospheric Aerosols	Theatre B
PMx	Moseley Theatre

Thursday 8th September, 17:10-18:00. The following groups meet:

Fundamentals	Blackett Theatre
Combustion	Rutherford Theatre
Instrumentation	Bragg Theatre
Particle-Lung Interactions	Moseley Theatre
Electrical Effects	Theatre A

Presentation Information

Abstracts

All abstracts will be published in electronic form and distributed to participants on a USB memory stick. Abstracts are arranged in folders by working group and scientific topic and are most easily located by searching for the abstract number. Identifying the slot occupied by a presentation is possible by cross-referencing against the list on the stick and the website ordered by abstract number.

Instructions for oral presentations

Please report to the Oral Presenters' Office 2.219 as far in advance of your presentation as possible to hand in your presentation on a USB memory stick. For organisational reasons, personal laptops cannot be used for presentations. A copy of your presentation will be made available on the PC installed in the appropriate conference room. Speakers are requested to come to their oral session at least 10 minutes prior to its beginning and identify themselves to the chairs.
The time available for oral presentations is 20 minutes (15 minutes for the talk and 5 minutes for discussion).

Instructions for oral reserve presentations

Oral reserve presentations are poster presentations that will also be offered a slot for oral presentation should a vacancy become available. Presenters should check the situation with chairs at the start of the relevant oral session.

Instructions for poster presentations

Posters are displayed in the Poster Marquee in front of the conference centre, and in the space outside Theatre B on the first floor of the University Place building. The poster designation 4P*xyz* or 8P*xyz* indicates board *xyz* in session 4 (Tuesday) or session 8 (Thursday). The location of board *xyz* is indicated on the poster hall plans in this handbook.
– **Poster session A** (4P) on Tuesday 6th September, 10:30 – 12:00.
Posters for this session can be mounted from Monday lunchtime, and left on display until the Wednesday morning coffee break.
– **Poster Session B** (8P) on Thursday 8th September, 10:30 – 12:00.
Posters for this session can be mounted from Wednesday lunchtime and left on display until Friday lunchtime.

Presenting authors are kindly asked to be available to present their posters during the poster sessions. The poster board space is 120 cm high and 100 cm wide. Velcro pads for fixing will be available.

Late-breaking posters

Late breaking posters will be on display on the first floor of University Place, next to the poster area.

Next Aerosol Society Event

Annual Aerosol Science Conference
3rd & 4th April 2012

School of Chemistry, University of Bristol.

The scientific programme will include a broad range of aerosol science topics, including: nucleation, aerosol instrumentation, atmospheric aerosols, aerosol inhalation, etc.

Plenary Speakers:
Professor Gary Martin, Kings College London
Professor Jonathan Reid, University of Bristol

Contact: Sheila Coates, admin@aerosol-soc.org.uk
For a full programme of other meetings, please visit:
www.aerosol-soc.org.uk/

Programme overview

Extra Event

The EAC2011 Satellite Workshop: Aerosols from domestic biomass heating, characterisation and toxicity - Critical pathways towards sustainability of biomass based heating will be held 3-4 September 2011, University Place, Manchester, UK. Organised by the European Aerosol Association and Deutsches Biomasse Forschungs Zentrum gemeinnützige GmbH (DBFZ, German Biomass Research Centre).

Sunday 4th September	14:00-18:00	Registration in the foyer of University Place Conference Centre
	18:00-20:00	Drinks Reception – The Manchester Museum and Whitworth Hall

		THEATRE A	THEATRE B	RUTHERFORD	MOSELEY	BRAGG	BLACKETT
Monday 5th September	09:00-10:00	Opening Ceremony and Plenary 1. Jasper Kirkby: Atmospheric nucleation in the CERN CLOUD experiment - THEATRE B					
		Break

NOTES:

Monday 5th September

09:00-10:00 Opening Ceremony and Plenary 1
Jasper Kirkby: *Atmospheric nucleation in the CERN CLOUD experiment*
Room: Theatre B
Chairs: Ian Ford / Hugh Coe

10:30-12:30 **Session 1A: Ultrafine particles in Urban Areas**
Room: Theatre A
Chairs: Thomas Kuhlbusch / Gary Fuller

10:30	1A1	1075	**Martine Van Poppel**, Vinit Mishra, Patrick Berghmans *Concentrations of UFP in a tunnel in Belgium*
10:50	1A2	85	**Khan Alam**, Majid Hussain, Ahmad Mukhtar, Pierre Madl, Said Rehman, Thomas Trautmann, Thomas Blaschke *Measurement of Atmospheric aerosol size distribution, mass concentration and lung deposition in four cities of Pakistan*
11:10	1A3	657	**Tibor Borsos**, Imre Salma, Tamás Weidinger, Pasi Aalto, Markku Kulmala *Ultrafine particles in various urban microenvironments in Budapest*
11:30	1A4	162	**Noor Yahaya**, Noor Zaitun *Analysing roadside Particle Number Concentrations using Boosted Regression Trees (BRT)*
11:50	1A5	633	**Guy Coulson**, Ian Longley, Woodroe Pattinson, Simon Kingham, Lou Reddish, Gustavo Olivares *Street-to-street variations in PM, PNC and BC in a motorway-dominated urban neighbourhood*
12:10	1A6	560	**Rayk Rinke**, Andreas Wieser, Bernhard Vogel, Ulrich Corsmeier, Christoph Kottmeier *Determination of the spatial variability of particle number concentration, particle size distribution and*

			the concentrations of NO and NO2 in an urban region and the surrounding using one year mobile measurements with the AERO-TRAM
Reserve	1AR	1100	**Holger Gerwig**, Werner Pecher, Klaus Wirtz *Local sources of UFP at an urban BG station*

10:30-12:30 **Session 1B: Aerosol-Cloud Interactions 1**
Room: Theatre B
Chairs: Martina Krämer / David Topping

10:30	1B1	76	**Heike Wex** *Ground-based and airborne examination of particle hygroscopicity at Barbados*
10:50	1B2	212	**Karin Ardon-Dryer**, Zev Levin, Heinz G. Bingemer, Holger Klein *Atmospheric ice nuclei in the Eyjafjallajökull volcanic ash plume over Germany and Israel*
11:10	1B3	619	**Darrel Baumgardner**, Neda Boyouk, Martial Haeffelin *Single particle depolarization studies: Unraveling the mysteries of Paris Fog*
11:30	1B4	686	**Jonathan Reid**, Rachael E.H. Miles, Taina Yli-Juuti, Ilona Riipinen *Factors affecting the molecular flux during evaporation and condensation of water on an aqueous droplet surface*
11:50	1B5	566	**Martin Gysel**, Marie Laborde, Nicolas Bukowiecki, Zsofia Juranyi, Emanuel Hammer, Paul Zieger, Urs Baltensperger, Ernest Weingartner *In situ measurement of cloud droplet activation behaviour of black carbon particles*
12:10	1B6	960	**Paul Connolly**, Tom Choularton, Chris Dearden *Aerosol Cloud Interactions in a deep tropical convective storm, Hector*
Reserve	1BR	462	**Gary Lloyd**, Thomas Choularton and Paul Connolly *Anthropogenic Snowfall Events from Urban Fogs*

10:30-12:30 **Session 1C: Molecular Characterisation of Aerosol Constituents**

Room: Rutherford Lecture Theatre

Chairs: Markus Kalberer / Manabu Shiraiwa

10:30	1C1	488	**Scot Martin**, Qi Chen, Yingjun Liu, Neil Donahue, John Shilling *Measured O:C and H:C Elemental Ratios Constrain the Production Mechanisms of Biogenic Secondary Organic Material*
10:50	1C2	157	**Barbara Noziere** *Reaction products of glyoxal in atmospheric aerosols*
11:10	1C3	748	**Markus Kalberer**, Angela Rincon, Stephen Fuller, Peng Lin, Jianzhen Yu, Celia Alves, Catia Goncalves, Ana Calvo, Heidi Bauer, Anne Kasper-Giebl *Influence of biomass burning on organic aerosol composition - an ultra-high resolution mass spectrometry study*
11:30	1C4	943	**Angela-Guiovana Rincon**, Ana Isabel Calvo, Mathias Dietzel, Christine Braban, Markus Kalberer *S-containing organic components from water soluble fraction of Atmospheric Aerosol Collected in Cambridge and Auchencorth Moss EMP supersite*
11:50	1C5	499	**Johany Ringuet**, Eva Leoz-Garziandia, Helene Budzinski, Eric Villenave *Particulate PAHs and nitro/oxy-PAHs: on sampling degradation and size distribution in the south-west of Paris.*
12:10	1C6	959	**Paul Winkler**, John Ortega, Jun Zhao, Hans Friedli, James Smith *Size resolved nanoparticle composition from SOA formation events*
Reserve	1CR	370	**Lili Tang**, Shengjie Niu, Dantong Liu, Xuwen Li, Xiangzhi Zhang, Shuxian Fan,Hong Nie, Hugh Coe *Size Distribution and Source Analysis of Polycyclic*

			Aromatic Hydrocarbons (PAHs) contained in PM10 in Waliguan and Xining of China

10:30-12:30 **Session 1D: Physico-chemical PM properties**
Room: Moseley Lecture Theatre
Chair: Jordy Vercauteren / Maria Chiara Pietrogrande

10:30	1D1	471	**Maria Chiara Pietrogrande**, Dimitri Bacco, Sara Chiereghin *Simultaneous determination of water-soluble organic tracers in atmospheric aerosol using silyl-derivatization and GC-MS analysis*
10:50	1D2	461	**Marsailidh Twigg**, Chiara Di Marco, Ian Leith, Sara Leeson, Netty van Dijk, Ivan Simmons, Matt Jones, Eiko Nemitz, Neil Cape *Four years of high resolution monitoring of inorganic water soluble aerosol components over a semi-natural ecosystem in South East Scotland*
11:10	1D3	931	**Jose Bothorel-Nicolas** *Aerosol chemical mass closure in Corsica Island: towards a better understanding of the seasonal variation of aerosol sources in the Western Mediterranean*
11:30	1D4	1102	**Mats Gustafsson**, Göran Blomqvist, Eva Brorström-Lundén *PAH in PM10 from tyre and pavement wear*
11:50	1D5	302	**Beatrix Turóczi**, András Hoffer, Nóra Kováts, András Ács, András Gelencsér *Characterization of resuspended and respirable urban particulate matter*
12:10	1D6	353	**Anna Verena Broich**, Lydia Elisabeth Gerharz, Otto Klemm *Personal Monitoring of Exposure to Particulate Matter with a High Temporal Resolution*

10:30-12:30 **Session 1E: Engineered Nanoparticle Release from Nanostructured Materials into the Air**

Room: Bragg Lecture Theatre

Chairs: Heinz Fissan / Keld Alstrup Jensen

10:30	1E1	1135	**Keld Alstrup Jensen**, Ismo K. Koponen *Exposure to nanostructured particles during powder handling and mixing, sanding nanoparticle-doped paints and grinding windmill blades*
10:50	1E2	545	**Burkhard Stahlmecke**, Juri Romazanov, Christof Asbach, Heinz Fissan, Thomas Kuhlbusch *Investigations on (Nano-) Particle Release during Mechanical Treatment of Different Composite Materials*
11:10	1E3	227	**Daniel Göhler**, Lars Hillemann, Michael Stintz *Sanding induced nanoparticle release into air from artificially aged/weathered surface coatings*
11:30	1E4	1137	**Matthias Meier**, M. Mertler, W, Wohlleben *Release of nanoparticles from composite materials under abrasive stress*
11:50	1E5	284	**Albert Hellmann**, Siegfried Ripperger, Markus Berges, Stefan Sticher, Thomas Burkhart *Characterisation of Particles produced by Abrasion of Nanocomposites with a Grinding Machine*
12:10	1E6	490	**Heinz Fissan,** Burkhard Stahlmecke, Christof Asbach, Thomas Kuhlbusch, Karsten Wegner *Strategies for Nanoparticle Release Assessment from Powders, Liquid and Solid Materials into the Environment*

10:30-12:30 **Session 1F: Aerosol Nucleation**
Room: Blackett Lecture Theatre
Chairs: Charles Clement / Yannis Drossinos

10:30	1F1	58	**Hanna Vehkamäki**, Matthew J. McGrath, Theo Kurten, Kari Lehtinen, Markku Kulmala *Rethinking the first nucleation theorem in atmospheric nucleation*
10:50	1F2	693	**Jens Olaf Pepke Pedersen**, Martin Enghoff, Ulrik Uggerhøj, Sean Paling, Henrik Svensmark *Aerosol nucleation induced by a high energy particle beam*
11:10	1F3	674	**Jonathan Duplissy** *Binary sulfuric acid–water nucleation, including ion-induced nucleation mechanism*
11:30	1F4	913	**Brian Steer**, Vinay Ranganathan, Harald Gnewuch, Boris Gorbunov, Fiona Larner *Formation of Zn and ZnO nanoparticles by homogeneous nucleation*
11:50	1F5	1118	**Christopher Hogan**, Ranganathan Gopalakrishnan, Thaseem Thajudeen *A Shape Independent Collision Kernel Valid for All Knudsen Numbers*
12:10	1F6	948	**Joao Almeida-Simoes**, Curtius, Joachim, Kirkby, Jasper and the CLOUD collaboration *Nucleation rates and parametrisation in the CLOUD experiment*
Reserve	1FR	804	**Kimmo Neitola**, David Brus, Mikko Sipilä, Tuija Jokinen, Pauli Paasonen, Heikki Lihavainen *Influence of trimethylamine to sulphuric acid-water homogeneous nucleation*

13:30-15:30 **Session 2A: Bioaerosols**

Room: Theatre A

Chairs: Uli Pöschl / Janine Fröhlich

13:30	2A1	132	**Christoph Haisch**, Kathrin R. Schwarzmeier, Maria Knauer, Reinhard Niessner, Natalia P. Ivleva *Bioaerosol analysis by a combined microarray / SERS (surface-enhanced Raman scattering) approach*
13:50	2A2	454	**Ian Colbeck**, Viswanath Mula, Zaheer Ahmad Nasir, Mark Loeffler *Assessment of bacterial and fungal aerosol in hospital air*
14:10	2A3	1088	**Ulrich Poeschl** *Bioaerosols in the Earth System: Sources, Interactions and Effects*
14:30	2A4	445	**Francis Pope**, Jon-Selous Borlace, Paul Griffiths, Pete Gallimore, Markus Kalberer *Pollen are efficient cloud condensation nuclei*
14:50	2A5	335	**Maosheng Yao** *Development of a Lightweight, Simple and Efficient Exhaled Breath Condensate Collection Device and Method*
15:10	2A6	845	**Jeroen Buters**, M. Thibaudon, M. Smith, C. Galan, R. Brandao, C. Antunes, L. Grewling, A. Uruska, G. Reese, B. Weber, A. Rantio-Lehtimäki, M. Sofiev, S. Jäger, U. Berger, I. Sauliene, Albertini, L. Cecchi *Allergens from Birch, Grass and Olive in ambient air deviate from pollen counts across Europe: the EU-HIALINE project*
Reserve	2AR	330	**Maosheng Yao** *Development of a Lightweight, Simple and Efficient Exhaled Breath Condensate Collection Device and Method*

13:30-15:30 **Session 2B: New Particle Formation 1: Chamber Studies**
Room: Theatre B
Chairs: Jasper Kirkby / Joachim Curtius

13:30	2B1	853	**Siegfried Schobesberger**, Alessandro Franchin, Heikki Junninen, Mikael Ehn, Katrianne Lehtipalo, Stephanie Gagne, Tuomo Nieminen, Markku Kulmala, Douglas R. Worsnop *Measurements of ions and ion clusters in the CLOUD chamber nucleation events by mass spectrometry*
13:50	2B2	1025	**Francesco Riccobono**, Ernest Weingartner, Urs Baltensperger, CLOUD collaboration *Early stage particle growth rates during the CLOUD experiment*
14:10	2B3	701	**Sebastian Ehrhart**, Luisa Ickes, Jan Kazil, Karl D. Froyd, Edward R. Lovejoy, Joachim Curtius *Modelling of ion-induced binary nucleation in the CERN CLOUD experiment*
14:30	2B4	434	**Jens Voigtländer**, Frank Stratmann *Numerical simulation of H2SO4 cycle and new particle formation in the Cern CLOUD chamber*
14:50	2B5	716	**Linda Rondo** *Sulphuric acid measurements by CIMS at the CLOUD chamber and cross-check with independent methods to derive [H2SO4]*
15:10	2B6	767	**Alessandro Franchin** *Physical characterization of ions in the CLOUD chamber*
Reserve	2BR	517	**Einhard Kleist**, Thomas Mentel, Astrid Kiendler-Scharr, Sebastian Broch, Monika Springer, Katja Behnke, Jörg-Peter Schnitzler, Ralf Tillmann, Stefanie Andres, Florian Rubach, Bettina Steitz, Jürgen Wildt *SOA formation from stress induced biogenic VOC emissions and the contribution of isoprene to particle formation and growth – lessons learned from grey poplar trees*

13:30-15:30 **Session 2C: Instrumentation for Chemical Characterisation of Aerosol**

Room: Rutherford Lecture Theatre

Chairs: Jonathan Reid / Ari Leskinen

13:30	2C1	34	**Stefan Georg Gonser**, Andreas Held *Development of a novel aerosol mass spectrometer for nucleation mode particles*
13:50	2C2	324	**Alexander Laskin** *Molecular Characterization of Organic Compounds in Atmospheric Aerosols*
14:10	2C3	673	**Stephen Fuller**, Jenny Nutter, Stephen Platt, Lisa Pfaffenberger, Peter Barmet, Josef Dommen, Urs Baltensperger, Andre Prevot, Markus Kalberer *On-line measurements of particle bound ROS in ambient and combustion aerosols*
14:30	2C4	892	**Scott Noblitt**, Charles Henry, Jeffrey Collett, Susanne Hering, Gregory Roberts *Microchip Electrophoresis Interfaced to a Cloud Condensation Nuclei Collector for Online Monitoring of CCN Chemistry*
14:50	2C5	709	**Jose Ruiz-Jimenez** *Comprehensive GCxGC, a valuable technique for the screening and semiquantitation of different chemical compounds in ultrafine aerosol particles*
15:10	2C6	855	**Peter Mertes**, Josef Dommen, Markus Kalberer, Urs Baltensperger *A new sensitive long-path absorption spectrometer for peroxide measurements in secondary organic aerosol*
Reserve	2CR	537	**Alexander Vogel**, Aline Bayerle, Martin Beck, Mikko Äijälä, Mikael Ehn, Heikki Junninen, Tuukka Petäjä, Douglas Worsnop, Markku Kulmala, Jonathan Williams, Thorsten Hoffmann *Field measurement of secondary organic aerosol in a boreal forest site in southern Finland using on-line soft ionization ion trap mass spectrometry*

13:30-15:30 **Session 2D: Source Apportionment Studies**
Room: Moseley Lecture Theatre
Chairs: Juergen Schnelle-Kreis / Regina Hitzenberger

13:30	2D1	981	**Cozic Julie**, Piot Christine, Jean-Luc Besombes, Jean-Luc Jaffrezo and the Particulair Team *Source apportionments in a multi rural sites experiment in France (Particulair): Seasonality and regional specificities*
13:50	2D2	806	**Michael Bressi**, Jean Sciare, Veronique Ghersi, Nicolas Bonnaire, Sophie Moukhtar, Jose Nicolas, Amandine Rosso, Jean-Eudes Petit, Philippe Lameloise, Anais Feron, Malvina Artufel, Mikael Reynaud *A comprehensive study of the major sources of fine aerosols (PM2.5) in the region of Paris (France): contribution of local versus imported emissions*
14:10	2D3		**Godwin Ayoko** *Multi-criteria ranking and source apportionment of air pollutants*
14:30	2D4	501	**Matthias F.D. Gianini**, Robert Gehrig, Andrea Fischer, Adrian Wichser, Andrea Ulrich, Julie Cozic, Jean-Luc Jaffrezo, Christoph Hueglin *Chemical composition and source apportionment of PM10 at different Swiss locations 2008/2009 compared to 1998/1999.*
14:50	2D5	205	**Jürgen Schnelle-Kreis**, Jianwei Gu, Gülcin Abbaszade, Jürgen Diemer, Ralf Zimmermann *Spatial distribution of ambient particulate matter and source contributions in Augsburg, Germany*
15:10	2D6	392	**Ravindra Khaiwal**, Samantha Lawrence, Ranjeet Sokhi *Source apportionment modelling to quantify atmospheric particle emissions using tunnel measurements*

13:30-15:30 **Session 2E: Gas-phase Synthesis of Nanoparticles**
Room: Bragg Lecture Theatre
Chairs: Robert Grass / Einar Kruis

13:30	2E1	793	**Alexander Stepuk** *Flame-spray derived complex fluoride upconversion nanoparticles*
13:50	2E2	138	**Christian Mehringer**, Benjamin Butz, Erdmann Spiecker, Wolfgang Peukert *Aerosol synthesis of silicon-germanium nanostructures*
14:10	2E3	760	**Henning Förster**, Christian Wolfrum, Wolfgang Peukert *Copper nanoparticle synthesis by an arc evaporation / condensation process*
14:30	2E4	479	**Russell Saunders**, John Plane *Photochemical synthesis of olivine (Mg2xFe2-2xSiO4; 0 <x < 1) nanoparticles*
14:50	2E5	1131	**Adam Boies**, Steven Calder, Pingyan Lei, Steven Girshick *Chemical Kinetic Model of the In-Flight Silica Coating of Nanoparticles by Photo-Induced Chemical Vapour Deposition*
15:10	2E6	830	**Jan Frederik Quaatz**, Marcus Giglmaier, Nikolaus Andreas Adams *Assessment of Size Distribution Models in Coupled 3D CFD Simulations for the Prediction of Nanoparticle Coagulation in Transonic Flows*
Reserve	2ER	151	**Andrei Onischuk**, Anatoly Baklanov, Olga Borovkova, Vladimir Karasev, Stefano di Stasio, Sergey Vosel *Formation of metal nanoparticles from supersaturated vapor (Zn, Bi).*

13:30-15:30 **Session 2F: Aerosol Mobility and Capture**
Room: Blackett Lecture Theatre
Chairs: J. L. Castillo / F-X. Ouf

13:30	2F1	754	**Anastasios Melas**, Athanasios G. Konstandopoulos, Yannis Drossinos *Calculation of the mobility radius of fractal aggregates*
13:50	2F2	442	**Anne Maißer**, Vinay Premnath, Abhimanyu Gosh, Michel Attoui, Chris Hogan *Mobility measurements of electrosprayed protein ions in the sub 10 nm size range*
14:10	2F3	275	**Sarah Dunnett**, Charles Clement *Deposition on fibrous filters in the interception region*
14:30	2F4	685	**Mika Ihalainen**, Terttaliisa Lind, Salih Güntay, Jorma Jokiniemi *Break-up of agglomerated TiO2 particles due to impaction*
14:50	2F5	206	**François-Xavier OUF**, Sun Wenxin, Mourad Kessoum, Dominique Thomas, François Gensdarmes, Pierre Rolland *Characterization of nanoparticles aggregates deposits produced by filtration: influence of aggregates morphology and filtration velocity*
15:10	2F6	308	**Dagmar Koch**, Alfred P. Weber *Transfer of gas-borne carbon nanoparticles onto liquid surfaces*
Reserve	2FR	149	**Virginia Gómez**, C.H. Huang, F. Alguacil and M. Alonso, *Deposition of Nanoparticles on Wire Screens by Diffusion and Image Force*

16:00-18:00 **Session 3A: Bioaerosols / Specific Aerosol Types**
Room: Theatre A
Chairs: J. Schneider / M.R. Alfarra

16:00	3A1	612	**Noa Burshtein**, Naama Lang-Yona, Yinon Rudich *Ergosterol, arabitol and mannitol as tracers for biogenic aerosols in the eastern Mediterranean*
16:20	3A2	1126	**Michael Gatari**, Samuel Gaita, Keith Shepherd, Johan Boman, Sofia Thorsson, Annamarie Wagner *Long range transported mineral dust to the Equatorial Global Atmosphere Watch (GAW) Station on Mt Kenya*
16:40	3A3	329	**Maosheng Yao** *Real-time Detection of Airborne Influenza A Viruses Using Silicon Nanowire Field Effect Transistor*
17:00	3A4	564	**Silvia Becagli**, Rita Traversi, Costanza Ghedini, Silvia Nava, Massimo Chiari, Franco Lucarelli, Giulia Calzolai, Alcide di Sarra, Giandomenico Pace, Daniela Meloni, Damiano Massimiliano Sferlazzo, Carlo Bommarito, Francesco Monteleone, Roberto Udisti *Characterization of aerosol from ship emissions in the Central Mediterranean Sea (Lampedusa island)*
17:20	3A5	437	**Johan Friberg**, Bengt G. Martinsson, Sandra M. Andersson, Carl A. M. Brenninkmeijer, Markus Hermann, Peter P.F. van Velthoven, Andreas Zahn *Particulate Carbon and Sulfur in the Lower Stratosphere*
17:40	3A6	909	**Darius Ceburnis**, Jurgita Ovadnevaite, Russell Greaney, Cinzia Perrino, Jakub Bialek, Baerbel Langmann, Martin Hensch, Harald Berresheim, Colin O'Dowd *New insights into physical and chemical properties of volcanic ash from Eyjafjallajokull eruption during long-range transport*

16:00-18:00 **Session 3B: New Particle Formation 2: Experimental Studies**

Room: Theatre B

Chairs: Birgit Wehner / Michael Boy

16:00	3B1	498	**Imre Salma**, T. Borsos, T. Weidinger, P. Aalto, M. Dal Maso, M. Kulmala *Relationship between new particle formation and pollutant gases in an urban environment*
16:20	3B2	375	**Jovana-Maria Diesch**, Frank Drewnick, Vinayak Sinha, Jonathan Williams, Stephan Borrmann *Influence of key aerosol, trace gas and meteorological parameters on new particle formation in Southern Spain*
16:40	3B3	918	**Michael Pikridas**, I. Riipinen, L. Hildebrandt, E. Kostenidou, H. Manninen, N. Mihalopoulos, N. Kalivitis, J. F. Bukhart, A. Stohl, M. Kulmala, S. Pandis *New particle formation at a remote marine site in the Eastern Mediterranean*
17:00	3B4	455	**Karine Sellegri** *First observations of nucleation of new particles in a volcanic plume*
17:20	3B5	967	**Miikka Dal Maso**, Thomas Mentel, Astrid Kiendler-Scharr, Einhard Kleist, Ralf Tillmann, Mikko Sipilä, Tuukka Petäjä, Jani Hakala, Li Liao, Katrianne Lehtipalo, Heikki Junninen, Mikael Ehn, Joonas Vanhanen, Jyri Mikkilä, Markku Kulmala, Jurgen Wildt, Douglas Worsnop *Nanoparticle formation from sulphuric acid and BVOC oxidation at atmospheric concentrations*
17:40	3B6	280	**Boris Bonn**, Stratos Bourtsoukidis, Boris Bonn, Werner Haunold, Evan Palmer-Young, Jonathan Gershenzon *New particle formation by tobacco plants stressed by ozone: The potential role of mono- and sesquiterpenes*
Reserve	3BR	517	**Einhard Kleist**, Thomas Mentel, Astrid Kiendler-Scharr, Sebastian Broch, Monika Springer, Katja

			Behnke, Jörg-Peter Schnitzler, Ralf Tillmann, Stefanie Andres, Florian Rubach, Bettina Steitz, Jürgen Wildt *SOA formation from stress induced biogenic VOC emissions and the contribution of isoprene to particle formation and growth – lessons learned from grey poplar trees*

16:00-18:00 **Session 3C: Chemical Mechanisms and Transformation Processes in Aerosol**
Room: Rutherford Lecture Theatre
Chairs: Barbara Noziere / Andreas Tilgner

16:00	3C1	692	**Jonathan Reid**, Ben J. Dennis-Smither, Rachael E.H. Miles, Nana-O.A. Kwamena *Evolving morphology, hygroscopicity and volatility of mixed oleic acid/sodium chloride/aqueous aerosol during oxidative aging*
16:20	3C2	858	**Christian Pfrang**, Manabu Shiraiwa, Uli Pöschl *Ozonolysis of oleic acid: mixed systems, oligomerisation and phase changes.*
16:40	3C3	982	**Slowik Jay** *Real-time, controlled OH-initiated oxidation of biogenic secondary organic aerosol*
17:00	3C4	209	**Manabu Shiraiwa**, Yulia Sosedova, Aurélie Rouvière, Hong Yang, Yingyi Zhang, Jonathan P. D. Abbatt, Markus Ammann, Ulrich Pöschl *Long-lived reactive oxygen intermediates in the reaction of ozone with aerosol particles and aerosol health effects*
17:20	3C5	319	**Will Morgan**, James Allan, Michael Le Breton, Jennifer Muller, Carl Percival, Hugh Coe *The power of the dark side: Night-time measurements of aerosol chemical composition in North-Western Europe*
17:40	3C6	135	**Douglas Lowe**, Steven Utembe, David Topping, Gordon McFiggans

			Predictions of Night-time Atmospheric Processes using a Coupled Model of Multi-phase Chemistry and Aerosol Microphysics
Reserve	3CR	185	**Asit Ray**, Venkat Rajagopalan, Eric A. Grulke *Phase transformation of evaporating solution droplets of immiscible polymers*

16:00-18:00 **Session 3D: PMx Data Interpretation**
Room: Moseley Lecture Theatre
Chair: Andre Prevot

16:00	3D1	953	**Robert Wolf**, Claudia Mohr, Monica Crippa, Jay Slowik, André S.H. Prévôt, Urs Baltensperger *Mobile measurements of submicron particulate matter in Central Europe during wintertime inversions*
16:20	3D2	388	**Dominik van Pinxteren** *A GIS based approach to combine back trajectory statistics and land cover analysis for the source apportionment of aerosol constituents*
16:40	3D3	730	**Alessandro Di Menno di Bucchianico**, Giorgio Cattani, Alessandra Gaeta, Giuseppe Gandolfo, Anna Maria Caricchia *To exceed, or not to exceed: are the air quality standards adequate to describe the particulate matter pollution?*
17:00	3D4	601	**Francesco Canonaco**, Jay Slowik, Andre Prévôt, Urs Baltensperger *Long-term on-line measurement of non-refractory submicron aerosol in the city of Zurich*
17:20	3D5	833	**Ernie Weijers**, Martijn Schaap, Lan Nguyen, Jan Matthijsen, Hugo Denier van der Gon, Harry ten Brink, Ronald Hoogerbrugge *Anthropogenic and natural constituents in particulate matter in the Netherlands*

17:40	3D6	463	**Andre Prevot**, Iakovos Barmpadimos, Miriam Nufer, Daniel Oderbolz, Johannes Keller, Sebnem Aksoyoglu-Sloan, Christoph Hueglin *The weekly cycle of ambient concentrations and traffic emissions of coarse (PM10-PM2.5) atmospheric particles*
Reserve	3DR	606	**Tareq Hussein**, Rasha Abu Al-Ruz, Tuukka Petäjä, Heikki Junninen, Dia-Eddin Arafah, Kaarle Hämeri, Markku Kulmala *Local air pollution versus short–range transported dust episodes: a comparative study for submicron particle number concentration*

16:00-18:00 **Session 3E: Aerosol-based Nanotechnology Fundamentals**

Room: Bragg Lecture Theatre

Chairs: Heinz Fissan / Alfred Weber

16:00	3E1	298	**Anna Lähde**, Noora Kokkonen, Antti Karttunen, Sirpa Jääskeläinen, Unto Tapper, Tapani Pakkanen, Jorma Jokiniemi *Chemical vapor synthesis of Cu-Si/SiO2 nanoparticles*
16:20	3E2	220	**Albert Nasibulin**, Marina Timmermans, Antti O. Kaskela, Kimmo Mustonen, Toma Susi, Virginia Ruiz, Simas Rackauskas, Ying Tian, Ilya V. Anoshkin, Sergey D. Shandakov, Esko I. Kauppinen *Applications of single-walled carbon nanotubes synthesised by aerosol CVD method*
16:40	3E3	470	**Scot Martin**, Mikinori Kuwata, Qi Chen *Cloud condensation nuclei (CCN) activity and oxygen-to-carbon elemental ratios following thermodenuder treatment of organic particles grown by α-pinene ozonolysis*
17:00	3E4	101	**Andrei Onischuk**, Sergey Vosel, Peter Purtov *Surface tension of nanosized drops of mono- and bivalent metals*

17:20	3E5	407	**Michel ATTOUI**, M. Chen , P. H. McMurry *Study of Heterogeneous Nucleation upon Nanoparticles in Condensation Particle Counters (CPCs): Effects of Particle and Vapor Composition*
17:40	3E6	354	**Silvan Schmid**, Tom Larsen, Anja Boisen *Particle mass spectrometry based on micro string resonators for the application in portable aerosol monitors*
Reserve	3ER	159	**Bon Ki Ku**, Gregory Deye and Leonid A. Turkevich *Characterizing lengths and aerodynamic diameters of airborne glass fibers*

16:00-18:00 **Session 3F: Thermal and Optical Effects**
Room: Blackett Lecture Theatre
Chairs: P. L. Garcia-Ybarra / David Bones

16:00	3F1	430	**Rory Power**, Jim Walker, Antonia Carruthers, Jonathan Reid *Using holographic optical landscapes to manipulate aerosol arrays, compare particle hygroscopicity and study aerosol coagulation*
16:20	3F2	935	**Manuel Arias-Zugasti**, Daniel E. Rosner *Impact of Temperature Gradients on Brownian Coagulation*
16:40	3F3	975	**Alexander Cheremisin**, Kushnarenko Andrei *Photophoretic interaction of aerosol particles in rarefied gas medium*
17:00	3F4	83	**Konstantin Volkov**, Vladislav Emelyanov *Optical breakdown and detonation in aerosol systems*
17:20	3F5	231	**Edouard Brugiere**, François Gensdarmes, François-Xavier Ouf, Jérôme Yon, Alexis Coppalle *Thermophoresis of non-spherical particle: experimental prospect on soot particles*
17:40	3F6	250	**Yi-Hung Liu**, Graham Calvert, Colin Hare, Mojtaba Ghadiri, Shuji Matsusaka

			Size measurement of dry ice particles in a jet flow using laser diffraction method

Notes:

Tuesday 6th September

09:00-10:00 Plenary 2

Wendelin Stark: *Aerosols for materials: medical and industrial applications and the role of nanotoxicology.*

Room: Theatre B

Chair: John McAughey

10:30-12:00 Session 4P: Poster Session A

Room: Poster Marquee and adjacent to Theatre B

Aerosol Chemistry			
4P1	148	Smog chamber experiments	**Pavel Mikuska**, Martin Vojtesek, Zbynek Vecera, Kamil Krumal, *Semi-continuous system for analysis of water-soluble fraction of metals in atmospheric aerosols*
4P2	358	Smog chamber experiments	**Urmas Hõrrak**, Aare Luts, Tiia-Ene Parts, *Gaseous iodine as a substantial cause of new specific air ions*
4P3	373	Smog chamber experiments	**Zhijun Wu**, L. Poulain, O. Böge, R. Gräfe, H. Herrmann, A. Wiedensohler, Helbig, T. Schröder, J. von Sonntag, I. Hartmann, *Modifications in hygroscopicity and volatility of wood combustion aerosols after chemical aging*.
4P4	421	Smog chamber experiments	**Mijung Song**, Claudia Marcolli, Ulrich K. Krieger, Thomas Peter *Morphology and phase transitions of internally mixed dicarboxylic acids/ammonium sulfate/water particles during hygroscopic cycles*
4P5	487	Smog chamber experiments	**Mukesh Sharma**, Sailesh N. Behera, *Influence of Existing Particle Surfaces on Formation of Secondary Inorganic Aerosols in Fine Mode*
4P7	706	Smog chamber experiments	**Jose Ruiz-Jimenez,** *Influence of the sampling site, the season of the year, the particle size and the number of nucleation events on the chemical composition of atmospheric ultrafine particles*.

4P8	713	Smog chamber experiments	**Jose Ruiz-Jimenez**, *Elucidation of organic volatile compounds in Antarctic aerosol particles. Influence of the nucleation events on the chemical composition of the particles*.
4P9	747	Smog chamber experiments	**Mikael Ehn,** *Ion studies of organic precursor molecules for secondary particle formation*.
4P10	847	Smog chamber experiments	**Mathias Barthel**, S. Seeger, O. Hahn, O. Wilke, W. Horn and O. Jann, *Quantitative and qualitative characterisation of ultrafine particles emitted by laser printing devices*.
4P11	952	Smog chamber experiments	**Ravi Kant Pathak**, K. Salo, T. F. Mentel, R. Tillmann, E.U. Emanuelsson, A. Lutz,M. Hallquist, *Effect of reaction temperature on the volatility of limonene ozonolysis products*.
4P12	1130	Secondary Organic Aerosol - SOA	**Ioan Hoare**, David Stewart, Gemma Brittan, Andrew Russell, Sami Al Mabrok, Marianna Ghosh, Christian Pfrang, George Marston, *The Formation of Secondary Organic Aerosol from Intermediates in the Ozonolysis of α-pinene*.
4P13	1002	Secondary Organic Aerosol - SOA	**Eleni Athanasopoulou**, Heike Vogel, Max Bangert, Christoph Knote, Bernhard Vogel, Ben Murphy, Alexandra Tsimpidi, Spyros Pandis, *Simulating secondary organic aerosol (SOA) formation over Europe using the volatility basis-set approach (VBS) in the online coupled model COSMO-ART*.
4P14	946	Secondary Organic Aerosol - SOA	**Teresa Raventos-Duran**, Marie Camredon, Richard Valorso, Camille Mouchel-Vallon, Sasha Madronich, Julia Lee-Taylor, Bernard Aumont, *Modelling SOA formation from Anthropogenic VOCs using an explicit chemical mechanism*.
4P15	894	Secondary Organic Aerosol - SOA	**Harald Saathoff**, Karl-Heinz Naumann, Ottmar Möhler, Neil Donahue, Thomas Mentel, Ralf Tillmann, Thomas Leisner, *Reaction of OH radicals with secondary organic aerosol from the ozonolysis of alpha-pinene*.

4P16	746	Secondary Organic Aerosol - SOA	**Sergei Dubtsov**, Galina Dultseva, *Gas-to-particle conversion in biogenic aromatic aldehydes and their complexes with heavy metals: a contribution into the biogeochemical cycles of elements*.
4P17	745	Secondary Organic Aerosol - SOA	**Tatyana Maksimova**, Sergei Dubtsov, Galina Dultseva, *Evaluation of the atmospheric aerosol-forming potential of aliphatic and aromatic aldehydes in the presence of nitrogen oxides and/or ozone: modelling and experiment*.
4P18	672	Secondary Organic Aerosol - SOA	**Claudia Keunecke**, Thomas Zeuch, *Observation of decreased final product volatility in the gas ozonolysis of unsaturated carboxylic acids in the absence of oxygen*.
4P19	537	Secondary Organic Aerosol - SOA	**Alexander Vogel**, Aline Bayerle, Martin Beck, Mikko Äijälä, Mikael Ehn, Heikki Junninen, Tuukka Petäjä, Douglas Worsnop, Markku Kulmala, Jonathan Williams, Thorsten Hoffmann, *Field measurement of secondary organic aerosol in a boreal forest site in southern Finland using on-line soft ionization ion trap mass spectrometry*.
4P20	282	Secondary Organic Aerosol - SOA	**Boris Bonn**, Friedemann Ebach, Matthias Hummel, Stratos Bourtsoukidis, Boris Bonn, Werner Haunold, Robert Sitals, *Understanding particle formation by alkene-ozone reactions: Experimental studies and theoretical simulations*.
4P21	359	Monoterpene and isoprene SOA chemistry	**Anke Mutzel**, Yoshiteru Iinuma, Olaf Böge, Ariane Kahnt, Hartmut Herrmann, *Oxidation of nopinone - Influence of relative humidity and particle acidity on particulate products*.
4P22	277	Secondary Organic Aerosol - SOA	**Marco Paglione**, Emanuela Finessi, Stefano Decesari, Astrid Kiendler-scharr, Amewu Mensah, Matteo Stocchero, MariaCristina Facchini, *NMR spectroscopic characterization and factor analysis of the oxidized organic*

			aerosol components in Cabauw, Netherlands, during the May 2008 EUCAARI IOP.
4P23	1015	Molecular characterization of aerosol constituents	**Silvia De Pieri**, Joan Coppola, Elisa Morabito, Carlo Barbante, Andrea Gambaro, *Determination of organic compounds in ultrafine particles*.
4P24	803	Molecular characterization of aerosol constituents	**Ehgere Abidi**, Nicolas Marchand, Anne Monod, Julie Cozic, Jean-Luc Jaffrezo, *Wintertime and summertime source apportionment of PM2.5, using organic compounds as tracers, in a European megacity : Paris*.
4P25	761	Molecular characterization of aerosol constituents	**Roberta Zangrando**, Elena Barbaro, Elisa Scalabrin, Valentina Fellin, Carlo Barbante and Andrea Gambaro, *Microcystins and Bisphenol A in the urban aerosol of the Venice Lagoon*.
4P26	57	Molecular characterization of aerosol constituents	**Celia Alves**, Cátia Gonçalves, Ana Patrícia Fernandes, Luís Tarelho, Casimiro Pio, *PM2.5 emissions from wood combustion in a fireplace and a woodstove: carbon content and inorganic speciation*.
Fundamentals			
4P27	159	General physical properties of aerosols	**Bon Ki Ku**, Gregory Deye, Leonid A. Turkevich, *Characterizing lengths and aerodynamic diameters of airborne glass fibers*
4P28	341	General physical properties of aerosols	**Delphine Lottin**, Daniel Ferry, Jean-Marc Gay, David Delhaye, Jérôme Yon, François-Xavier Ouf, *On methods determining the fractal dimension of combustion aerosols and particle clusters*.
4P30	589	General physical properties of aerosols	**Thaseem Thajudeen**, Christopher J Hogan Jr, *Computationally efficient methods for computing the free molecular and continuum friction factors of non spherical aerosol particles*.

4P31	640	General physical properties of aerosols	**Gerhard Steiner**, Tuija Jokinen, Heikki Junninen, Mikko Sipilä, Georg P. Reischl, Doug R. Worsnop, Markku Kulmala, *Simultaneous Mobility and Mass Determination of Ionic Molecular Clusters produced in a bipolar 241Am Charger*.
4P32	605	Optical properties	**Vladimir Maksimenko**, Vladimir Ignatov, *Optical cloaking and agglomerated fractal clusters*.
4P33	90	Aerosol interaction with surfaces	**Russell Lyons**, *Non conventional indoor model for submicron particulates*.

4P308	955	Aerosol Cloud Interaction	**Bettina Nekat**, Dominik van Pinxteren, Thomas Gnauk, Konrad Müller, Hartmut Herrmann, *The Size- and Time-Resolved Determination of the Water-Soluble Organic Fraction of Submicron Aerosol Particles from the Beijing Area*.
4P310	989	Aerosol Cloud	**Ilona Riipinen**, Jeffrey R. Pierce, Taina Yli-

		Interaction	Juuti, Silja Häkkinen, Christos Fountoukis, Markku Kulmala, Douglas R. Worsnop, Merete Bilde, Spyros N. Pandis, Neil M. Donahue, *On ultrafine aerosol growth and the condensation/evaporation properties of atmospheric organics*.
4P311	993	Aerosol Cloud Interaction	**Su Hang**, Diana Rose, Yafang Cheng, Sachin S. Gunthe, Alfred Wiedensohler and Ulrich Pöschl, *Aerosol hygroscopicity distribution in size-resolved CCN measurements: the concept, validation and applications*.
4P312	1022	Aerosol Cloud Interaction	**Ondrej Vlcek**, L Corbet, J Licki, K Zemankova, *Effect of the biogenic emissions of isoprene and monoterpene on the CAMx model results in Central and South Europe*.
4P314	1117	Aerosol Cloud Interaction	**Ying I. Tsai**, Su-Ching Kuo, Chien-Lung Chen, Li-Ying Hsieh, Pei-Ling Wu, Yi-Hui Lee, *Chemical contribution of dicarboxylic acids to wet deposition and acidity of wet deposition in southern Taiwan*.

13:00-15:00 **Session 5A: PM Sources**

Room: Theatre A

Chairs: Sabine Wurzler / Oliver Bischof

13:00	5A1	1127	**Michael Gatari**, Johan Boman, Sofia Thorsson, Anna Mooe *Particle size distribution, number concentration, CO and sources of aerosol particles in Nairobi, Kenya*
13:20	5A2	838	**Carmen Nickel**, Heinz Kaminski, Bryan Hellack, Thomas A.J. Kuhlbusch *Source apportionment, surface area and particle number concentration analysis of ultra fine particles at an urban background station in the Ruhr area, Germany*
13:40	5A3	973	**Liisa Pirjola**, Aki Pajunoja, Aleksi Malinen, Jari Walden, Jukka-Pekka Jalkanen, Topi Rönkkö *Mobile measurements of ship emissions in two*

			harbour areas in Finland
14:00	5A4	586	**Gary Fuller**, Anja Tremper, Timothy Baker, Karl Espen Yritt, David Butterfield, Ian Mudway, Rosamund Dove, Frank Kelly *Contribution of biomass burning to London's PM10*
14:20	5A5	880	**Barbara D'Anna**, Nicolas Marchand, Jean-Luc Jaffrezo, Chrstian Georgem Olivier Favez, Antoinette Boreave, Melanie Nicolas, Imad El Haddad, Henry Wortham, A. Armengaud, C. Piot, J-L Desombes *Source apportionment of fine aerosol in Marseille and Grenoble*
14:40	5A6	922	**Andreas Massling**, Matthias Ketzel, Thomas Ellermann, Jacob K. Nøjgaard, Bjarne Jensen, Claus Nordstrøm, Peter Wåhlin *Measurements of the urban Copenhagen aerosol from 2002 – 2010: physical properties and their trends*
Reserve	5AR	1100	**Holger Gerwig**, Werner Pecher, Klaus Wirtz *Local sources of UFP at an urban BG station*

13:00-15:00 **Session 5B: Aerosol-Cloud Interactions 2**
Room: Theatre B
Chairs: Martin Gysel / Heike Wex

13:00	5B1	481	**Keith Bower**, Jonathan Crosier, Thomas Choularton, Paul Connolly, Chris Dearden, Martin Gallagher, James Dorsey, Gerard Capes, Chris Westbrook. Zhiqiang Cui, Alan Blyth *Observations and Modelling of Cloud-Aerosol Interaction in Mixed Phase Frontal Layer Cloud*
13:20	5B2	1011	**Di Chang**, Hang Su, Philipp Reutter, Jörg Trentmann, Meinrat O. Andreae, Ulrich Pöschl *The effects of biomass burning aerosols on the formation of convective mixed-phase clouds and precipitation*

13:40	5B3	844	**Martina Krämer**, J. Meyer , A. Afchine, D. Baumgardner, R. Newton, A. Abdelmonem, S. Benz, O. Möhler, M. Schnaiter *Partitioning of drops & ice in mixed phase clouds: laboratory and field observations*
14:00	5B4	857	**Nicolas Bukowiecki** *On the activation and ambient peak supersaturation of CCNs at Jungfraujoch, Switzerland (3580 m asl): Results from the CLACE 2010 campaign*
14:20	5B5	660	**Erik Fors** *Indirect measurement of water vapour supersaturation ratios in continental boundary layer clouds using H-TDMA and DMPS data*
14:40	5B6	980	**Greg Roberts**, S.D. Noblitt, J.M. Creamean, J.L. Collett, C.S. Henry, S.V. Hering, K.A. Prather *Linking CCN chemistry and supersaturation spectra: characterizing cloud-active aerosol in California's Sierra Nevada Mountains*
Reserve	5BR	350	**Anja Roth**, Stephan Mertes, Dominik van Pinxteren, Thomas Klimach, Johannes Schneider, Stephan Borrmann *Analysis of cloud and aerosol particles by single particle mass spectrometry during a hill-cloud-field experiment in Central Europe*

13:00-15:00 **Session 5C: Smog Chamber Experiments and SOA 1**
Room: Rutherford Lecture Theatre
Chairs: Yoshi Inuma / Rami Alfarra

13:00	5C1	802	**Josef Dommen**, Torsten Tritscher, Peter DeCarlo, Peter Barmet, Arnaud Praplan, Ernest Weingartner, Martin Gysel, Andre Prevot, Neil Donahue, Urs Baltensperger *Aging of secondary organic aerosol in a smog chamber*

13:20	5C2	771	**Ari Leskinen**, Kari Kuuspalo, Olli Sippula, Pasi Jalava, Maija-Riitta Hirvonen, Jorma Jokiniemi, Kari Lehtinen *Transformation of diesel exhaust in a new smog chamber*
13:40	5C3	599	**Erik Nordin**, Axel Eriksson, Jonatan Carlsson, Patrik Nilsson, Maija Kajos, Pontus Roldin, Jenny Rissler, Erik Swietlicki, Birgitta Svenningsson, Mats Bohgard, Markku Kulmala, Mattias Hallquist, Joakim Pagels *Smog Chamber Studies on SOA Formation from Gasoline Exhaust and Pure Precursors*
14:00	5C4	988	**Stephen Platt** *Investigations of primary and secondary organic aerosol emissions from mopeds*
14:20	5C5	163	**Eszter Horváth**, András Gelencsér, András Hoffer, Csaba Dobolyi, Flóra Sebok, Sándor Szoboszlay, Balázs Kriszt *Microscopic fungi as significant sesquiterpene emission sources*
14:40	5C6	440	**Stephanie Rossignol**, Laura Chiappini, Emilie Perraudin, Jean-François Doussin *Study of SOA formation from limonene ozonolysis in indoor environments: a new approach involving simultaneous investigation of gas and particulate phases molecular composition*
Reserve	5CR	373	**Zhijun Wu**, L. Poulain, O. Böge, R. Gräfe , H. Herrmann, A. Wiedensohler, Helbig, T. Schröder, J. von Sonntag, I. Hartmann *Modifications in hygroscopicity and volatility of wood combustion aerosols after chemical aging*

13:00-14:40 **Session 5D: Aerosols in Disease and Therapy**
Room: Moseley Lecture Theatre
Chair: Darragh Murnane

13:00	5D1	171	**Richard Thomas** *Large particle aerosols within high level microbiological containment*
13:20	5D2	1142	**Tom Pottage**, Allan Bennett, Simon Parks *Anthrax, aerosols and drums*
13:40	5D3		**Lea Ann Dailey**, *From deposition to molecular action – studies from the interface*
14:00	5D4		**Sean J Cheng,** *Controlling dry powder inhaler performance by using computational fluid dynamics to tune miniature cyclone separators*
14:20	5D5		**Darragh Murnane,** *Understanding fine particle interactions in powder delivery systems*

13:00-15:00 **Session 5E: Health Effects of Nanoparticles**
Room: Bragg Lecture Theatre
Chairs: Hanns-Rudolf Paur / Wendelin Stark

13:00	5E1	112	**Georgios Sotiriou** *Antibacterial activity by nanosilver ions and particles*
13:20	5E2	504	**Helmi Keskinen**, Romakkaniemi, Sami, Jaatinen, Antti, Miettinen, Pasi, Saukko, Erkka, Joutsensaari, Jorma, Mäkelä, Jyrki, Virtanen, Annele, Smith, James, and Laaksonen, Ari *Water uptake on silica nanoparticles*
13:40	5E3	682	**Christian Svensson**, Maria Messing, Alexander Schollin, Knut Deppert, Bengt Meuller, Joakim Pagels, Jenny Rissler, Mats Bohgard, Sara Linse, Tommy Cedervall *Direct deposition of aerosol generated AuNPs into biological buffers produce specific protein corona in*

			lung-fluid and blood serum
14:00	5E4	349	**Joonas Koivisto**, Mikko Aromaa, Jussi Lyyranen, Ari Auvinen, Jorma Jokiniemi, Kaarle Hämeri *Assessing inhalation exposure to nanoparticles during nanoparticle synthesis and packing*
14:20	5E5	260	**Luana Golanski** *Release-ability of nano fillers from different nanomaterials*
14:40	5E6	829	**Robert N. Grass**, K. Birbaum, L.K. Limbach, E. Martinoia, D. Gunther, W.J. Stark *No evidence of cerium oxide nanoparticle translocation in maize plants*
Reserve	5ER	218	**Jussi Lyyränen**, Merja Järvelä, Timo Tuomi, Joe Pimenoff, Ari Auvinen, Jorma Jokiniemi *Characterisation of CeO2 engineered nanoparticles from a liquid flame spray process – exposure of workers*

13:00-15:00 **Session 5F: Aerosols in Turbulent Flows 1**
Room: Blackett Lecture Theatre
Chair: Alain Pumir

13:00	5F1	917	**Bernhard Mehlig**, Kristian Gustavsson *Distribution of relative velocities in turbulent aerosols*
13:20	5F2	977	**Michael Reeks**, Elena Meneguz *Statistical properties of particle segregation in homogeneous isotropic turbulence*
13:40	5F3	315	**Roar Skartlien** *Particle and droplet transport in turbulence and inertial effects*
14:00	5F4	1070	**Mathieu Gibert**, Simon Klein, Eberhard Bodenschatz *Full motion measurement of finite-size neutrally buoyant particles together with the turbulent flow field carrying them*

14:20	5F5	140	**Max Eggersdorfer**, Dirk Kadau, Hans J. Herrmann, Sotiris E. Pratsinis *Aerosol Coagulation & Break-up in Homogeneous Isotropic Turbulent Flows*
14:40	5F6	669	**Fan Zhang**, Mike Reeks, Martin Kissane *Particle Resuspension Modeling in Turbulent Flows*

15:30-17:10 **Session 6A: New Particle Formation 3: Theory and Modelling**
Room: Theatre A
Chairs: Boris Bonn / Amar Hamed

15:30	6A1	910	**Christos Fountoukis** *Simulating Ultrafine Particle Formation in Europe using the 3-D Chemical Transport Model PMCAMx-UF*
15:50	6A2	75	**Theo Kurten**, Joseph Lane, Solvejg Jørgensen, Camilla Jensen, Henrik Kjaergaard *Computational studies of atmospheric sulfur oxidation mechanisms*
16:10	6A3	911	**Adam Kristensson**, Erik Swietlicki, Birgitta Svenningsson, Tareq Hussein, Tuomo Nieminen, Mikka Dal Maso, Heikki Junninen, Hanna Manninen, Vidmantas Ulevicius, Markus Fiebig, Peter Tunved, Johan Ström, Andreas Massling, Markku Kulmala *Geographical mapping of new particle formation events over Northern Europe*
16:30	6A4	549	**Ismael Kenneth Ortega Colomer**, Oona Kupiainen, Theo Kurten, Hanna Vehkamaki *Formation of neutral sulphuric acid clusters containing base molecules*
16:50	6A5	628	**Neil Donahue**, Erica Trump, Ilona Riipinen, Jeffrey Pierce *Growth of Particles via Organic Condensation: Is Gas-Phase Chemistry Enough?*

Reserve	6AR	105	**Hannele Korhonen**, Sanna-Liisa Sihto, Veli-Matti Kerminen, Kari E.J. Lehtinen *How accurate are the nucleation event analysis tools?*

15:30-17:10 **Session 6B: Climate Effects of Aerosols / Transport and Transformation**

Room: Theatre B

Chairs: Andreas Held / Eiko Nemitz

15:30	6B1	930	**Jonatan Carlsson**, Jenny Rissler, Erik Nordin, Axel Eriksson, Patrik Nilsson, Cerina Wittbom, Maija Kajos, Pontus Roldin, Erik Swietlicki, Birgitta Svenningsson, Mats Bohgard, Markku Kulmala, Joakim Pagels *Atmospheric processing of diesel soot aerosols studied in a smog chamber*
15:50	6B2	813	**Thomas Bjerring Kristensen**, Heike Wex, Bettina Nekat, Dominik van Pinxteren, Katrin Mildenberger, Frank Stratmann, Jacob K. Nøjgaard, Christian B. Koch, Anna G. Hallar, Thomas F. Mentel, Merete Bilde *Hygroscopic properties of HULIS from different environments*
16:10	6B3	820	**Wolfgang Junkermann**, Bernhard Vogel, Mark Sutton *On the regional effects of clean fossil fuel combustion aerosols*
16:30	6B4	683	**Rafaella - Eleni Sotiropoulou**, Nicholas Meskhidze, Jules Kouatchou, Lazaros Oreopoulos, Jose M. Rodriguez, and Athanasios Nenes *Sensitivity of cloud radiative forcing to cloud formation parameterization under three different meteorological fields*
16:50	6B5	289	**Helmuth Horvath**, Alexander Cheremisin, I. Shnipkov

			The global picture of aerosol layers formation in the stratosphere and in the mesosphere under the influence of gravito- and magneto-photophoretic forces.

15:30-16:50 **Session 6C: Smog Chamber Experiments and SOA 2**
Room: Rutherford Lecture Theatre
Chairs: Josef Dommen / Harald Saathoff

15:30	6C1	1002	**Eleni Athanasopoulou**, Heike Vogel, Max Bangert, Christoph Knote, Bernhard Vogel, Ben Murphy, Alexandra Tsimpidi, Spyros Pandis, *Simulating secondary organic aerosol (SOA) formation over Europe using the volatility basis-set approach (VBS) in the online coupled model COSMO-ART*.
15:50	6C2	583	**M. Rami Alfarra**, Jacqui Hamilton, Kevin Wyche, Timo Carr, Annette Ryan, Rogelio Ayala, Paul Monks, Robert MacKenzie, Alastair Lewis, Nick Hewitt, Gordon McFiggans *Chemical composition, Hygroscopicity and CCN properties of biogenic secondary organic aerosols*
16:10	6C3	801	**Eva Emanuelsson**, B. Bohn, A. Buchholz, B. Kammer, A. Kiendler-Scharr, B. Kortner, Th. F. Mentel, S. Nehr, R. Tillmann, E. Kleist, K. Kristensen, M. Fenger-Lauridsen, M. Glasius, M. Hallquist *Physical and chemical characterisation of mixed anthropogenic and biogenic secondary organic aerosol*
16:30	6C4	279	**Marco Paglione**, Stefano Decesari, Emanuela Finessi, Risto Hillamo, Samara Carbone, Sanna Saarikoski, Tomi Raatikainen, Manuel Dall'Osto, Colin O'Dowd, Astrid Kiendler-scharr, Amewu Mensah, Urs Baltensperger, Andre Prevot, Douglas Worsnop, MariaCristina Facchini *Source apportionment of atmospheric organic aerosols by nuclear magnetic resonance (NMR)*

			spectroscopy during the EUCAARI project
16:50	6C5	1145	**Urs Baltensperger**, Maarten Heringa, Roberto Chirico, Stephen Platt, Lisa Pfaffenberger, Peter Barmet, Jay Slowik, Peter DeCarlo, Josef Dommen, Andre Prevot *Discrimination of secondary organic aerosol from different sources*
Reserve	6CR	282	**Boris Bonn**, Friedemann Ebach, Matthias Hummel, Stratos Bourtsoukidis, Boris Bonn, Werner Haunold, Robert Sitals, *Understanding particle formation by alkene-ozone reactions: Experimental studies and theoretical simulations*.

15:30-17:10 **Session 6D: Direct Impacts of Aerosol on Climate (ADIENT Project)**
Room: Moseley Lecture Theatre
Chairs: Don Grainger / Gareth Thomas

15:30	6D1	318	**Will Morgan**, James Allan, Michael Bane, Keith Bower, Bethan Harris, Bas Henzing, Eleanor Highwood, Astrid Kiendler-Scharr, Gordon McFiggans, Gavin McMeeking, Amewu Mensah, Simon Osborne, Megan Northway, Paul Williams, Radovan Krejci, Hugh Coe *Measurement and modelling of ammonium nitrate aerosol and its impacts in North-Western Europe*
15:50	6D2	234	**Eleanor Highwood**, Megan Northway, Gavin McMeeking, Hugh Coe, William Morgan, Dantong Liu, Claire Ryder, Paul Williams, Keith Bower, Simon Osborne *Optical and Radiative Properties of Aerosol as Determined During the ADIENT Project*
16:10	6D3	291	**Gareth Thomas**, Nicky Chalmers, Bethan Harris, Ellie Highwood, Don Grainger *ADIENT satellite based aerosol direct radiative forcing*

16:30	6D4	278	**Helen Brindley**, Alexandros Georgiadis, Jacqueline Russell *Testing methods to derive top of the atmosphere reflected shortwave fluxes in the presence of aerosol during the ADIENT campaign: application to GERB and SEVIRI*

15:30-17:30 **Session 6E: Enhanced Aerosol Measurement Technology**
Room: Bragg Lecture Theatre
Chairs: Jim Davis / Martin Fierz

15:30	6E1	856	**Peter Jani**, Lenard Vamos, Attila Nagy, Attila Kerekes *Nanoparticle measurements with photon correlation LDA*
15:50	6E2	864	**Axel Eriksson**, A.C. Eriksson, E. Z. Nordin, P. T. Nilsson, J. E. Carlsson, C. Wittbom P. Roldin, M.K. Kajos, J. Rissler , F. Abdisa, M. Hallquist, M. Kulmala, B. Svenningssson, J. Pagels and E. Swietlicki *Soot Particle AMS measurement in smog chamber experiments*
16:10	6E3	787	**Erkka Saukko**, Heino Kuuluvainen, Annele Virtanen *Aerosol particle phase state measurement technique using a low pressure impactor*
16:30	6E4	527	**James Davies**, Allen Haddrell, Jon Wills, Jonathan Reid *Rapid measurements of single aerosol droplets in conditions far from equilibrium using an electrodynamic balance*
16:50	6E5	732	**Regina Hitzenberger**, Elisabeth Traxler, Bernadette Rosati *Interferences in thermo-optical measurements of elemental and organic carbon caused by other aerosol constituents*

17:10	6E6	88	**Constantinos Sioutas**, Nancy Daher, Zhi Ning, Arthur K. Cho, Martin Shafer, James J. Schauer *Comparison of the chemical and toxicological characteristics of particulate matter (PM) collected by different methods: filters, impactors and BioSamplers*
Reserve	6ER	902	**Harald Bresch**, Falk Reinhardt, Ulrich Waldschlaeger, Beatrix Pollakowski, Burkhard Beckhoff, Stefan Seeger *Size selected nanoparticle quantification of deposited aerosol by GIXRF*

15:30-17:10 **Session 6F: Aerosols in Turbulent Flows 2**
Room: Blackett Lecture Theatre
Chair: Mike Reeks

15:30	6F1	587	**Charles Clement** *Turbulence and Condensation*
15:50	6F2	867	**Juergen Vollmer** *Rain in the test tube?*
16:10	6F3	1128	**Andrew Bragg**, David C Swailes *Non-local closure model for particle dispersion tensors in a turbulent boundary layer*
16:30	6F4	826	**Michael Wilkinson**, Alain Pumir *Tumbling in turbulence and irrational quantisation*
16:50	6F5	1124	**Alain Pumir** *Motion of large particles in turbulent flow: rotational motion and lift*
17:10	6F6	669	**Fan Zhang**, Mike Reeks, Martin Kissane *Particle Resuspension Modeling in Turbulent Flows*

17:10-18:00 EAA Working Group meetings

Aerosol Modelling	Theatre A
Aerosol Chemistry	Rutherford Theatre
Aerosol-based Nanotechnology	Blackett Theatre
Atmospheric Aerosols	Theatre B
PMx	Moseley Theatre

NOTES:

Wednesday 7th September

09:00-10:00 Plenary 3
Uta Griesenbach: UK Cystic Fibrosis Gene Therapy Consortium: Developing and Delivering a Complex Respiratory Therapy
Room: Theatre B
Chair: Darragh Murnane

10:00-10:15 Awards Ceremony Theatre B

10:45-12:45 **Session 7A: Carbonaceous Aerosol and Meteorology**
Room: Theatre A
Chairs: Regina Hitzenberger / Andre Prevot

10:45	7A1	588	**Jonathan Taylor** *Changes in black carbon undergoing SOA coating measured with SP2, SP-AMS and optical instruments.*
11:05	7A2	950	**Sandra Wagener**, Marcel Langner, Ute Hansen, Heinz-Joern Moriske, Wilfried Endlicher *Spatial and seasonal variations of biogenic organic compounds in ambient PM10 and PM1 samples in Berlin*
11:25	7A3	225	**James Allan**, Jonathan Taylor, Michael Flynn, Hugh Coe, Tim Onasch, Paola Massoli, John Jayne, Douglas Worsnop, Greg Kok, Xiaolu Zhang and Rodney Weber *Composition and Optical Properties of Black Carbon and its Coatings in the Los Angeles Area During CalNex*
11:45	7A4	611	**Godwin Ayoko**, Leigh Crilley, Mandana Mazaheri, Graham Johnson, Lidia Morawska, Eduard Stelcer and David Cohen *Effect of vehicle emissions on the chemical composition of airborne particulates in urban schools*

12:05	7A5	990	**Hang Su**, Y. Cheng, A. Wiedensohler, M. Berghof, B. Wehner, P. Achtert, A. Nowak, D. Rose, S. Gunthe, Y. Gong, N. Takegawa, Y. Kondo, M. Shao, M. Hu, T. Zhu, L. M. Zeng, U. Pöschl, Y. H. Zhang *Size-resolved mixing state of soot (black carbon) particles in the Beijing Megacity, China: aging rates, the condensable vapor pressure and parameterizations*
12:25	7A6	584	**Claire Ryder**, Ralf Toumi *Does aerosol in London create an urban solar flux island?*
Reserve	7AR	1043	**Kornélia Imre**, András Gelencsér, Ágnes Molnár, Viktor Dézsi *Role of the hysteresis and water content in PM10 measurements*

10:45-12:45 **Session 7B: Aerosol-Cloud Interactions 3**
Room: Theatre B
Chairs: Paul Connolly / Katrin Mildenberger

10:45	7B1	386	**Dominik van Pinxteren** *Hill Cap Cloud Thuringia 2010 (HCCT-2010) – Overview and first results*
11:05	7B2	577	**Johannes Schneider**, Anja Roth, Stephan Mertes, Dominik van Pinxteren, Stephan Borrmann *Microphysical and chemical characterization of cloud droplets, cloud droplet residuals, and interstitial aerosol particles during a hill-cloud field experiment in Central Europe*
11:25	7B3	202	**Ming Chee Yeung**, Chak K. Chan *Understanding phase transition and hygroscopic behavior of organic acid particles and their mixtures with ammonium sulfate by micro-Raman spectroscopy*

11:45	7B4	1031	**Staffan Sjogren**, E. Fors, E. Swietlicki, M. Martin, B. Sierau *Cloud Condensation Nuclei Closure Study on Summer Arctic Aerosol*
12:05	7B5	937	**Noenne Prisle**, D. Topping, S. Romakkaniemi, G. McFiggans, M. Dal Maso, H. Kokkola *Importance of different surfactant representations for cloud droplet numbers predicted with the ECHAM5.5-HAM2 aerosol-climate model*
12:25	7B6	947	**Max Bangert**, Athanasios Nenes, Bernhard Vogel, Heike Vogel, Donifan Barahona, Prashant Kumar *The impact of mineral dust particles on cloud properties and the state of the atmosphere during an intense Saharan dust event over Western Europe*
Reserve	7BR	265	**Florian Ditas**, Birgit Wehner, Holger Siebert, Heike Wex, Gregory C. Roberts, Katrin Mildenberger, Tina Schmeißner, Frank Stratmann, Alfred Wiedensohler *Aerosol number size distributions in the vicinity of trade wind cumuli*

10:45-12:45 **Session 7C: High Temperature Systems: Sampling and Quenching before Detection**

Room: Rutherford Lecture Theatre

Chairs: Jorma Jokiniemi / Ralf Zimmermann

10:45	7C1	292	**Santiago Jiménez**, Javier Ballester *Experimental study of aerosols and vapours at high temperatures: past and recent application of aerodynamic quenching*
11:05	7C2	322	**Jarmo Kalilainen**, Teemu Kärkelä, Ari Auvinen, Pekka Rantanen, Johanna Forsman, Leif Kåll, Jorma Jokiniemi *Automated sampling system for studying iodine chemistry at high temperature*

11:25	7C3	690	**Ralf Zimmermann**, T.Streibel, M.Sklorz, C. Busch, M.Elsasser, J.Schnelle-Kreis, C. Deuerling, J.Orasche, T. Adam, M.C. Astorga-Llorens, H.Hartmann *On-line measurement of chemical composition and size distribution of high-temperature combustion aerosols*
11:45	7C4	702	**Michael Strand**, Eva Gustafsson, Leteng Lin, Jingjing Yang *High-Temperature extraction of aerosol particles from biomass combustion and gasification*
12:05	7C5	723	**Olli Sippula**, Jarno Ruusunen, Tarmo Koponen, Mika Ihalainen, Jorma Jokiniemi *Porous tube diluting probe for high temperature sampling of aerosols*
12:25	7C6	874	**Miren Larrion**, Cristina Gutierrez-Canas, Luisa Marroquin, Gaizka Aragon, Inaki Mugica, Egoitz Pena and Juan Andres Legarreta *The effect of dilution and cooling on the chemistry and structure of samples from stainless steel and Al welding fumes*

10:45-12:45 **Session 7D: Particle-Lung deposition and Pharmacological Aerosol**

Room: Moseley Lecture Theatre

Chair: Jan Marijnissen / David Broday

10:45	7D1	687	**Caner Yurteri**, J.C.M. Marijnissen *Producing Drug particles for Inhalation via Electrospray*
11:05	7D2	518	**Ross Cabot** *Development of an anatomically correct segmented model of the human mouth for deposition studies of the particle and vapour phase of tobacco smoke during inhalation*

11:25	7D3	393	**Winfried Möller**, Uwe Schuschnig, Gülnaz Khadem Saba, Gabriele Meyer, Manfred Keller, Karl Häussinger and Wolfgang G. Kreyling *Pulsating Aerosols for Topical Treatment of Upper Airway Diseases*
11:45	7D4	79	**Andrei Onischuk**, Tatiana Tolstikova, Irina Sorokina, Anatoly Baklanov,Vladimir Karasev, Vladimir Boldyrev,Vasilyi Fomin *Anti-inflammatory and analgesic effect from nanoparticlate non-steroid anti-inflammatory drugs inhaled by male mice*
12:05	7D5	158	**Alison Buckley**, Rachel Smith, Robert Maynard *Carbon Nanotubes – too "big" AND too "small" to deposit efficiently in the lungs?*
12:25	7D6	1061	**Lukas Pichelstorfer**, Werner Hofmann *Modelling coagulation of liquid particles within the human respiratory system*
Reserve	7DR	837	**John McAughey**, Colin Dickens *Regional lung deposition of tobacco smoke constituents*

10:45-12:45 **Session 7E: New Developments in Aerosol Instrumentation**

Room: Bragg Lecture Theatre

Chairs: Oliver Bischof / Martin Pesch

10:45	7E1	257	**Chuen-Jinn Tsai** *A Novel IOSH-NCTU Personal Nanoparticle Sampler*
11:05	7E2	233	**Chris Stopford**, Paul Kaye, Edwin Hirst, Richard Greenaway, Warren Stanley *Portable real-time detection of airborne asbestos fibres for tradespersons*
11:25	7E3	191	**Maria Giamarelou**, Giorgos Biskos *The Transfer Function and the Resolution of a DMA with Multiple Monodisperse Outlets: Sensitivity Analysis for the Case with the Two Monodisperse*

			Particle Outlets
11:45	7E4	369	**Francisco Romay**, Aaron M. Collins, William D. Dick, Benjamin Y.H. Liu *Development and Characterization of a Novel Approach for Water-Based Condensation Growth of Aerosols*
12:05	7E5	919	**Markus Gaelli**, Kathleen Erickson, Fred Quant, Rob Caldow, Sean Morell, Jeremy Kolb, Brian Osmondson, Edwin Pickens *Comparison Testing of Model 3783 Environmental Particle Counters*
12:25	7E6	750	**Soohyun Ha**, Chirag K. Vyas, Atul Kulkarni, Vijay K. Manchanda, Taesung Kim *A Novel Optical Real Time Sensor for Radioactive Aerosol*
Reserve	7ER	365	**Martin Fierz**, Peter Steigmeier, Michael Glettig, Benjamin Wyrsch, Heinz Burtscher *Direct integration of a GPS-GPRS unit into a miniature diffusion size classifer*

10:45-12:45 **Session 7F: Modelling Nuclear Particles and Health Effects**

Room: Blackett Lecture Theatre

Chairs: A. Jones / E. Nemitz

10:45	7F1	534	**Alan Jones**, Roland Zeyen *Nuclear aerosols in primary circuit and containment: a review of the Phebus experiments*
11:05	7F2	772	**Claudia Lopez del Pra**, Luis E. Herranz *Uncertainty Analysis of Aerosol Retention in the Break Stage of a Vertical Steam Generator under SGTR Accident Conditions*
11:25	7F3	925	**Martin Lustfeld**, Thomas Barth, Manuel Banowski *Multilayer deposition and resuspension studies of aerosol particles between periodic steps in turbulent channel flows*

11:45	7F4	366	**David Broday**, Rob Levy, Ayala Cohen *Classification of Dust Days over Israel by Integration of Satellite Remote Sensing Products*
12:05	7F5	585	**Jakob Löndahl**, Erik Swietlicki, Elisabet Lindgren, Steffen Loft *Aerosol exposure in combination with aerosol impacts on climate: What is the total health outcome?*
12:25	7F6	439	**Mingzhou Yu** *Modeling and Measurement of ENP Dynamics in a Ventilated Two-Zone Chamber*
Reserve	7FR	399	**Eiko Nemitz**, Massimo Vieno, Ulrike Dragosits, Chiara F. Di Marco, Marsailidh Twigg, Mark A. Sutton *The response of PM concentrations in the UK to changes in industrial and agricultural emissions: implications for the exceedance of Air Quality Standards*

13:45-14:30 Alan Cussens Award, Bragg Theatre

NOTES:

Thursday 8th September

09:00-10:00 Plenary 4
Phil Rasch: The scientific challenges involved in using aerosols as a strategy for geoengineering climate.
Room: Theatre B
Chair:Charles Clement

10:30-12:00 Session 8P: Poster session B
Location: Poster Marquee and adjacent to Theatre B

Combustion Aerosols			
8P1	72	Industrial aerosols	**Rainer Jonas**, Gerfried Lindenthal, *Determination of loss factors of aerosol particles in the sampling systems of nuclear power plants*.
8P2	141	Industrial aerosols	**Chang-Mao Hung**, *Development of high-performance Cu-La nanomaterials as efficient catalyst for ammonia removal*.
8P3	182	Industrial aerosols	**Lin-Chi Wang**, *Global control strategies for polybrominated diphenyl ethers require significant changes*.
8P4	238	Industrial aerosols	**Ting-Yu Hsieh**, W.J. Lee, L.P. Changand L.C. Wang, *Polybrominated diphenyl ethers (PBDEs) in the stack flue gases*.
8P5	248	Industrial aerosols	**Chih-Chung Lin**, Shui-Jen Chen, Jen-Hsiung Tsai, Kuo-Lin Huang, Wu-Jou Yu, Chun-Li Chou, *Particle size distributions of ambient aerosol in the vicinity of semiconductor plants*.
8P6	268	Industrial aerosols	**Jose Luis Dorronsoro Arenal**, J.Rodriguez Maroto, D. Sanz Rivera, E. Rojas García, M. Fernández Díaz, P. Galán Valera and E. Conde Vilda, *Distributions of heavy metal traces by particle size (PM10, PM2.5 y PM1). Emissions from non ferrous smelters* .
8P7	396	Industrial aerosols	**Elzbieta Jankowska**, *Workplace exposure to fine particles from welding fumes*.
8P8	515	Industrial aerosols	**Andrei Bologa**, Hanns.-Rudolf Paur, Helmut Seifert, Friedhelm Weirich, Klaus Woletz, *Study of*

			particle chemical composition and size distribution in the pyrolysis gas flow.
8P9	541	Industrial aerosols	**Tomasz Jankowski**, *Evaluation of the efficiency of the fume cupboards in the laboratory*.
8P10	615	Industrial aerosols	**Shun-I Shih**, W.J. Lee, Y.C. Hsu, Z.S. Wu, L.C. Wang, G.P. Chang-Chien, *Removal of Polychlorinated Dibenzo-p-dioxins and Dibenzofurans for physico-chemical pre-treatment and thermal treatment of Electric Arc Furnace fly ashes*.
8P11	107	Automotive combustion aerosols	**Gabriele Hörnig**, Reinhard Niessner, *The role of diffusiophoresis in fouling of exhaust gas recirculation heat exchangers*.
8P12	184	Automotive combustion aerosols	**Jen-Hsiung Tsai**, Shui-Jen Chen, Kuo-Lin Huang, Shiunn-Cheng Chuang, Lin-Chi Wang, Chih-Chung Lin, *Characterizations of PCDD/Fs emitted from gasoline and diesel fueled vehicles*.
8P13	203	Automotive combustion aerosols	**Lothar Keck**, Markus Pesch, Matthias Richter, Georg Reischl, *Performance of a new condensation particle counter for engine exhaust gas (PMP-CPC)*.
8P14	215	Automotive combustion aerosols	**Johannes Schmid**, Benedikt Grob, Reinhard Niessner and Natalia P. Ivleva, *Characterization of soot structure and reactivity based on Raman microspectroscopy*.
8P15	294	Automotive combustion aerosols	**Wen-Yinn Lin**, Shui-Jen Chen, Shiunn-Cheng Chuang, Kuo-Lin Huang, Lin-Chi Wang, Juei-Yu Chiu, Chuen-Huey Chiu, Chih-Chung Lin, *Characterization of PCDD/Fs emitted from motorcycles*.
8P16	489	Automotive combustion aerosols	**Svetlana Stevanovic**, Branka Miljevic, Nicholas Surawski, Steven Bottle, Richard Brown, Zoran Ristovski, *Reactive oxygen species (ROS) emissions from diesel engines running on various biofuels*.
8P17	516	Automotive combustion aerosols	**Reinhard Niessner**, *Electrical conductivity as sensor principle for a sensor to measure soot aerosols*.
8P18	540	Automotive combustion aerosols	**Jan-Christoph Wolf**, Reinhard Niessner, *Laboratory investigation of post-combustion nitro-PAH formation*.

8P20	658	Automotive combustion aerosols	**Anssi Arffman**, Topi Rönkkö, Panu Karjalainen, Tero Lähde, Juha Heikkilä, Liisa Pirjola, Dieter Rothe, Jorma Keskinen, *Thermodenuder with low nanoparticle losses: design, simulations, laboratory tests and diesel exhaust particle studies*.
8P21	758	Automotive combustion aerosols	**Souzana Lorentzou**, Margaritis Kostoglou, Athanasios Konstandopoulos, *Microstructural Aspects of Catalytic Soot Oxidation in Diesel Particulate Filters*.
8P22	762	Automotive combustion aerosols	**Ken-Hui Chang**, W.Y. Lin, J.Y. Syu, Y.Y. Chang, C.C. Chen, *Effects of Emulsion Fuels on the Characterization of Exhaust from a Diesel Engine Generator*.
8P23	805	Automotive combustion aerosols	**Souzana Lorentzou**, Dimitrios Zarvalis, Ioannis Dolios, Christodoulos Lekkos, Christos Agrafiotis, Athanasios Konstandopoulos, *Pilot-Scale Aerosol Infiltration Synthesis and Deposition of Catalyst Particles on Diesel Particulate Filters*.
8P24	987	Automotive combustion aerosols	**Michal Vojtisek-Lom**, Martin Mazac, Rafael Lozano Espasandin, *Particulate matter emissions from a winter operation of a modern on-road diesel engine powered by heated rapeseed oil*.
8P25	1138	Automotive combustion aerosols	**Markus Pesch**, Georg Reischl, Lothar Keck, *A new device for high speed measurements of nano particles*.
Particle-Lung Interactions			
8P26	175	Dosimetry and detection of particles in organisms tissues and cells	**Der-Jen Hsu**, Ming-Hsiu Chuang, *Deposition efficiency of micro-size particles in the upper airway of Taiwanese adults*.
8P27	312	Biological response of organisms cells and proteins to particle exposure	**Takako Oyabu**, T. Myojo, Y. Morimoto, A. Ogami, M. Hirohashi, Y. Mizuguchi, M. Hashiba, T. Kambara, BW. Lee, I. Tanaka, *Biopersistence and pulmonary effects of intratracheally instilled titanium dioxide nanoparticles at four different doses to rat lungs*.
8P28	355	Biological	**Dirk Broßell**, Sabine Plitzko, Nico Dziurowitz,

		response of organisms cells and proteins to particle exposure	Erhardt Gierke, Volker Bachmann, Gunter Linsel, Nkwenti Azong-Wara, Christof Asbach, Heinz Fissan, Andreas Schmidt-Ott, *A Thermal Precipitator for Nanoparticle Cytotoxicity Screening*.
8P29	415	Biological response of organisms cells and proteins to particle exposure	**Marco Sala**, *A 3-year-follow-up Study of Traffic Related Respiratory Alterations in Schoolchildren in Milan, Italy*.
8P30	416	Biological response of organisms cells and proteins to particle exposure	**Francesco Cetta**, *Alteration of respiratory function in asymptomatic subjects living in Milan (Italy) and in Aprica (Italy), an Alpine site with different levels of environmental pollution. Spirometric and laboratory evaluation.*
8P31	417	Biological response of organisms cells and proteins to particle exposure	**Luigi Allegra**, *A plea for a more "doubtful" and "skeptic" approach to the role of intrinsic toxicity of airborn pollutants as the main responsible for observed cardiovascular, respiratory and cancerous diseases or deaths in humans.*
8P32	374	Aerosol-based medical diagnostics and drug delivery	**Lukasz Zywczyk**, *Deposition of aerosol particles in dosing tubes (endotracheal tubes) used in aerosol drugs therapy for infants*.
8P33	426	Aerosol-based medical diagnostics and drug delivery	**Laura Moltoni**, *"Perinatal susceptible window" as a main responsible for cardiovascular and respiratory diseases occurring later in life because of PM exposure*.
8P34	428	Aerosol-based medical diagnostics and drug delivery	**Jacopo Martellucci**, *The "harmful potential" of PM, evaluated "in vitro" must be used with a great causation as a surrogate for risk assessment in humans*.
8P35	399	Modelling aerosol impact on human	**Eiko Nemitz**, Massimo Vieno, Ulrike Dragosits, Chiara F. Di Marco, Marsailidh Twigg, Mark A. Sutton, *The response of PM concentrations in the*

		health	*UK to changes in industrial and agricultural emissions: implications for the exceedance of Air Quality Standards*.
8P36	840	Modelling aerosol impact on human health	**James McGrath**, Miriam Byrne, Mike Ashmore, Andrew Terry, Sani Dimitroulopoulou, *Modelling the effect of variable air exchange rates on indoor aerosol concentrations*.
8P37	301	Particle lung deposition clearance and translocation to other organs	**Agata Penconek**, Arkadiusz Moskal, *Artificial lung as an alternative for measurement pulmonary deposition in vivo.*
8P38	325	Particle lung deposition clearance and translocation to other organs	**Jakub Elcner**, Frantisek Lizal, Matej Forman, Jan Jedelsky, Miroslav Jicha, *Respiratory airflow in human upper airways*.
8P39	460	Particle lung deposition clearance and translocation to other organs	**Mathias Forjan**, Katharina Stiglbrunner, Andreas Drauschke, *Development of a Setup for the Purpose of Respiratory Research and Aerosol Deposition in the Lung Using a Novel Active Lung Simulator*.
8P40	677	Particle lung deposition clearance and translocation to other organs	**Attila Nagy**, Arpad Farkas, Imre Balashazy, *Numerical simulation of aerosol deposition and clearance in the large bronchial airways*.
8P41	837	Particle lung deposition clearance and translocation to other organs	**John McAughey**, Colin Dickens, *Regional lung deposition of tobacco smoke constituents*.
8P42	1051	Particle lung deposition clearance and translocation to other organs	**Pierre Madl**, Renate WInkler-Heil, Werner Hofmann, *Implementation of morphometric mouse lung data into a stochastic deposition model*.
8P43	1107	Particle lung deposition clearance and translocation to other organs	**Majid Hussain**, Werner Hofmann, *Comparison of stochastic particle lung deposition predictions with experimental data*.

8P44	326	Particle-induced health effects - toxicology and epidemiology	**Yasuo Morimoto**, Y. Morimoto, M. Hirohashi, A. Ogami, T. Oyabu, T. Myojo, M. Hashiba, Y. Mizuguchi, T. Kambara, B-W. Lee K. Mizuno, N. Kobayashi, and I. Tanaka, *Pulmonary toxicity of well-dispersed single-wall carbon nanotube following 4 week inhalation*.
8P45	418	Particle-induced health effects - toxicology and epidemiology	**Rosalia Zangari**, *Comparison between in vitro results of PM incubation with cell-lines and health effects in children.*.
8P46	423	Particle-induced health effects - toxicology and epidemiology	**Paolo Paladini**, *Mesothelioma incidence is likely not going to decline, despite asbestos ban in Western countries*.
8P47	427	Particle-induced health effects - toxicology and epidemiology	**Simona Benoni**, *Measurement of damages to exposed populations during concomitant evaluation of PM concentration and health effects usually doesn't consider damage to newborns.*
8P48	717	Particle-induced health effects - toxicology and epidemiology	**Mikko Happo**, Oskari Uski, Pasi Jalava, Joachim Kelz, Thomas Brunner, Jorma Jokiniemi, Ingwald Obernberger, Maija-Riitta Hirvonen, *Comparison of toxicological responses in mice lung induced by PM1 emissions from heating appliances of old and new technologies*.
8P49	722	Particle-induced health effects - toxicology and epidemiology	**Niklas Moehle**, *Prevalidation of the CULTEX method: In vitro analysis of the acute toxicity of inhalable fine dusts and nanoparticles after direct exposure of cultivated human cells from the respiratory tract.*
8P50	1083	Particle-induced health effects - toxicology and epidemiology	**Paulo Artaxo**, Valdir S. Andrade Filho, Melina Paixao, Sandra Hacon and C.N. Carmo, *Particulate matter emitted in biomass burning and respiratory diseases hospitalizations in children of Manaus, central Brazilian Amazon region*.
8P51	495	Other	**Sonja Muelhopt**, Christoph Schlager, Hanns-Rudolf Paur, *A novel exposure system for testing the lung toxicity of domestic wood combustion aerosols*.
8P52	958	Other	**Riikka Sorjamaa**, Timo Lanki, Josef Cyrys, Otto Hänninen, *From Outdoor Particle Concentration to*

			the Health Impact of Aerosol Particles – a Multidisciplinary Modelling Study, Part I.
8P53	102	Indoor aerosols	**Ludmila Maskova**, Jiri Smolik, Jakub Ondracek, Lucie Ondrackova, Susana Lopez-Aparicio, *Relationship of Indoor and Outdoor PM and Gaseous Pollutants in the National Library in Prague*.
8P54	173	Indoor aerosols	**Teresa Nunes**, Joana Silva, Alexandre Caseiro, Priscilla Pegas, Célia Alves, Casimiro Pio, *Chemical characterisation of PM10 in primary schools, Portugal*.
8P55	197	Indoor aerosols	**Peter Molnár**, Sandra Johannesson, *Smoking neighbours – a possible source to ETS exposure in homes*.
8P56	791	Indoor aerosols	**Maria Grazia Perrone**, Zelda Lazzati, Roberta Zangrando, Luca Ferrero, Giorgia Sangiorgi, Andrea Gambaro, Ezio Bolzacchini, *Bispehnol A concentrations in indoor and outdoor PM2.5 samples*.
8P57	1089	Indoor aerosols	**Shinhao Yang**, *Inactivation efficiency of avian influenza H6N1 bioaerosol using the aptamer-filter*.
8P58	1044	Indoor air quality and associated health effects	**Christina Isaxon**, Andreas Dahl, Erik Nordin, Gunilla Wieslander, Dan Norback, Anders Gudmundsson, Aneta Wierzbicka, Mats Bohgard, *Particles in Indoor Air – measurements in residential dwellings*.
8P59	422	Lung morphology and patho-physiology	**Gianfranco Schiraldi**, *Environmental pollution in Metropolitan Areas and alterations of respiratory function*.
8P60	590	Lung morphology and patho-physiology	**Donald Hagen**, Elizabeth Black, Philip Whitefield, Prem Lobo, *Surface Area Deposition Index for Jet Engine PM Exhaust*.
8P61	387	Bioaerosols and allergens	**Kathrin Selzle**, Yingyi Zhang, Hong Yang, Ulrich Pöschl, *Protein Nitration and Health Effects*.
8P62	643	Bioaerosols and allergens	**Gregor Jereb**, Štefan Pintaric, Uroš Krapež, Alenka Dovc, *Pigeons as Source of Airborne Circoviruses*.

Aerosol Chemistry			
8P63	927	Structuring of engineered nanoparticles	**Georgia Kastrinaki**, Athanasios G Konstandopoulos, *Synthesis and Surface Area evaluation of Solid Core Porous Shell Particles*.
8P64	99	Chemical mechanisms and transformation processes in aerosol	**Yuri Samsonov**, *Physicochemical transformations and photochemical reactions of high-disperse pesticide chemicals*.
8P65	185	Chemical mechanisms and transformation processes in aerosol	**Asit Ray**, Venkat Rajagopalan, Eric A. Grulke, *Phase transformation of evaporating solution droplets of immiscible polymers*.
8P66	360	Chemical mechanisms and transformation processes in aerosol	**Tiia-Ene Parts**, Aare Luts, Urmas Hõrrak, *Diethylamine and new charged particles formation*.
8P67	441	Chemical mechanisms and transformation processes in aerosol	**Andrey Sorokin**, *To some mechanisms of UV-light induced SO2 Oxidation to H2SO4 and Aerosol Formation*.
8P68	897	Chemical mechanisms and transformation processes in aerosol	**Peter Gallimore**, Francis Pope, Pattanun Achakulwisut, Markus Kalberer, *Importance of aerosol phase and water uptake for understanding organic aerosol oxidation*.
8P70	210	Multiphase chemical processes and interactions involving aerosol	**Manabu Shiraiwa**, Markus Ammann, Thomas Koop, Ulrich Pöschl, *Gas uptake and chemical aging of amorphous semi-solid aerosol particles*.
8P71	343	Multiphase	**Ingrid George**, Barbara Brooks, Lisa Whalley,

		chemical processes and interactions involving aerosol	Andrew Goddard, Pascale Matthews, Neil Howes, Maria-Theresa Baeza-Romero, Dwayne Heard, *Heterogeneous uptake of HO2 onto submicron aerosol particles*.
8P72	394	Multiphase chemical processes and interactions involving aerosol	**Andreas Tilgner**, Peter Bräuer, Ralf Wolke, Hartmut Herrmann, *SPACCIM model studies of tropospheric aerosol-cloud interactions with the extended multiphase chemistry mechanism MCM-CAPRAM*.
8P73	410	Multiphase chemical processes and interactions involving aerosol	**Ingrid George**, Lisa Whalley, Daniel Stone, Dwayne Heard, *The impact of clouds on radical concentrations: Observations of OH and HO2 during HCCT-2010*.
8P74	486	Multiphase chemical processes and interactions involving aerosol	**Scot Martin**, Mackenzie Smith, Allan Bertram, *Phase Transitions and Separation of Mixed Organic-Inorganic Particles*.
8P75	505	Multiphase chemical processes and interactions involving aerosol	**Raluca Ciuraru**, Michael Ward, Nicolas Visez, Sylvie Gosselin, Denis Petitprez, *Experimental study of heterogeneous reactivity between*.
Aerosols in Geoengineering			
8P76	438	Aerosols in geoengineering	**Anton Laakso**, *Injection of sulfur compounds into the stratosphere by using modified commercial aircrafts*.
8P77	581	Aerosols in geoengineering	**Annabel Jenkins**, Piers Forster, *Geoengineering the Earth's Climate – An assessment of potential effectiveness and side-effects*.
8P78	733	Aerosols in geoengineering	**Francois Benduhn**, Mark G. Lawrence, *Sensitivity Studies on the Role of Particle Sedimentation and*

			Subscale Microphysics within a Geoengineered Stratosphere.
Atmospheric aerosols - Aerosol Processes and Properties			
8P79	259	Climate effects of aerosols	**Anna Esteve**, Víctor Estellés, Pilar Utrillas, José Antonio Martínez-Lozano, *Radiative forcing from aerosols measured at a coastal site in the Mediterranean*.
8P80	348	Climate effects of aerosols	**Tzi-yi Wu**, Yan-Min Chen, *Atmospheric transport characteristics of dust storm arrive at Taiwan*.
8P81	809	Climate effects of aerosols	**Roberto Pedros**, J.L. Gómez-Amo, C. Marcos, M.P. Utrillas, J.A. Martínez-Lozano, M. Sicard, *Preliminary results on the influence of the vertical distribution of aerosols in the direct radiative forcing*.
8P82	954	Climate effects of aerosols	**Rafaella - Eleni Sotiropoulou**, Donifan Barahona and Athanasios Nenes, *Global distribution of cloud droplet number concentration, autoconversion rate and first aerosol indirect effect under diabatic droplet activation*.
8P83	1116	Climate effects of aerosols	**Paulo Artaxo**, *Spatial variability of the direct radiative forcing of biomass burning aerosols in the Amazon Basin and the influence of surface reflectance*.
Atmospheric aerosols – Specific Aerosol Types			
8P84	346	Carbonaceous aerosol	**Patricia Krecl**, Admir C. Targino, Christer Johansson, *Spatiotemporal distribution of light-absorbing carbon in Stockholm*.
8P85	770	Carbonaceous aerosol	**Jaiprakash Jaiprakash**, Saood Manzer, Tarun Gupta, Gazala Habib, Papiya Mandal, J. K. Basin4, *Carbonaceous aerosol in Delhi: Link with regional meteorology and long range transport*.
8P86	949	Carbonaceous aerosol	**Darius Ceburnis**, Andrius Garbaras, Soenke Szidat, Karl Espen Yttri, Vidmantas Remeikis, Colin O'Dowd, *Source apportionment of ambient particulate carbonaceous matter at Mace Head during the joint EMEP/EUCAARI intensive measurement periods in fall 2008 and spring 2009*.
8P87	956	Carbonaceous	**Ágnes Filep**, Tibor Ajtai, Noémi Utry, András

		aerosol	Gelencsér, András Hoffer, Zoltán Bozóki, Gábor Szabó, *In-situ spectral characterisation of atmospheric aerosols after the red sludge disaster in Hungary during the autumn of 2010 based on our novel multi-wavelength photoacoustic instrument*.
8P91	1004	Carbonaceous aerosol	**Robert Bergstrom**, David Simpson, *Carbonaceous aerosol in Europe – Multi-year study with the EMEP PCM model including validation using source-apportionment data*.
8P92	1041	Carbonaceous aerosol	**Andrius Garbaras**, R. Bariseviciute, K. Kvietkus, J. Sakalys, J. Didzbalis, R. Skipityte, V. Remeikis, *Chemical composition and δ13C values of OC and EC in the size-segregated aerosol particles*.
8P93	1105	Carbonaceous aerosol	**Peter Zotter**, A.S.H. Prévôt, Y. Zhang, S. Szidat, X. Zhang, Y.-H. Lin, P. Hayes, J. D. Surratt, J.L. Jimenez, R. Weber, J. Slowik, U. Baltensperger, *Diurnal cycle of fossil and non-fossil total carbon using 14C analyses during CalNex*.
8P94	71	Biomass burning	**Jennifer Brooke**, Jim McQuaid, Barbara Brooks, Simon Osborne and Jackie Wilson, *Transformation by aging processes of soot particles from laboratory combustion experiments*.
8P96	266	Biomass burning	**Vijay Kumar Verma**, *Gaseous and fine particle emissions from the combustion of agro-forestry pellets in a residential boiler*.
8P97	297	Biomass burning	**Haryono Huboyo**, Puji Lestari, Susumu Tohno, *The basic performance of Jatropha curcas seed stove and its indoor air pollution over traditional wood stoves*.
8P98	304	Biomass burning	**Celia Alves**, A.I. Calvo, A.P. Fernandes, L.A.C. Tarelho, J.R. Pinho, M.C. Duarte, J.F. Silva, *Characterization of trace gases and PM2.5 emitted during the combustion of shrub biomass in a Portuguese stove*.
8P99	310	Biomass burning	**Ana Vicente**, *Gases and aerosols emitted from wildfires in summer 2009 (central Portugal)*.
8P101	1045	Biomass burning	**Su-Ching Kuo**, Ying I. Tsai, Li-Ying Hsieh, Chien-Lung Chen, Yu-Ting Hsu, *Organic markers and*

			anhydrosugars in particulate matter from incense burning.
Atmospheric aerosols - Aerosol Processes and Properties			
8P102	208	Turbulent aerosol transport and exchange	**Pierre Roupsard**, Muriel Amielh, Alexis Coppalle, Hubert Branger, Philippe Laguionie, Olivier Connan, Didier Hébert, Denis Maro, Martine Talbaut, *Submicronic aerosols dry deposition on urban surfaces: a wind tunnel study to improve the lack of knowledge*.
8P103	523	Turbulent aerosol transport and exchange	**James Whitehead**, James Dorsey, Martin Gallagher, Michael Flynn, Gordon McFiggans, *Particle fluxes over arctic sea ice during COBRA*.
8P104	680	Turbulent aerosol transport and exchange	**Matteo Carpentieri**, Prashant Kumar, Alan Robins, *Dispersion of nanoparticles in vehicle wake – Part II: analysis of wind tunnel work*.
8P105	939	Turbulent aerosol transport and exchange	**Philippe Laguionie**, Denis Maro, Basile Letellier, Serge Le Cavelier, *Rain scavenging of below-cloud aerosol particles: field measurements using Electrical Low Pressure Impactor and Scanning Mobility Particle Sizer coupled with Aerodynamic Particle Sizer*.
Aerosol Chemistry			
8P106	56	Identification of tracers	**Celia Alves**, *Organic composition of size-distributed particles emitted from field burning of garden and agriculture residues*.
8P107	64	Instrumentation for chemical characterization of aerosol	**Pushpa Raju Made**, P.D.Safai, P.S.P.Rao, P.C.S.Devara and K.B.Budhavant, *Aerosol Characteristics over the Tropical Urban Station Pune, India*.
8P108	224	Instrumentation for chemical characterization of aerosol	**Friederike Freutel**, Thomas Klimach, Johannes Schneider, Frank Drewnick, Stephan Borrmann, *Cluster analysis of single particle data acquired with a Light Scattering Probe AMS during the MEGAPOLI campaigns in Paris, France*.
8P109	402	Instrumentation for chemical	**Christopher Pöhlker**, Meinrat O. Andreae, Paulo Artaxo, Mary K. Gilles, Arthur L. D. Kilcoyne, Scot

		characterization of aerosol	T. Martin, Ryan C. Moffet, Ulrich Pöschl, Bärbel Sinha, Mackenzie Smith, Kenia Wiedemann, *STXM-NEXAFS Investigations of Laboratory Secondary Organic Aerosols and Amazonian Background Aerosols*.
8P110	503	Instrumentation for chemical characterization of aerosol	**Murray Booth**, David Topping, Gordon McFiggans, Carl Percival, *Physico-chemical property measurements for aerosols at Manchester*.
8P111	553	Instrumentation for chemical characterization of aerosol	**Klaus-Peter Hinz**, Elmar Gelhausen, Karl-Christian Schäfer, Zoltan Takats, Bernhard Spengler, *Instrumental improvements and applications of the compact laser mass spectrometer LAMPAS 3 for on-line single particle characterization*.
8P112	98	Other	**Dhananjay Deshmukh**, M.K. Deb, *Chemical characterization of fine aerosols over eastern central India*.
8P113	370	Other	**Lili Tang**, Shengjie Niu, Dantong Liu, Xuwen Li, Xiangzhi Zhang, Shuxian Fan,Hong Nie and Hugh Coe, *Size Distribution and Source Analysis of Polycyclic Aromatic Hydrocarbons (PAHs) contained in PM10 in Waliguan and Xining of China*.
8P114	666	Other	**Ditte Mogensen**, Sampo Smolander, Anke Nölscher, Jonathan Williams, Vinayak Sinha, Tuomo Nieminen, Markku Kulmala, Luxi Zhou, Andrey Sogachev, Alex Guenther, Michael Boy, *Modelling atmospheric OH-reactivity over boreal forest*.
8P115	835	Other	**Ana María Sánchez de la Campa**, A. Gracía, J.L. Ramos and J. de la Rosa, *Characterization chemical and microbiological of atmospheric particulate matter during an intense African Dust Event on Sourth Spain*.
8P116	839	Other	**Jesús D. de la Rosa**, Sánchez de la Campa, Ana M.; Fernández-Camacho, Rocío; González-Castanedo, Yolanda, *Levels and composition of atmospheric particulate matter deposited in the Doñana Natural Park, southwest of Spain*.

8P118	872	Other	**Milagros Santacatalina**, Eduardo Yubero, Adoración Carratalá, *Rainfall composition evolution in an urban industrial area: Comparison with PM10 wet chemistry.*
Spark generators for nanoparticle generation			
8P117	667	Spark generators for nanoparticle generation	**Shubhra Kala**, Frank Einar Kruis, Marcel Rouenhoff, Christian Blumberg, *Scaling up the production rate of Ge nanoparticles by spark discharge*.
Aerosol Modelling			
8P119	229	Modelling new particle formation	**Christoph Winkelmann**, Arkadiusz K. Kuczaj, Steffen Stolz, Bernard J. Geurts, *Multi-scale modeling of aerosol formation in pipe flow*.
8P120	377	Modelling new particle formation	**Alexander Girin**, *Distribution of stripped droplets by sizes at drop shattering in a uniform flow*.
8P121	404	Modelling new particle formation	**Henri Vuollekoski**, Hannele Korhonen, Luxi Zhou, Kari E. J. Lehtinen, Veli-Matti Kerminen, Michael Boy, Markku Kulmala, *UHMAEMO – University of Helsinki Multicomponent Aerosol Module*.
8P122	509	Modelling new particle formation	**Luxi Zhou**, Michael Boy, Henri Vuollekoski, Chatriya Wathcarapaskorn, Ditte Mogensen, Sampo Smolander, Andrea Sogachev, Markku Kulmala, *The first long-term model study of particle formation and growth with detailed chemistry and aerosol dynamics in a boreal forest environment*.
8P123	561	Modelling new particle formation	**Rosa Gierens**, Lauri Laakso, Johanna Lauros, Risto Makkonen, Ville Vakkari, Luxi Shou, Ditte Mogensen, Henri Vuollekoski, Michael Boy, *Modelled new particle formation and growth in Southern African savannah environment*.
8P124			**Ari Laaksonen**, *Representation of new particle formation in large scale models: Selection criteria for activation and kinetic coefficients*
8P125	631	Modelling new particle	**Xinze Zhen**, Hans-Joachim Schmid, *Simulation of binary aerosol droplet formation*.

		formation	
8P126	650	Modelling new particle formation	**Johannes Leppa**, Stéphanie Gagné, Lauri Laakso, Markku Kulmala, Veli-Matti Kerminen, *Behaviour of the aerosol charging state under asymmetric concentrations of small ions*.
8P127	714	Modelling new particle formation	**Matthias Karl**, Allan Gross, Caroline Leck, Liisa Pirjola, *Can dimethyl sulphide cause new particle formation over the central Arctic Ocean?*
8P128	751	Modelling new particle formation	**Emmi Laukkanen**, Hannele Korhonen, Hao Liquing, Jorma Joutsensaari, James Smith, Kari Lehtinen, Harri Korhonen, *Adsorption in biogenic SOA formation*.
Atmospheric aerosols - Specific Aerosol Types			
8P129	251	Mineral dust	**Ikuko Mori**, Masataka Nishikawa, *Relationship between water soluble calcium and anions in a kosa (Asian dust) aerosol*.
8P130	552	Mineral dust	**Konrad Kandler**, Kirsten Lieke, Nathalie Benker, Martin Ebert, Lothar Schütz, Dirk Scheuvens, Simon Jäckel, Alexander Schladitz, Branimir Šegvic, Stephan Weinbruch, *Mineral dust chemistry, mineralogy, shape, mixing state, complex refractive index and microphysics determined by electron/optical microscopy and by X-ray diffraction at Praia, Cape Verde, in winter 2008*.
8P131	778	Mineral dust	**Vasiliki Vasilatou**, Diapouli, Karanasiou, Skoullos, Eleftheriadis, *Investigation of potential Sahara dust transport event indicators by means of aerosol trace metal concentration ratios in the Eastern Mediterranean.*
8P132	782	Mineral dust	**Matt Woodhouse**, Ken Carslaw, Micheal Krom, Ivan Savov, Alex Baker, Barb Brooks, Tim Jickells, Liane G Benning1, *Small increase in dust fractional iron solubility due to physical sorting of large particles during trans-Atlantic transport*.
8P133	1042	Mineral dust	**Jose A. G. Orza**, Maria Cabello, Asuncion Romero-Diaz, Francisco Belmonte-Serrato, Aitor Berasaluce, Miguel Angel Barrero, Lourdes Canton, *Characterization of Severe Wind Erosion Episodes*

			in a Western Mediterranean Location.
8P134	1125	Mineral dust	**Maria Cabello**, Jose A.G. Orza, Aitor Berasaluce, Miguel Angel Barrero, Lourdes Canton, Asuncion Romero-Diaz, Francisco Belmonte-Serrato, *Wind Erosion and Suspended Particle Concentration in an area of Ephemeral Lakes*.
Atmospheric aerosols - Aerosol Processes and Properties			
8P135	622	Other	**Valentina Yakovleva**, Artem Vukolov, Ivan Ippolitov, Vladimir Karataev, Petr Nagorsky, Sergey Smirnov, *Futures of atmospheric radioactive aerosol monitoring by β- and γ-radiation*.
8P136	756	Other	**Jonathan Dredge**, *Aerosol contributions to speleothem chemistry*.
8P137	901	Other	**Svetlana Samoilova**, *Investigations of the vertical distribution of tropospheric aerosol layers using the data of multi-wavelength lidar sensing*.
8P138	338	Remote sensing of aerosol properties	**Franco Marenco**, Ben Johnson, Robin Hogan, *Quantifying the concentration of volcanic ash aerosol in ground-based lidar returns*.
8P139	395	Remote sensing of aerosol properties	**Monica Campanelli**, Victor Estelles, Tim Smyth, Teruyuki Nakajima, Makiko Hashimoto, Angelo Lupi, Claudio Tomasi, *Retrieval of aerosol radiative properties from sun-sky radiometers measurements of ESR network: comparison between the inversion codes Skyrad4.2.pack and the new Skyrad5.pack*.
8P140	444	Remote sensing of aerosol properties	**Svetlana Terpugova**, Mikhail Panchenko, Victor Polkin, Valerii Kozlov, *Modelling of aerosol scattering and absorption parameters in the troposphere of West Siberia*.
8P141	511	Remote sensing of aerosol properties	**Vassiliki Kotroni**, Stelios Kazadzis, Kostas Lagouvardos, Vasilis Amiridis, Evangelos Gerassopoulos, *Influence of wind field patterns on aerosol optical depth over Athens and the Aegean sea*.
8P142	550	Remote sensing of	**Eleni Marinou**, Vasilis Amiridis, Stelios Kazadzis, Alexandros Papayiannis, *Aerosol Optical Depth in*

		aerosol properties	*East Mediterranean using MODIS and CALIPSO satellite retrievals*.

8P291	342	Application of new instrumentation for study of new processes and phenomena	**Hee-Siew Han**, *Performance of a High Resolution Optical Particle Spectrometer*.
8P292	403	Application of new instrumentation for study of new processes and phenomena	**Leonidas Ntziachristos**, Pavlos Fragkiadoulakis, Zissis Samaras, Kauko Janka, Juha Tikkanen, *Sensor for vehicle on-board particle measurements*.
8P293	520	Application of new instrumentation for study of new processes and phenomena	**Paul Warrington**, *Development of an instrument to simulate puffing, inhaling and exhaling cigarette smoke*.
8P294	543	Application of new instrumentation for study of new processes and phenomena	**Burkhard Stahlmecke**, Margit Hildebrandt, Nico Dziurowitz, Sabine Plitzko, Heinz-Juergen Kiesling, Matthias Voetz, Thomas Kuhlbusch, *Effect of Different Sampling Methods on the Collection Efficiency of CNF- and CNT-Fibres*.
8P295	638	Application of new instrumentation for study of new processes and phenomena	**Tamara Pinterich**, Paul M. Winkler, Paul E. Wagner, Aron Vrtala, *Development of a Versatile Size Analyzing Nuclei Counter (vSANC)*.
8P296	656	Application of new instrumentation for study of new	**Anssi Arffman**, Marko Marjamäki, Jorma Keskinen, *Impaction velocities of particles in low pressure impactor*.

		processes and phenomena	
8P297	703	Application of new instrumentation for study of new processes and phenomena	**Sanchita Roy**, *Simulation of light scattering from air borne tea dust particles: possible carriers of pathogen*.
8P298	742	Application of new instrumentation for study of new processes and phenomena	**Achim Trimborn**, Urs Rohner, Marc Gonin, John Jayne, Douglas Worsnop, *New and Compact Single Particle Laser Ablation Mass Spectrometer (LAAPTOF)*.
8P299	757	Application of new instrumentation for study of new processes and phenomena	**Birgit Wehner**, Markus Hermann, Holger Siebert, Florian Ditas, Alfred Wiedensohler, *Setup and characterization of a new fast mixing type CPC*.
8P300	876	Application of new instrumentation for study of new processes and phenomena	**Dean Venables**, Jun Chen, John C. Wenger, *Extinction of aerosols in an atmosphere simulation chamber: broadband cavity spectrometer measurements extending from 320 to 450 nm*.
8P301	886	Application of new instrumentation for study of new processes and phenomena	**Jacob Swanson**, D.B. Kittelson, A. Bergmann, B. Giechaskiel, M. Twigg, *Design and Evaluation of a Mini Catalytic Stripper*.
8P302	68	Implementation of existing measurement methods and instruments for novel studies	**Amina Akachat**, Hakima Rebbah, *Diisocyanate aerosols in polyurethane manufacture*.
8P304	345	Implementation of existing measurement methods and instruments for	**Martin Hollertz**, John T. Elliott, Jacob Lewis, Eric R. Mansfield, Wynchester D. Whetten, Thomas A. Knotts IV, Michael J. Tarlov, Michael R. Zachariah, Leonard F. Pease III, *Hormone structural differentiation using a high resolution DMA*.

		novel studies	
8P305	365	Implementation of existing measurement methods and instruments for novel studies	**Martin Fierz**, Peter Steigmeier, Michael Glettig, Benjamin Wyrsch, Heinz Burtscher, *Direct integration of a GPS-GPRS unit into a miniature diffusion size classifer*.
8P306	573	Implementation of existing measurement methods and instruments for novel studies	**Thomas Barth**, Martin Lustfeld, *Influence of probe nozzle diameter on aerosol particle size distribution for isokinetic sampling in gas streams*.
8P307	596	Implementation of existing measurement methods and instruments for novel studies	**Konrad Kandler,** Eckart Schultz, *Recent enhancements and new applications of passive sampling of ambient particles*.
8P308	613	Implementation of existing measurement methods and instruments for novel studies	**Jeonghoon Lee**, Seung Cheol Han, *Using nigrosin as a surrogate for black carbon to study aerosol light absorption*.
8P309	718	Implementation of existing measurement methods and instruments for novel studies	**Jaan Salm**, Urmas Hõrrak, *Diffusion of charged particles in a DMA with inclined electric field and with a particle collector in gas outlet*.
8P310	861	Implementation of existing measurement methods and instruments for novel studies	**Florian Rubach**, Achim Trimborn, Thomas Mentel, Andreas Wahner, *Adapting the Aerodyne Aerosol Mass Spectrometer for Zeppelin-based measurements*.
8P311	865	Implementation of existing measurement methods and instruments for novel studies	**Juha Kangasluoma**, Heikki Junninen, Katrianne Lehtipalo, Tero Toivola, Tuukka Petäjä, Markku Kulmala, *Calibration of Condensation Particle Counters – analysis of sub-3nm calibration ions using mass spectrometry*.

8P312	906	Implementation of existing measurement methods and instruments for novel studies	**Caner Yurteri**, M. Stowers, W.A. Kleefsman, J.C.M. Marijnissen., *Mobilization of Aerosol MALDI Mass Spectrometry for Bioaerosol Analysis*.
8P313	1003	Implementation of existing measurement methods and instruments for novel studies	**Michelle Barker**, Cameron McLeod, Diane Ciaparra, Kevin Jackson, *Development and validation of a novel experimental system to investigate particulate matter emitted from a steelworks*.
8P314	1115	Implementation of existing measurement methods and instruments for novel studies	**Attila Nagy**, Attila Kerekes, Attila Nagy, Daniel Oszetzky, Aladar Czitrovszky, *Development of a pulmonary waveform generator for study the aerosol propagation and deposition in transparent hollow airway models*.

13:00-15:00 **Session 9A: Aerosols in Geoengineering**
Room: Theatre A
Chairs: Thomas Leisner / Francis Pope

13:00	9A1	823	**Hauke Schmidt** (Invited talk) *Implications of geoengineering assessed in simulations with complex climate models*
13:20	9A2	774	**Francis Pope**, Tony Cox, Markus Kalberer, Peter Braesicke, Andy Ward, Matt Watson *Impact of Geoengineered Aerosols on Stratospheric Ozone Chemistry*
13:40	9A3	567	**Thomas Leisner** (Invited talk), Stefan Müller-Klieser, Ulrich Platt *Near vessel dynamics of sea salt sprays: How efficient can maritime clouds be seeded?*
14:00	9A4	862	**Kristina Lundgren**, Max Bangert, Heike Vogel, Bernhard Vogel *The impact of controlled sea salt emissions on cloud features based on comprehensive regional model studies*

14:20	9A5	451	**Antti-Ilari Partanen**, Harri Kokkola, Sami Romakkaniemi, Veli-Matti Kerminen, Kari E.J. Lehtinen, Hannele Korhonen *Effects of sea spray geoengineering on clouds and Earth's radiative balance*
14:40	9A6	223	**Kirsty Pringle**, Ken Carslaw, Tingting Fan *Exploring efficiency of sea spray geo-engineering*

13:00-15:00 **Session 9B: Field Observations from Global Hot Spots**
Room: Theatre B
Chairs: Andreas Minikin / M. Krämer

13:00	9B1	116	**Petri Tiitta**, Lauri Laakso, Ville Vakkari, Philip Croteau, Miroslav Josipovic, Paul Beukes, Pieter Van Zyl, Andreas Venter, Kerneels Jaars, Heikki Laakso, John Jayne, Kobus Pienaar, Markku Kulmala, Ari Laaksonen, Douglas Worsnop *First on-line aerosol chemical composition measurements in South African grassland region*
13:20	9B2	453	**Ville Vakkari**, Heikki Laakso, Markku Kulmala, Desmond Mabaso, Lauri Laakso *Aerosol particle size distributions in clean and polluted environments in South Africa*
13:40	9B3	898	**Paulo Artaxo**, L.V. Rizzo, K.T. Wiedemann, E. Swietlicki, A. Wiedensohler *Long term aerosol optical properties in pristine and biomass burning areas in the Amazon Basin*
14:00	9B4	235	**Niall Robinson**, J. D. Allan, G. Allen, H. Coe *Inflow and outflow of Borneo: the regional setting of aerosol compositional measurements in and above a maritime tropical rainforest*
14:20	9B5	241	**Jai Devi Jeyaraman**, Priya Choudhry, Marykutty Michael, S.N. Tripathi, Tarun Gupta *Direct Evidence of Elevated Absorbing Layer Associated with Coarse Mode Particles over CTCZ Region from Aircraft Experiment 2009*

14:40	9B6	174	**Wenjie Zhang**, Zhipeng Bai, Jianzhong Ma, Jianhua Chen, Wen Yang, Baohui Yin *In-situ aircraft observations on gases and particulate pollutants around Beijing area: distributions and influencing factors*
Reserve	9BR	807	**Luca Ferrero**, D. Cappelletti, M. Petitta, F. Scardazza, M. Castelli, M.G. Perrone, G. Sangiorgi, E. Bolzacchini *Vertical profiles of aerosol physico-chemical and optical properties measured along Italy over basin valleys*

13:00-15:00 **Session 9C: Biomass and Biofuels**
Room: Rutherford Lecture Theatre
Chair: Olli Sippula

13:00	9C1	571	**Alejandro Keller**, Heinz Burtscher *Micro Smog Chamber: a Candidate Tool for Evaluating Wood Burning Emissions*
13:20	9C2	464	**Terhi Penttilä**, Heikki Lamberg, Annika Hukkanen, Olli Sippula, Jarkko Tissari, Jorma Jokiniemi. *Comparison of emissions from wood and oil boilers in small (20–25 kW) and medium (5–10 MW) scale*
13:40	9C3	815	**Heikki Lamberg**, Olli Sippula, Jarkko Tissari, Jorma Jokiniemi *The effects of air-staging and fuel characteristics on PM1 emissions from small-scale pellet combustion*
14:00	9C4	860	**Joakim Pagels**, Joakim Pagels, Axel Eriksson, Erik Z. Nordin, Robin Nyström, Esbjörn Pettersson, Erik Swietlicki and Christoffer Boman *Time resolved PAH-emissions from residential wood combustion investigated with aerosol mass spectrometry*
14:20	9C5	621	**Heinz Burtscher**, Alejandro Keller, Martin Fierz *Electrostatic precipitators for domestic wood stoves*
14:40	9C6	512	**Andrei Bologa**, Hanns-Rudolf Paur, Klaus Woletz *High temperature electrostatic precipitation for small*

			scale biomass combustion
Reserve	9CR	662	**Nickolas Meyer**, Thomas Heck *Wood combustion emissions in Switzerland and associated impact assessments*

13:00-15:00 **Session 9D: In-vitro toxicity and health effects of PM**
Room: Moseley Lecture Theatre
Chairs: Francesca Cetta / Otmar Schmid

13:00	9D1	424	**Marcello Galeazzi** *The inflammatory response elicited in vitro by air pollutants is greater in synoviocytes from patients with Rheumatoid Arthritis than in those with osteoarthrosis*
13:20	9D2	306	**Iris Raquel Gutiérrez** *Microbial test battery for risk assessment of fine particles originating from the combustion of wood*
13:40	9D3	724	**Pasi Jalava**, Joachim Kelz, Thomas Brunner, Mikko Happo, Jorma Mäki-Paakkanen, Pasi Hakulinen, Terhi Penttilä, Annika Hukkanen, Jorma Jokiniemi, Ingwald Obernberger, Maija-Riitta Hirvonen *Residential wood combustion technology affects the toxicological responses of particulate emissions*
14:00	9D4	321	**Lisa Künzi**, Sarah Schneider, Peter Mertes, Josef Dommen, Urs Baltensperger, Andre Prevot, Markus Kalberer, Marianne Geiser *Responses of lung cell cultures after realistic exposure to primary and secondary carbonaceous aerosols*
14:20	9D5	443	**Susanne Gauggel**, Joachim Wiese, Bart Pieterse, Daniel R. Dietrich *General and PAH-mediated cytotoxicity in particulate matter from wood combustion*
14:40	9D6	307	**Birte Hegemann** *Health risk assessment of wood combustion fine dust particles with Caenorhabditis elegans*
Reserve	9DR	355	**Dirk Broßell**, Sabine Plitzko, Nico Dziurowitz, Erhardt Gierke, Volker Bachmann, Gunter Linsel, Nkwenti

			Azong-Wara, Christof Asbach, Heinz Fissan, Andreas Schmidt-Ott *A Thermal Precipitator for Nanoparticle Cytotoxicity Screening*

13:00-15:00 **Session 9E: Aerosol-based Nanotechnology: Methods and Applications**

Room: Bragg Lecture Theatre

Chairs: Andreas Schmidt-Ott / Michael Mertler

13:00	9E1	226	**Stephanie Bubenhofer**, Wendelin Stark, Robert Grauss *From Embedded to Supported Metal/Oxide Nanomaterials: Thermal Behavior and Structural Evolution at Elevated Temperatures*
13:20	9E2	1047	**Dennis Kiesler**, Thomas Bastuck, Frank Einar Kruis, Markus Kennedy *Scaling of an aerodynamic lens for use in coating technology*
13:40	9E3	167	**Christoph Kellenberger** *Use of aerosol-derived nanoparticles for the fabrication of polymer ultrafiltration membranes*
14:00	9E4	120	**Nicole Neubauer**, Martin Seipenbusch, Gerhard Kasper *A new measurement technique for the process monitoring of the catalytic activity of nanoparticles during their production process*
14:20	9E5	168	**Sotiris Pratsinis** *Hybrid Plasmonic-Magnetic Biomarkers*
14:40	9E6	436	**Peter Pikhitsa**, Daegyu Kim, Hongjoo Yang, Mansoo Choi *Room temperature gas sensor based on carbon nanoparticles*

13:00-15:00 **Session 9F: Charged Aerosols**
Room: Blackett Lecture Theatre
Chairs: A. Bologa / C. Yurteri

13:00	9F1	962	**Stephanie Sigmund**, Mingzhou Yu, Joerg Meyer, Martin Seipenbusch, Markus Wild, Gerhard Kasper *Electrostatic controlled coating of particle surfaces with nanoparticles*
13:20	9F2	834	**Luewton Agostinho**, E.C. Fuchs, J. Wartena, C. U. Yurteri, J. C. M. Marijnissen *Characterization of EHDA in the simple-jet mode*
13:40	9F3	514	**Andrei Bologa**, Hanns.-Rudolf Paur, Helmut Seifert, Klaus Woletz *Study of corona discharge ionizer for high temperature/high pressure electrostatic precipitator*
14:00	9F4	106	**Dmitry Samsonov**, Celine Durniak, Paul Harvey, Neil Oxtoby, Jason F. Ralph, Sergey Zhdanov, Grogor Morfill *Particle diagnostics and wave phenomena in complex plasmas*
14:20	9F5	878	**Stephan Rennecke**, Alfred P. Weber *Contact charging of metal nanoparticles*
14:40	9F6	1071	**Lena Knobel**, Hans-Joachim Schmid *Comparison of methods to achieve a stationary charge distribution*
Reserve	9FR	929	**Markus Wild**, Joerg Meyer, Gerhard Kasper *A simplified procedure for particle charge distribution measurements and its application to the characterization of the annual DBD aerosol neutralizer*

15:30-17:10 **Session 10A: Aerosols in Geoengineering / Aerosols in Global Climate Models**
Room: Theatre A
Chairs: Hannele Korhonen / James Haywood

15:30	10A1	938	**Francois Benduhn**, Kenneth Carslaw *A New Hybrid Solver of Dissolution of Inorganics into*

			the Particle Liquid Phase: Evaluation and Global Scale Implications on Aerosol Properties.
15:50	10A2	409	**Zhiqiang Cui**, Kenneth Carslaw, Alan Blyth *More precipitation from melting ice particles in deep convective clouds in a warm and moist environment*
16:10	10A3	936	**Matthew Woodhouse**, Graham Mann, Ken Carslaw, Olivier Boucher *Weak response of CCN to changes in DMS flux: implications for the CLAW feedback in current climate assessments*
16:30	10A4	818	**Catherine Scott**, Piers Forster, Kenneth Carslaw, Dominick Spracklen *Estimating the radiative impacts of biogenic secondary organic aerosol, their variation with location and climate, and the implications for climate geoengineering*
16:50	10A5	389	**Jim Haywood**, Andy Jones, Lieven Clarisse, Adam Bourassa, John Barnes, Paul Telford, Nicolas Bellouin, Olivier Boucher, Paul Agnew, Cathy Clerbaux, Pierre Coheur, Doug Degenstein, Peter Braesicke *Modelling the volcanic eruption of Sarychev*

15:30-17:10 **Session 10B: Remote Sensing of Aerosol Properties**
Room: Theatre B
Chairs: Lucas Alado-Arboledas / Paul Zieger

15:30	10B1	339	**Franco Marenco**, Ben Johnson, Kate Turnbull, Jim Haywood, Stuart Newman, Alan Vance, James Dorsey, Martin Gallagher, Hugo Ricketts *The FAAM volcanic ash flights in May 2010: results from the lidar, the CAS, and ARIES*
15:50	10B2	469	**Alain Miffre**, Grégory David, Benjamin Thomas, Patrick Rairoux *Volcanic ash optical properties with an UV-depolarization Lidar*

16:10	10B3	570	**Carmen Cordoba-Jabonero**, Mar Sorribas, Juan-Luis Guerrero-Rascado, Jose-Antonio Adame, Yballa Hernandez, Hassam Lyamani, Victoria Cachorro, Manuel Gil, Lucas Alados-Arboledas, Emilio Cuevas, Benito de la Morena *Synergetic monitoring of Saharan dust plumes: A case study of dust transport from Canary Islands to Iberian Peninsula. Part 1: Dust detection, identification and vertical structure analysis*
16:30	10B4	825	**Lucas Alados-Arboledas**, F. Navas-Guzmán, J.A. Bravo-Aranda, H.Lyamani, J D. Pérez-Ramírez, J. L. Guerrero-Rascado , I. Foyo, I. Alados, M.J. Granados, G. Titos, J. Fernández Gálvez, A. Valenzuela, M. Antón, A. Quirantes, X. Querol, A. Alastue, F. J. Olmo *Multi-instrumental characterization of the mixing of Eyjafjallajökull volcanic aerosols and boundary layer aerosols at Granada, Spain*
16:50	10B5	875	**Paul Zieger** *Closure study of aerosol optical properties using in-situ and remote sensing techniques*
Reserve	10BR	951	**Mika Komppula**, Tero Mielonen, Kimmo Korhonen, Antti Arola, Heikki Lihavainen, Lauri Laakso, Ville Vakkari, Heikki Laakso, Paul Beukes, Pieter Van Zyl, Kobus Pienaar, Petri Tiitta, Rikus le Roux, Kgaugelo Chiloane, Holger Baars, Ronny Engelmann, Dietrich Althausen, Kari Lehtinen *One year of Raman lidar measurements at the South African EUCAARI site*

15:30-17:10 **Session 10C: Control Technologies for Combustion Emissions**

Room: Rutherford Lecture Theatre

Chairs: A.G. Konstandopoulos / C. Gutierrez-Canas

15:30	10C1	513	**Cristina Gutierrez-Canas**, Miren Larrion, Alfredo Perez, Egoitz Pena, Sergio Fernandez, and Juan Andres

			Legarreta *Nanostructure of fine and ultrafine particles from start-ups and shutdowns of a 250MW natural gas power plant*
15:50	10C2	1082	**Johannes Ebert**, Gernot Pranghofer, Ole Petzoldt *Optimization of Dust Collectors in Incineration Plants to control Fine Particulate, Dioxins and NOx by using ePTFE Membranes and Catalytic Filtration Technologies*
16:10	10C3	314	**David Sanz**, Jesús J. Rodríguez-Maroto, Jose L. Dorronsoro, Enrique Rojas, Alberto Bahillo, Raquel Ramos, Esperanza Ruiz, Pilar Galán, María A. Martínez, Cristina Gutierrez-Cañas, Miren Larrion, Egoitz Peña, Wilhelm Hagemann, Saioa Astarloa *Hybrid filtration and catalytic control of toxic pollutants from a 1.2MW waste biomass cofiring boiler*
16:30	10C4	789	**Dimitrios Zarvalis**, Suzana Lorentzou, Alexantra Zygogianni, Athanasios Konstandopoulos, Christopher Severin, Markus Shönen, Raimund Vedder, Michel Fiebig, Stephane Zinola, Jacques Lavy *Diesel Engine Exhaust Emission Control: Performance Assessment of a Multi-Functional Reactor under Conventional and Advanced Combustion Conditions*

15:30-17:10 **Session 10D: Turbulent Aerosol Transport and Exchange / Transport and Transformation**

Room: Moseley Lecture Theatre

Chairs: Birgit Wehner / Thomas Kristensen

15:30	10D1	763	**Birgit Wehner**, Florian Ditas, Alfred Wiedensohler, Holger Siebert *Vertical transport of aerosol particles in the marine boundary layer near Barbados*
15:50	10D2	412	**Daniele Contini**, Antonio Donateo, Cosimo Elefante, Fabio Grasso *Analysis of particles and CO2 fluxes in an urban area: correlation with traffic rate and micrometeorology*

16:10	10D3	364	**Malte Julian Deventer**, Frank Griessbaum, Otto Klemm *Highly size resolved particle fluxes over an urban area*
16:30	10D4	870	**Mark Gordon**, Ralf Staebler, John Liggio, Jeff Brook, Shao-Meng Li, Jeremy Wentzell, Cris Mihele, Gang Lu, Patrick Lee *Transport and mixing of aerosols due to highway-generated turbulence*
16:50	10D5	137	**Prashant Kumar**, Matteo Carpentieri *Dispersion of nanoparticles in vehicle wake – Part I: analysis of field measurements*
Reserve	10DR	208	**Pierre Roupsard**, Muriel Amielh, Alexis Coppalle, Hubert Branger, Philippe Laguionie, Olivier Connan, Didier Hébert, Denis Maro, Martine Talbaut *Submicronic aerosols dry deposition on urban surfaces: a wind tunnel study to improve the lack of knowledge*

15:30-17:10 **Session 10E: Spark Generators for Nanoparticle Generation**

Room: Bragg Lecture Theatre

Chairs: Knut Deppert / Einar Kruis

15:30	10E1	649	**Shubhra Kala**, Frank Einar Kruis, Ralf Theissmann *Generation of Au-Ge nanocomposites by spark discharge*
15:50	10E2	970	**Maria E Messing**, S. Blomberg, N.M. Martin, J. Gustafson, J.N. Andersen, L.E. Walle, A. Borg, H. Grönbeck, M.E. Grass, Z. Liu, E. Lundgren and K. Deppert *In situ high pressure XPS investigations of PdAg alloy nanoparticles: Towards cheaper catalysts*
16:10	10E3	877	**Tobias Pfeiffer**, Anca Anastasopol, Vincent Vons, Walter Legerstee, Stephan Eijt, Fokko Mulder, Andreas Schmidt-Ott *Direct Synthesis of Magnesum Hydride using Spark*

			Discharge
16:30	10E4	1076	**Konstantinos Barmpounis**, Tobias Pfeiffer, Vincent Vons, George Biskos, Andreas Schmidt-Ott *Self-charge Distribution of Nanoparticles Generated by Spark Discharge*
16:50	10E5	971	**Maria E Messing**, C.R. Svensson, B.O. Meuller, M. Bohgard, K. Deppert, J. Pagels and J. Rissler *Spark generated particles for nanotoxicology studies*

15:30-17:10 **Session 10F: Modelling Aerosol Formation**
Room: Blackett Lecture Theatre
Chairs: K. Carslaw / H. Junninen

15:30	10F1	419	**Florian Couvidat**, Youngseob Kim, Karine Sartelet, Christian Seigneur *H2O: A new model to predict secondary organic aerosol formation*
15:50	10F2	871	**Carolina Rojo**, Xavier Vancassel, Jean-Luc Ponche *Environmental impact of aviation-produced aerosols: Towards alternative fuels*
16:10	10F3	863	**Heikki Junninen**, Mikhail Paramonov, Anne Hirsikko, Miikka Dal Maso, Markku Kulmala *Automatic classification of new particle formation events*
16:30	10F4	883	**Carly Reddington**, Ken S. Carslaw, Dominick V. Spracklen, Maria Grazia Frontoso, Lindsay Collins, Joonas Merikanto, Andreas Minikin, Thomas Hamburger, Hugh Coe, Markku Kulmala, Pasi Aalto, Harald Flentje, Christian Plass-Duelmer, Wolfram Birmili, Alfred Wiedensohler, Thomas *Primary versus secondary contributions to particle number concentrations in the European boundary layer during the EUCAARI campaign*
16:50	10F5	920	**Christos Fountoukis** *Organic Aerosol over Europe: Model Evaluation and Response to Increasing Temperature*

Reserve	10FR	229	**Christoph Winkelmann**, Arkadiusz K. Kuczaj, Steffen Stolz, Bernard J. Geurts *Multi-scale modeling of aerosol formation in pipe flow*

17:10-18:00 EAA Working group meetings

Fundamentals	Blackett Theatre
Combustion	Rutherford Theatre
Instrumentation	Bragg Theatre
Particle-Lung Interactions	Moseley Theatre
Electrical Effects	Theatre A

Friday 9th September

09:00-10:00 Plenary 5
Andreas Petzold: Global aviation and particulate matter: from climate impact to volcanic ash and back
Room: Theatre B
Chair: Martina Krämer

10:00-10:15 Awards Ceremony – Theatre B

10:45-12:45 **Session 11A: Biomass Burning**
Room: Theatre A
Chairs: M.R. Alfarra / J. Schneider

10:45	11A1	912	**Christine Piot**, Matthias Gianini, Julie Cozic, Lucie Polo, Jean-Luc Besombes, Aurélie Charron, Jean-Luc Jaffrezo, Christoph Hueglin *Comparison of qualitative and quantitative approaches for source apportionment of PM at urban and rural alpine sites*
11:05	11A2	459	**Xuefang Sang** *Stable carbon isotope ratio analysis of anhydrosugars in biomass burning aerosol*
11:25	11A3	311	**Cátia Gonçalves** *Organic compounds in PM2.5 emitted from fireplace and wood stove combustion of typical Portuguese wood species*
11:45	11A4	607	**Jürgen Orasche**, Jürgen Schnelle-Kreis, Gülcin Abbaszade, Hans Ruppert, Ralf Zimmermann *Diurnal concentrations of organic tracers originated from wood combustion*
12:05	11A5	398	**Harri Portin**, Tero Mielonen, Mika Komppula, Ari Leskinen, Antti Arola, Ari Laaksonen, Kari Lehtinen *Biomass burning aerosols measured with in-situ and remote sensing instruments in Eastern Finland during the forest fires in Russia 2010*

12:25	11A6	465	**Mikhail Sviridenkov**, Gennady Gorchakov, Natalia Chubarova, Yevgenia Semutnikova, Alexander Emilenko *Optical and microphysical characteristics of smoke aerosol during fire events in Moscow region in summer 2010*
Reserve	11AR	547	**Chung-Te Lee** *Carbonaceous aerosols in the Asian Brown Clouds transported from Southeast Asia: downstream observations at Mt. Lulin in Taiwan*

10:45-12:45 **Session 11B: Chemical and Physical Properties of SOA**
Room: Theatre B
Chairs: Gordon McFiggans / Neil Donahue

10:45	11B1	187	**Mark Barley**, David Topping, Gordon McFiggans, Douglas Lowe *Modelling the sensitivity of aerosol properties to variations in key inputs:- 1) vapour pressures; 2) non-ideality; 3) hydrolysis of acid-anhydrides*
11:05	11B2	866	**Neil Donahue**, Lea Hildebrandt, Kaytlin Henry, Jesse Kroll, Douglas Worsnop, Spyros Pandis, Neil Donahue *Evaluating the mixing of organic aerosol components using high-resolution aerosol mass spectrometry*
11:25	11B3	1008	**Angela Buchholz**, TH. F. Mentel, F. Rubach, C. Spindler, R. Tillmann, E. Kleist, J. Wildt *Towards a better understanding of hygroscopic growth and cloud droplet activation of biogenic secondary aerosols*
11:45	11B4	608	**Taina Yli-Juuti**, Alessandro Zardini, Markku Kulmala, Merete Bilde, Joakim Pagels, Axel Eriksson, Erik Swietlicki, Douglas Worsnop, Ilona Riipinen *Study on equilibrium vapour pressure of succinic acid in binary aqueous solution and ternary inorganic - organic aqueous solutions using flow tube*

			experiments
12:05	11B5	361	**Lorena Miñambres**, Estíbaliz Méndez, María N. Sánchez, Fernando Castaño and Francisco J. Basterretxea *Water Uptake Properties of internally mixed sodium halide and succinic acid particles*
12:25	11B6	885	**Johannes Ofner**, Natalia Balzer, Joelle Buxmann, Hinrich, Grothe, Heinz-Ulrich Krueger, Ulrich Platt, Philippe Schmitt-Kopplin, Cornelius Zetzsch *Aerosol-halogen interaction: Halogenation processes of secondary organic aerosols*
Reserve	11BR	989	**Ilona Riipinen**, Jeffrey R. Pierce, Taina Yli-Juuti, Silja Häkkinen, Christos Fountoukis, Markku Kulmala, Douglas R. Worsnop, Merete Bilde, Spyros N. Pandis, Neil M. Donahue *On ultrafine aerosol growth and the condensation/ evaporation properties of atmospheric organics*

10:45-12:45 **Session 11C: Combustion Aerosol Measurements and Analysis**

Room: Rutherford Lecture Theatre

Chair: Stefano di Stasio

10:45	11C1	658	**Anssi Arffman**, Topi Rönkkö, Panu Karjalainen, Tero Lähde, Juha Heikkilä, Liisa Pirjola, Dieter Rothe, Jorma Keskinen *Thermodenuder with low nanoparticle losses: design, simulations, laboratory tests and diesel exhaust particle studies*
11:05	11C2	888	**Jonathan Johnsson**, Anders Karlsson, Nils-Erik Olofsson, Henrik Bladh, Per-Erik Bengtsson *Soot particle aggregates: numerical construction and analysis of influence on laser-induced incandescence and elastic light scattering signals*
11:25	11C3	207	**François-Xavier Ouf**, Jérôme Yon, Ghislaine Frebourg, Sébastien Pontreau

			Electronic tomography of nanoparticles aggregates: from 2D to 3D
11:45	11C4	61	**Stefano di Stasio**, J.Brian A. Mitchell, Jean-Luc LeGarrec *Effect of Alkali Metal Salt Addition on Hierarchic Assembly of Flame Aerosol Nanoparticles detected by Synchrotron Small-Angle X-ray Scattering*
12:05	11C5	474	**Alexis Coppalle**, J. Yon, C. Caumon, K. F. Ren, G. Martel *Determination of the refractive index of soot particles in the visble spectrum by extinction spectra*
12:25	11C6	213	**Reinhard Niessner**, Johannes Schmid, Benedikt Grob and Natalia P. Ivleva *Prediction of soot oxidation reactivity by Raman microspectroscopy*
Reserve	11CR	383	**Jérôme Yon**, Chloé Caumont-Prim, Alexis Coppalle, Kuan Fang Ren, *Measurement of soot size distribution in flames by inversion of angular light scattering*.

10:45-12:45 **Session 11D: From PM exposure to health effects 1**
Room: Moseley Lecture Theatre
Chairs: Jeroen Buters / Otto Hanninen

15:25	12C6	221	**Panu Karjalainen**, Matti Happonen, Topi Rönkkö, Toni Kinnunen, Piotr Bielaczyc, Rafal Sala, Jakub Dzida, Jorma Keskinen *Exhaust particles of a light duty diesel engine equipped with an oxidative aftertreatment operating with different sulfur level fuels*
Reserve	12CR	489	**Svetlana Stevanovic**, Branka Miljevic, Nicholas Surawski, Steven Bottle, Richard Brown, Zoran Ristovski *Reactive oxygen species (ROS) emissions from diesel engines running on various biofuels*

13:45-15:45 **Session 12D: From PM exposure to health effects 2**
Room: Moseley Lecture Theatre
Chair: Mats Bohgard

13:45	12D1	143	**Tobias Schripp**, Ina Kirsch, Sebastian Willenborg, Tunga Salthammer *Exposure Analysis for the Inhalation of Ultra-fine Particles Emitted from Household Devices*
14:05	12D2	974	**Anja Schmidt**, Ken Carslaw, Bart Ostro, Marge Wilson, Thor Thordarson, Graham Mann *Modelling excess mortality in Europe following a future Laki-style Icelandic eruption*
14:25	12D3	688	**Jenny Rissler**, Joakim Pagels, Christian Svensson, Jakob Löndahl, Maria Messing, Mats Bohgard *Novel methodology for estimation of mass and surface area of aggregated particles deposited in the human respiratory tract*
14:45	12D4	632	**Ian Longley**, Jennifer Gadd *Optical scattering observations in two occupied*

			residences with wood-burning stoves
15:05	12D5	727	**Alessandro Di Menno di Bucchianico**, Giorgio Cattani, Alessandra Gaeta, Giuseppe Gandolfo, Anna Maria Caricchia, Marco Inglessis, Gaetano Settimo, Biagio Bruni, Cinzia Perrino *Outdoor/indoor particle infiltration factor in Rome and its relation with urban air quality*
15:25	12D6	169	**Admir Targino**, Patricia Krecl, Christer Johansson *Simulated airway particle deposition in an urban environment impacted by biomass smoke*
Reserve	12DR	590	**Donald Hagen**, Elizabeth Black, Philip Whitefield, Prem Lobo *Surface Area Deposition Index for Jet Engine PM Exhaust*

13:45-15:45 **Session 12E: Application of New Instrumentation for Study of New Processes and Phenomena**
Room: Bragg Lecture Theatre
Chairs: Denis Boulaud / Igor Agranovski

13:45	12E1	244	**James Farnsworth**, Don Grant, Gary Van Schooneveld, Mark Litchy, Brian Osmondson, Robert Caldow *Ultrafine nebuliser for aerosolization of nanoparticles in colloidal suspensions*
14:05	12E2	272	**Mariana Ghosh**, S.Almabrok, D.J. Stewart, I.Hoare, G.Marston, C.Pfrang *A Study of Terpenes by Raman Acoustic Levitation*
14:25	12E3	531	**Christof Asbach**, Heinz Kaminski, Daniel von Barany, Christian Monz, Nico Dziurowitz, Johannes Pelzer, Knut Berlin, Silvio Dietrich, Uwe Götz, Heinz-Jürgen Kiesling, Rudolf Schierl *Handheld nanoparticle monitors – An intercomparison study*
14:45	12E4	841	**Gensdarmes Francois**, Roynette Audrey, Maro Denis, Laguionie Philippe, Boulaud Denis, Tikanen

			Juha *Evaluation of PEGASOR PPS response time for real time aerosol concentration measurements*
15:05	12E5	849	**Juergen Spielvogel**, Maximilian Weiss *A new versatile condensation particle counter for research and environmental monitoring*
15:25	12E6	887	**Kathy Erickson**, Fred Quant, Sean Morell, Susanne Hering, Robert Caldow *Two New Fast Response Laminar-Flow Water-based CPCs*

13:45-15:45 **Session 12F: Atmospheric Applications of Aerosol Modelling**

Room: Blackett Lecture Theatre

Chairs: A. Asmi / K. Barsanti

13:45	12F1	305	**Joni-Pekka Pietikäinen**, Declan O'Donnell, Markku Kulmala, Daniela Jacob, Ari Laaksonen *Model comparison between global and regional climate-aerosol models ECHAM5-HAM and REMO-HAM: European aerosols*
14:05	12F2	480	**Kelley Barsanti**, Annmarie Carlton, Serena Chung *Development and Application of Two-Product Secondary Organic Aerosol Model Parameters Based on Volatility Basis Set Fits*
14:25	12F3	1132	**Marta G. Vivanco**, Manuel Santiago, Ariel Stein, *Modelling SOA formed in a chamber from a mixture of organic gases*.
14:45	12F4	665	**Marion Devilliers**, Christian Seigneur, Edouard Debry, Karine Sartelet *A new algorithm to solve condensation/evaporation growth, coagulation and nucleation of nanoparticles*
15:05	12F5	578	**Craig Stroud**, Paul Makar, Mike Moran, Wanmin Gong, Junhua Zhang, Jeff Brook, Gang Lu, Jay Slowik, Jonathan Abbatt, Maygan McGuire, Greg Evans, David Sills, Q. Li

			Evaluation of Chemical-Transport-Model Predictions of Primary Organic Aerosol for Air Masses Classified using Back Trajectory and Particle-Component Factor Analysis
15:25	12F6	678	**Christoph Knote**, Dominik Brunner, Ulrike Lohmann *Aqueous-phase chemistry and its interactions with gases and aerosols in COSMO-ART*

15:45-16:00 Closing ceremony Theatre B

Sponsors and Exhibitors

Air Monitors Limited

Unit 2, Bredon Court
Brockeridge Park
Twyning - Tewkesbury
Gloucestershire GL20 6FF

Tel: +44 (0) 1684 857530
Fax: +44(0) 1242 292028

www.airmonitors.co.uk

Air Monitors Limited is a Sales and Service organisation representing market leading manufacturers. Specialising in the supply of instrumentation and systems for the monitoring of gaseous and particle/ aerosol parameters in ambient air, AML also has expertise in process and workplace applications.

Products include continuous particulate monitors using TEOM, Beta Attenuation and Light-Scattering technologies, Aethalometers and Nephelometers, together with Filter based Samplers, portable/ personal monitors and sampling equipment.

Our portfolio of products also features fixed and portable gas analysers, together with gas detection instrumentation, traffic monitoring and meteorological parameters, allowing AML to configure high performance, fully configured, cost effective AQM systems, with extensive diagnostic capability. AML also works with innovators to assist in the development of new technology, including web-based data acquisition (combining AQ, Traffic and Met. data), nanoparticle and mobile multi-gas monitoring.

AML are represented at EAC 2011 on Booth 2, further information is also available at www.airmonitors.co.uk

AirModus Oy
Katariina
Saksilaisen katu
14 A 11
00560 Helsinki
Finland

Tel: +358 44 3038 378
E-mail: joonas.vanhanen@airmodus.com
www.airmodus.com

Airmodus offers state of the art measurement solutions for nanosized aerosol particles. Airmodus is a group of aerosol physicists specialized in aerosol particle measurement technology, having long experience both in laboratory and field experiments. The company is based in Helsinki and as a spin-off company from the University of Helsinki it has straight contact to the leading research in the field of aerosol physics.
We specialize in providing tools for measuring the smallest sub - 2 nm aerosol particles.

The Airmodus Particle Size Magnifier A09 has been successfully used in nucleation laboratory experiments giving insight of the initial steps of atmospheric nucleation (Sipila et al. 2010, Science). It is also suitable for atmospheric measurements in field stations. It is capable of measuring aerosol particles down to 1.1 nm in diameter making it a powerful tool for filling the gap between conventional aerosol particle measurements and gas measurements.

Biotest UK Ltd

28 Monkspath Business Park
Highlands Road
Solihull
West Midlands
B90 4NZ

Tel: +44 121 733 3393
Fax: +44 121 733 3066
sales@biotestuk.com
www.biotestuk.com

Biotest with our sister company Heipha are a manufacturer and supplier of a full range of high quality room temperature storage, long shelf life Media for sterility testing. Equipment for particle monitoring, including the APC Smart touch which is the world's first dual flow rate machine for both validation and routine monitoring, and Microbial air sampling with the new RCS High Flow touch.

Biral

P O Box 2,
Portishead
Bristol,
BS20 7JB
United Kingdom

Tel: +44 (0)1275 847787
Fax: +44 (0)1275 847303
Email: aerosol@biral.com
www.biral.com

Biral specialises in the design and manufacture of aerosol size, shape and fluorescence instruments as well as forward scatter visibility and present weather sensors. Biral also represents Dekati and Met One in the UK and Ireland, further enhancing our particle measurement offering.

Biral's Aspect™ instrument measures the size and shape of particles using our unique ASAS (Aerosol Size and Shape) light scattering technology and when combined with the Biral AFS™, our dual waveband fluorescence chamber, this adds measurement of fluorescence for discrimination of many types of organic particles.

If you need accurate and detailed aerosol information for atmospheric and environmental studies such as cloud physics, ice crystal formation, particle populations, atmospheric pollutants, indoor pollution, source apportionment, fluorescence of organic aerosols (including ultrafines), or similar we may have just what you are looking for.

Please visit our booth to see sophisticated aerosol characterisation instrumentation or to discuss the design of a customised solution tailored to meet your research needs.

Cambustion Ltd

J6 The Paddocks
347 Cherry Hinton Road
Cambridge CB1 8DH
United Kingdom

Tel: +44 1223 210250
Email: cambustion@cambustion.com
www.cambustion.com

Cambustion instrumentation is already used in over 25 countries for both academic research and commercial R&D, with local representation in China, France, India, Japan and North America.

The new Centrifugal Particle Mass Analyzer (CPMA) allows classification of ultrafine aerosol according to mass: charge ratio. With a touch screen interface plus analog and digital connectivity to other aerosol instruments (e.g. CPCs) the CPMA facilitates a wide range of aerosol studies.

Our DMS series instruments offer the fastest (from 200 ms $T_{10\text{-}90\%}$ at 10 Hz) real-time electrical mobility size/number spectra available from 5nm – 2.5µm, with unrivalled sensitivity. Applications include ambient monitoring, combustion aerosol, workplace exposure and engineered nanoparticle research.

With fully integrated sampling and dilution options, DMS series instruments can be used for both ambient applications and straightforward direct sampling of high concentration aerosol sources through software selection of appropriate dilution.

Meet us at the Cambustion exhibit – booth No. 3

Copley Scientific Ltd

Colwick Quays Business Park
Private road no. 2
Colwick
Nottingham 234
United Kingdom

Tel: +44 (0)115 961 6229
E-mail: sales@copleyscientific.co.uk
www.copleyscientific.com

Copley Scientific is a major supplier of air sampling and aerosol characterisation equipment for academic research and industrial applications. In the pharmaceutical industry, the company is also recognised as the world's leading manufacturer and supplier of inhaler test equipment and is a major provider of testing systems for other pharmaceutical dosage forms.

Having offices in the UK and Switzerland, Copley Scientific works in partnership with US based aerosol particle science experts MSP Corporation, whose air sampling and aerosol characterisation products the company distributes throughout Europe. Such products include the market leading range of MOUDI cascade impactors, the real-time fibre monitor model 7400AD and the unique wide-range particle spectrometer (WPS) covering the particle size range: 5 nm to 10 microns.

Dekati Ltd.

Osuusmyllynkatu 13
33700 Tampere
Finland

Tel: +358 3357 8100
E-mail: sales@dekati.fi
www.dekati.com

Dekati Ltd. develops, manufactures and markets instrumentation needed in fine particle measurement and sampling. In 1995, Dekati introduced the world's first real-time fine particle concentration and size distribution measurement instrument. Since then, our R&D department has continually increased the range of products. Through the extensive global sales network, we are able to serve our customers around the world.
Dekati develops new products in close co-operation with the world's leading universities and companies. Our mission is to provide our customers with innovative fine particle measurement solutions that guarantee accurate results.

Dekati instruments are used for example in the following application areas:

- Combustion Processes (Diesel, Gasoline, Oil, Coal, Bio-fuels etc.)
- Environmental Ambient Aerosol Research and Monitoring
- Pharmaceutical Drug Screening and Inhalator R&D
- Nanotechnology
- Material Processing

Visit www.dekati.com for more details on our company and our products, or contact us at sales@dekati.fi for further information.

Derenda

Ingenieurbüro Norbert Derenda
Kieler Str. 9
D-14532 Stahnsdorf/Germany

Tel: +49 (0)3329-690 27 10
Email: info@derenda.de
www.derenda.de

In January 1972 Derenda Engineering Office was founded in Berlin by Norbert Derenda. Our current portfolio includes:

- Low- and High Volume Sampling devices and accessories
- Online Air Pollution Monitoring
- Automatic weighing systems for 47 and 150mm filters.

Our next generation of devices will be based on X-Ray diffraction with on-line analysis of the chemistry of the pollutants, as well as their size-distribution and shape.

Derenda is a pioneer in the field of fine-dust measuring, in cooperation with the Federal Health Office, Berlin the first fine dust measurement unit was developed to determine particulate concentrations in outdoor air. The resulting LVS was continuously refined over time and in 1999 adopted as reference unit in the European directives.

We listen to our customers carefully, to improve and service the existing material with our R&D department. Innovation is fueled by designing material that is based on the challenges our customers are or will be confronted with.

Digitel Elektronik AG

Regula Muther
DIGITEL Elektronik AG,
Alte Gasse 18, CH- 8604 Hegnau

Tel.: +41 44 908 20 30
Fax: +41 44 908 20 31
E-Mail: info@digitel-ag.com
www.digitel-ag.com

Since 1970 DIGITEL Elektronik AG has been a manufacturer of aerosol, gas and rain samplers in operation all over the world. Their experience and the state-of- the- art production processes stand for approved first-class quality products.

Digitel provide a full range of High and Low Volume sampler products for immission measurement such as PM10 according to the directives EN12341 and PM2,5 according to the
directives EN 14907 as well as for other measuring purposes with different flow rates and cut-off point characteristics. In addition to their standard products Digitel offer customer-specific solutions with specialised know-how and profound experience.

Droplet Measurement Technologies

2545 Central Avenue
Boulder
Colorado, 80301
United States

Tel: +1 303-440-5576
E-mail: info@dropletmeasurement.com
www.dropletmeasurement.com

Droplet Measurement Technologies offers accurate and sensitive instruments for real-time measurement of black carbon particles. The new Photoacoustic Extinctiometer (PAX) and Photoacoustic Soot Spectrometer (PASS) measure particulate light absorption and scattering at different wavelengths, producing BC mass and climate-relevant properties like single scattering albedo (SSA) from a single instrument. The Single Particle Soot Photometer (SP2) measures incandescence from BC-containing particles providing BC mass (independent of mixing state), number concentration and size distribution. Both techniques measure particles in-situ, eliminating filter artifacts.

DMT's extensive line of electro-optical particle analyzers are used by scientists worldwide for airborne and ground-based measurement applications in atmospheric and climate research, air quality monitoring, meteorology, aircraft certification, spray characterization, weather modification and cloud seeding,. In addition to black carbon, DMT instruments characterize aerosols, dust, volcano ash, sprays, cloud droplets, ice crystals, fog and precipitation, and cloud condensation nuclei.

For more information, please visit us in the exhibition hall, call +1 303-440-5576, visit our website www.dropletmeasurement.com, or email info@dropletmeasurement.

Ecotech Pty Ltd

1492 Ferntree Gully Road
Knoxfield
Victoria 3180
Australia

Tel: +61 3 9730 7800
E-mail: info@ecotech.com
www.ecotech.com.au

Specialising in EN and U.S. EPA approved ambient air quality monitoring instrumentation for gases, particulates and meteorological parameters, whilst also designing sophisticated data collection, validation and reporting software, Ecotech provides solutions that ensure air quality and climate data are accessible to everyone.

Our series of integrating nephelometers ranges from single to multiple wavelength versions and incorporates both polar and particle correlating options. Ecotech's Aurora range of integrating nephelometers are gaining a world-wide reputation for quality and reliability. Using an innovative LED light source, the Aurora 3000 nephelometer simultaneously measures at 525nm (green), 450nm (blue) and 635nm (red) to enable wide and in-depth analysis of particulate matter. The Aurora 3000 includes backscatter measurement in the standard unit.

Our MicroVol and HV3000 Air Particulate Samplers incorporate microprocessor technology to accurately measure and control the samplers flow rate and enable remote communication using conventional 3G modems. Our newest aerosol product is our MegaVol 3000 dust sampler. An ultra high volume sampler designed to sample dust, specifically heavy metals such as lead and radioactive particulates.

With more than 35 years designing and supplying air quality instrumentation Ecotech is regarded as one of the world's leading suppliers in air monitoring. Our network of distributors throughout the

world are highly trained and experienced in Ecotech's products and able to offer you the products you need at the price that you want.

Visit us at stand 1 to find out more or visit our website at www.ecotech.com

Enviro Techonology Services plc

Duncan Mounsor
Sales & Marketing Director
Enviro Technology Services Plc
Kingfisher Business Park
London Road
Stroud
Glos GL5 2BY
UK

Tel: +44 (0)1453 733200
Email: sales@et.co.uk
Web: www.et.co.uk

Enviro Technology Services Plc (ET) is a world leading supplier of continuous air quality monitoring instrumentation and systems.

Sectors served include Air Quality Monitoring (AQM), Continuous Emissions Monitoring (AQM) and gaseous and particulate monitors and samplers for Scientific & Research applications including, particulate chemical composition, atmospheric chemistry and stable isotopes. ET is proud to work with world leading instrument manufacturers including Teledyne API, Met One Instruments, Opsis, Digitel AG, URG Corp and Los Gatos Research.

ET specialises is "bespoke" air monitoring stations and networks.

GRIMM Aerosol Technik GmbH & Co. KG

Achim Edfelder
Dorfstrasse 9
83404 Ainring
Germany

Tel: +49 (0) 8654 578-33
E-mail: ae@Grimm-Aerosol.com
www.grimm-aerosol.com

GRIMM Aerosol Technik GmbH & Co.KG was founded over 25 years ago by Dr.-Ing. Hans-Jurgen Grimm in Bavaria/Germany. Today, GRIMM Aerosol Technik is one of the worldwide leading companies in the field of high-tech aerosol measurement instrumentation due to its innovations and quality manufacturing.

GRIMM Aerosol Technik offers a wide range of complete solutions for the continuous measurement of fine and ultrafine aerosols.
Instruments such as Environmental Dust Monitors, Aerosol Spectrometers, Particle Counters and Sizers, Filter Testers, and Aerosol Generators consistently meet the requirements of a world-wide increasing number of customers in research and industry. Specialists in-house will advise about the correct instruments for particular applications, e.g. for ambient air, emission, occupational health, filter efficiency and / or exhaust gas measurements, for quality control and for pharmaceutical, atmospheric or epidemiological studies.

Recently expanded production facilities are located in Pouch/Saxony-Anhalt/Germany. World-wide first-class customer service is offered through our U.S. subsidiary and our offices in Canada, UK, Middle East and Asia, and supplemented by a close network of international representatives.

Matter Aerosol

Andreas Knecht
Bremgarterstrasse 62
5610 Wohlen
Switzerland

Tel: +41 56 6186630
Fax: +41 56 6186639
E-mail: infot@matter-aerosol.ch
www.matter-aerosol.ch

Matter Aerosol (formally Matter engineering) specialises in the measurement and characterisation of nanoparticles from combustion processes and nanoparticles in ambient air. Matter Aerosol combines over 50 years of experience in instrument design and development with latest research results about nanoparticles, for application in laboratories to real-world problems.

Key Competencies:

- Equipment - design, development and production of equipment to sample, dilute, measure and characterise nanoparticles from combustion and ambient air.

- Services - nanoparticle emission measuring and testing programs for combustion engines, boilers, particle traps, fuels and additives at our partners' test benches or at the customer's site.

- Transfer - conferences and seminars on nanoparticle measurement.

Meritics

Tel: 01582 704807
E-mail: info@meritics.com
www.meritics.com

Meritics will be exhibiting the HCT range of aerosol and airborne particle counting and sizing instrumentation. From simple cleanroom particle sensors to the Scanning NanoParticle system the HCT range offers a solution for most measurement needs. The options available include PM sensors and a water based 1cfm CNC.

The National Physical Laboratory (NPL) is the UK's national measurement institute and is a world-leading centre of excellence in developing and applying the most accurate measurement standards, science and technology available. Our research and measurement services are aimed at new ways of measuring the mass and number concentration and composition of aerosols and particles in ambient air and emissions from a variety of industrial sources. We can carry out sampling and analysis for particle mass, number, anion and cation composition, black carbon, elemental/organic carbon, heavy metals, PAHs and bioaerosols. We have unique facilities for the calibration and intercomparison of aerosol/particulate measurement equipment, which we are offering for joint research and bespoke measurement projects.

Palas® GmbH

With more than 50 submitted patents, the Palas® GmbH has effectively set standards in aerosol technology since 1983. Today, Palas® offers a complete product range for the continuous aerosol measurement from 5 nm to 100 µm.

Our innovations result in superior quality and durability of the products that lead to unique technical and economic advantages for our customers. Our core competencies are:

- Particle generation
- Particle measurement systems (for high pressures, temperatures, processes, environment and workplace, inhalation)
- Nanoparticle measurement systems
- Filter test systems
- Fine dust monitor systems
- Dilution systems
- Cleanroom particle technology
- Calibration systems

Well-known industrial enterprises and research institutions worldwide have decided in favour of Palas® products and have thus established Palas® as a worldwide market leader.

As the global technology leader in the environmental monitoring industry, Particle Measuring Systems invests in research, engineering, manufacturing, and support of:

- particle counting and monitoring instrumentation
- microbial monitors
- molecular gas analyzers
- data management and automation software

Particle Measuring Systems also provides our customers value-added services including:

- risk analysis
- laboratory testing
- installation and commissioning
- project management
- validation and GMP compliance
- calibration and maintenance
- rentals and leases
- training

Our comprehensive instrumentation suite enables process-driven companies to monitor environmental quality and make fact-based decisions to improve process yield and meet regulatory requirements. Particle Measuring Systems equipment is used in monitoring applications across multiple by companies throughout the world. Our customers are concerned about the impact environmental contamination has on their products, processes, and equipment.

Sunset Laboratory Inc. has specialized in the analysis of air pollution for carbon aerosols since 1984. As well as performing the OCEC analysis, Sunset Laboratory also provides instrumentation for carbon aerosol analysis. Our equipment is suitable for the laboratory or in the field, and ready for use with the NIOSH method 5040, IMPROVE, and EUSAAR 2 protocols.
Clients include researchers working for government regulatory agencies, private companies, commercial laboratories, and universities.

Topas GmbH

Topas GmbH Dresden is a specialist company in the field of particle technology and filter testing systems. Our standard product range comprises:

- aerosol generators (mono - and polydisperse, solid and liquid particles)
- particle size measuring instruments for aerosols and liquids
- aerosol dilution systems
- electrostatic aerosol neutralizers
- process aerosol monitors
- filter testing technology and instruments
- clean room measuring equipment
- pore size measuring instruments

Topas also provides solutions for special applications like the dispersion of complex powders, test stands for particle filters and for adsorptive filters, filter media testing, blow-by measuring etc. Our corporate philosophy allows us to meet of a variety of customer needs. Many years of experience, our know-how as well as close cooperation with universities, research centres and industrial partners is the ideal basis for the development of new and innovative solutions. Our reliable measuring and testing equipment has proven successful worldwide.

For more than 50 years TSI Incorporated has been setting the standard for high performance measurement solutions. Our Particle Instrument product line is a comprehensive collection of precision instrumentation for counting, sizing and generating particles, from just two nanometers to a few hundred microns in diameter. TSI Particle Instruments are used the world over in such diverse applications as urban aerosol and fine dust measurements, climate studies, nanoparticle characterization, air filter testing, work place assessments and vehicle emissions testing.

A number of new TSI instruments will be highlighted at the EAC 2011. Our Nano Water-based CPC Model 3788 is the latest addition to TSI's CPC family and is designed for detecting nanoparticles down to 2.5 nm with a less than 100 milliseconds rise time response, making it the fastest CPC commercially available. Our new Advanced Aerosol Neutralizer Model 3087 offers a non-radioactive alternative to α- and β-neutralizers traditionally used for aerosol measurements and is drop-in compatible with TSI's 3936-series Scanning Mobility Particle Sizer™ (SMPS™) spectrometer. The new Aerosol Instrument Manager® software version 9.0 for the SMPS™ spectrometer enables computer flow control and records sheath flow temperature and absolute pressure before every sample. Our product line also features a new light and portable Optical Particle Sizer (OPS). The affordable OPS Model 3330 provides accurate measurements of particle concentration and size in the range from 0.3 to 10 microns, with superior resolution and adjustable size channels.
Please come and visit the TSI exhibition at booth No. 4-5-6!

Chapel Hill, North Carolina 27516 USA

Tel: 919-942-2753
E-mail: info@urgcorp.com
www.urgcorp.com

URG Corporation manufactures the **Ambient Ion Monitor (AIM) System** for the *continuous direct* measurement of particulate nitrate, sulfate, ammonium in PM2.5 plus gas measurements of nitric acid, SO_2 and ammonia. The **AIM System** analyzes particles, gases and organics. The **AIM System** incorporates a **Dionex Reagent-Free Ion Chromatograph**. The **AIM System** has detection limits of 0.1µg/m^3 for each of the required analytes and 0.081µg/m^3 for ammonia. The multi-pollutant data is instantly available on an hourly basis.

URG provides a wide variety of instruments for indoor and outdoor air sampling. Our **Annular Denuder System (ADS)** collects both acidic and basic gases and is designed to meet USEPA's Compendium Method IO-4.2. URG's complete collection of **aluminium cyclone inlets** are Teflon© coated, a patented process that minimizes the losses of reactive gases such as HNO_3 and NH_3 to the internal surfaces of the cyclone. URG provides **stainless steel cyclones** and **filter holders** for diesel emissions.

URG air sampling instrumentation is used in Europe, Asia, North America, Australia, Antarctica, Africa and South America.

Plenary: Atmospheric nucleation in the CERN CLOUD experiment

by Jasper Kirkby

Atmospheric nucleation in the CERN CLOUD experiment

Jasper Kirkby
On behalf of the CLOUD Collaboration
Physics Department, CERN, CH1211, Geneva, Switzerland
Keywords: atmospheric aerosols, particle formation, ion-induced nucleation, molecular clusters, CLOUD experiment.
jasper.kirkby@cern.ch

The possible influence of cosmic rays on aerosols and clouds is of considerable interest (Carslaw *et al.*, 2002). The CLOUD experiment at CERN is designed to study the effects of cosmic rays on aerosols, cloud droplets and ice particles under precisely controlled laboratory conditions.

The CLOUD chamber and gas system have been built to the highest technical standards of cleanliness and performance. Owing to its large volume (26 m^3), highly-stable operating conditions and advanced instrumentation, the chamber allows nucleation rates to be reliably measured over a wide range from 0.001 to above 100 $cm^{-3}s^{-1}$ and at aerosol growth rates down to a few $\times$ 0.1 nm h^{-1}.

The experiment has several unique aspects, including precise control of the "cosmic ray" beam intensity from the CERN Proton Synchrotron (PS), the capability to create an ion-free atmosphere inside the stainless-steel chamber with an electric field, precise and uniform adjustment of the sulphuric acid concentration by means of ultraviolet illumination from a fibre-optic system, and highly-stable operation at any temperature between 185K and 310K. The contents of the chamber are continuously analysed by a suite of state-of-art instruments connected to sampling probes that project into the chamber.

The measurements obtained by CLOUD at the CERN PS in 2010 and 2011 represent the most rigorous laboratory evaluation yet accomplished of binary, ternary and ion-induced nucleation of sulphuric acid particles under atmospheric conditions between the boundary layer and mid-troposphere. The results include first measurements of ion-induced versus neutral nucleation, and of the molecular composition of the critical clusters. The ternary vapours that have been studied include ammonia, amines and oxidised biogenic organic compounds. The measurements provide new insights into the nucleation mechanism and into the contributions of binary and ternary nucleation to particle formation in the atmosphere.

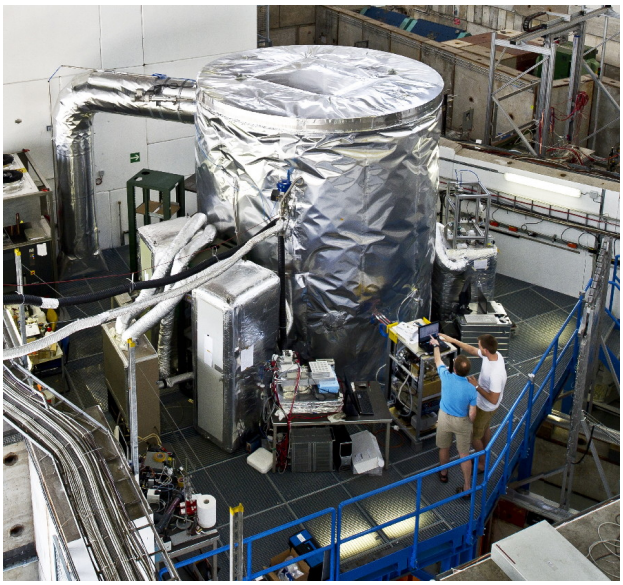

Figure 1: The CLOUD experiment in the CERN PS experimental zone, July 2010. The 3 m stainless-steel CLOUD chamber is enclosed inside the thermal housing visible in the photograph.

We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. This research has received funding from the EC's Seventh Framework Programme under the grant agreement no. 215072 (Marie Curie Initial Training Network "CLOUD-ITN"), the German Federal Ministry of Education and Research (project no. 01LK0902A), the Swiss National Science Foundation, and the Academy of Finland Center of Excellence Program (project no. 1118615).

Session 1A: Ultrafine particles in Urban Areas

Concentrations of UFP in a tunnel in Belgium

M. Van Poppel, V. Mishra, P., Berghmans
[1]VITO – Flemish Institute for Technological Research, 2400 Mol, Belgium

Keywords: ultrafine particles, traffic emissions, elemental carbon, $PM_{2.5}$, NOx

Presenting author email: martine.vanpoppel@vito.be

Epidemiological studies have suggested associations between traffic emissions and adverse health effects. In roadway tunnels, people can be exposed to higher concentrations, due to poor ventilation. In addition, a tunnel environment is an ideal case to study UFP dynamics to support UFP model development.
In this study, UFP concentrations have been measured together with nitrogen oxides, EC (elemental carbon) and PM mass fractions (PM_{10}, $PM_{2.5}$, PM_1) in the Craeybeckx tunnel in Antwerp (Belgium).

Measurements were performed in the Craeybeckx tunnel in June 2010. The tunnel is about 1600 meters long and is divided in two separate tubes, with four driving lanes per tube. Measurements were performed in the east bore of the tunnel, which carries the highway traffic towards Antwerp.
Size distribution of (ultrafine) particles was measured, with a Scanning Mobility Particle Sizer (SMPS, model 3936, TSI). $PM_{2.5}$ mass concentration measurements were performed using a low volume filter sampler (Partisol, Thermo). Filters were subsequently analyzed for EC/OC using TOT (Thermo Optical Transmission, Sunset) technique. In addition, the time profiles of PM fractions (PM_{10}, $PM_{2.5}$, PM_1) were measured using a Grimm optical counter (model 1.108). Nitric oxides were measured using a mobile platform (Airpointer, Recordum) comprising a Chemiluminescent technique for measuring NO and NO_2.
All pollutants were measured at 800 m from the tunnel entrance. Nitrogen oxides and PM fractions were measured at the tunnel entrance (at 100 m) and at 800m.
In addition, mobile measurements were performed during one day using DMS 50 (Cambustion) to measure the size distribution when driving through the tunnel. PNC were additionally measured using a handheld CPC (P-track, TSI), simultaneously inside and outside the car.

UFP number concentrations (PNC) and size distribution were measured as function of time in the middle of the tunnel. A good correlation of PNC with traffic intensities was observed. (Figure 1). Also size distributions showed a clear temporal trend, related to traffic intensities. When concentrations are higher, only one broad peak is observed (at 50 – 60 nm), whereas at lower concentrations a bimodal size distribution can be observed with an additional peak at 20 nm.

A temporal variation and correlation with traffic intensities was also observed for EC and NOx.
The average EC concentrations was 15.4 µg/m^3. The lowest value was observed on a Sundays (9.5 µg/m^3) and the highest on one of the weekdays (21.8 µg/m^3). The fraction of EC in total $PM_{2.5}$ mass ranges from 18.7 - 33.8% whereas TC (total carbon) accounts for 54.7 – 76.0 %. The average NOx concentration increased from 198 ppb (at 100 m) to 620ppb (at 800 m); 83 % of increased NOx concentration was NO, which is the major compound of NOx emitted by vehicles.
Correlations of number concentrations with NOx, EC and $PM_{2.5}$ will be discussed.

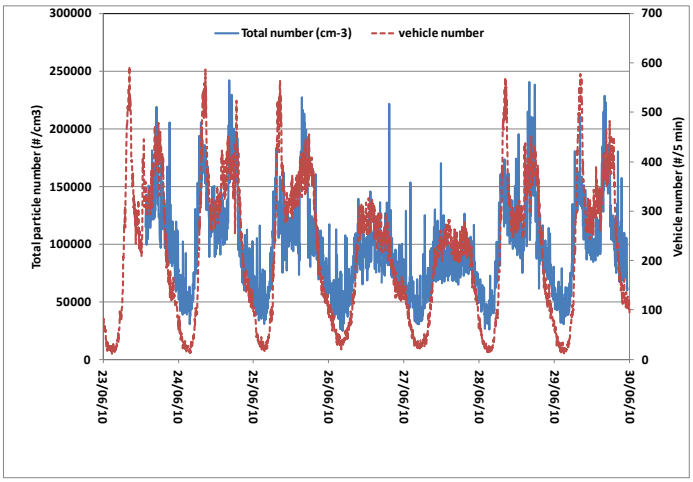

Figure 1: Total number concentrations and vehicle numbers as a function of time

Mobile measurements showed a change in size distribution when driving through the tunnel. A bimodal size distribution was observed with one peak below 10 nm and one around 55-65 nm. An increase of the largest peak was observed when driving through the tunnel, however the smallest peak decreased again in the middle of the tunnel and shifted to larger sizes. Total number concentrations in the car were about 70% compared to tunnel concentrations, in the size range (20 nm – 1 µm).

In this study increased concentrations of traffic-related pollutants (EC, NOx, PNC) were observed in a tunnel. A clear temporal trend of different particle characteristics and NOx was found. UFP size distribution showed highly transient dynamics (temporal

and spatial). These results can be used for UFP model optimization.

Measurement of Atmospheric aerosol size distribution, mass concentration and lung deposition in four cities of Pakistan

K. Alam[1*], M. Hussain[2], A. Mukhtar[3], P. Madl[2], S. Rehman[4], T. Trautmann[5], T. Blaschke[1]

[1]Department of Geography and Geology, University of Salzburg, Hellbrunnerstrasse 34, Salzburg 5020, Austria
[2]Department of Materials Research and Physics, Division of Physics and Biophysics, University of Salzburg, Hellbrunnerstrasse 34, Salzburg 5020, Austria
[3]Institute of Chemical Technologies and Analytics, Vienna University of Technology, A-1060 Vienna, Austria
[4]Pakistan Space and Upper Atmosphere Research Commission (SUPARCO), P.O.Box 8402, Off University Road, Karachi-75270, Pakistan
[5]German Aerospace Center, Remote Sensing Technology Institute, Oberpfaffenhofen, 82234 Wessling, Germany
Key words: Aerosols, Volume size distribution, PM_{10}, $PM_{2.5}$, Pakistan, lung deposition
Khanalamso@gmail.com

During March and April 2010 aerosol inventories of four big cities in Pakistan have been assessed in terms of size distribution, mass concentration (M), particle mass concentrations (PM), and aerosol lung deposition. For *Karachi*, *Lahore*, *Rawalpindi* and *Peshawar* mass concentration (M) and particulate matter (PM) concentrations were obtained from volume concentrations (V) using a native algorithm based on the Grimm model 1.109. The resulting V, M and PM concentrations confirm high levels for all four cities. The results reveal the following major contributions to the aerosol concentrations: resuspension of road dust, sea salt aerosols, and vehicular as well as industrial emission.

During the study period, the 24h average PM_{10} concentrations for three sites in *Karachi* were found to be 461 $\mu g/m^3$, 270 $\mu g/m^3$, and 88 $\mu g/m^3$, whereas the average values of 198 $\mu g/m^3$,448 $\mu g/m^3$ and 540 $\mu g/m^3$ were observed in *Lahore, Rawalpindi* and *Peshawar*, respectively (Figure 1). Likewise, the 24h $PM_{2.5}$ for the three sites in *Karachi* and *Lahore, Ralwalpindi* and *Peshawar* were found to be 185 $\mu g/m^3$, 151 $\mu g/m^3$, 60 $\mu g/m^3$, 91 $\mu g/m^3$, 140 $\mu g/m^3$, and 160 $\mu g/m^3$, respectively. The low $PM_{2.5}/PM_{10}$ ratios reveal a high share of coarser particles which originate from a) traffic, b) other combustion sources, and c) resuspension of dust.

Our calculated 24h averaged PM_{10} and $PM_{2.5}$ concentrations at all sampling points are 2-10 times higher than the WHO PM guideline values. The collected aerosol samples were analyzed for crustal elements (Al, Fe, Si, Mg, Ca) and trace elements (B, Ba, Cr, Cu, K, Na, Mn, Ni, P, Pb, S, Sr, Cd, Ti, Zn and Zr). The averaged concentrations for crustal and trace elements ranged from 1.02±0.76 $\mu g/m^3$ for Si (Sea view location in *Karachi*) to 74.96±7.39 $\mu g/m^3$ for Ca in *Rawalpindi* and from 7.0±0.75 ng/m^3 (B, SUPARCO, *Karachi*) to 17.84± 0.30 $\mu g/m^3$ (Na, M. A. Jinnah, *Karachi*) respectively. Furthermore, the deposition fractions upon inhalation in the human lung were calculated using the latest version of the IDEAL code, which is based on the stochastic airway generation model. The results derived from the model disclose that extrathoracic (ET) deposition is in the range of 20 to 25 % and total deposition in the lungs varies from almost 40 to 44 % for the measured particle size range.

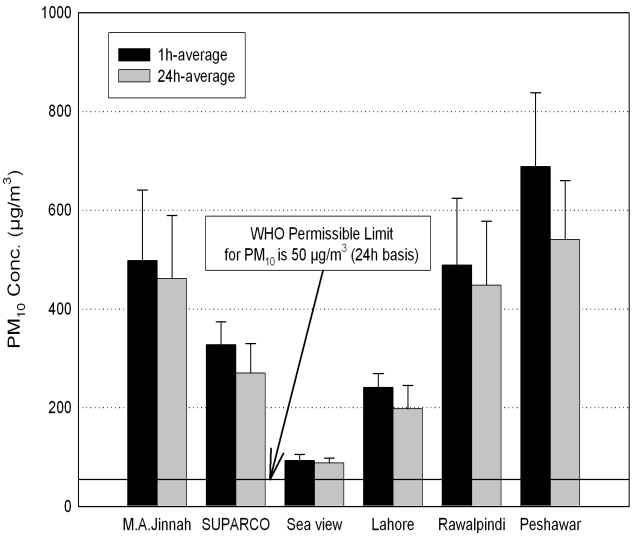

Figure 1. PM_{10} 1-h and 24-h average concentrations along with their corresponding standard deviations over six sampling sites in Pakistan. All the sampled sites reveal a 2-10 fold exceedance with respect to WHO PM_{10} value.

We would like to acknowledge the Higher Education Commission (HEC), Pakistan and the Austrian Exchange Service (ÖAD) for providing a three year Ph.D. scholarship 2008-2012 to Khan Alam.

Ultrafine particles in various urban microenvironments in Budapest

T. Borsós[1], I. Salma[1], T. Weidinger[2], P. Aalto[3] and M. Kulmala[3]

[1] Institute of Chemistry, Eötvös University, H-1525 Budapest, P.O. Box 32, Hungary
[2] Department of Meteorology, Eötvös University, H-1525 Budapest, P.O. Box 32, Hungary
[3] Department of Physical Sciences, University of Helsinki, FIN-00014 Helsinki, P.O. Box 64, Finland
Keywords: DMPS, number size distribution, urban aerosols.
Presenting author email: bteebi@gmail.com

Ultrafine aerosol has an important role in urban environments as far as its health and environmental effects are concerned. Our research was initiated to study formation and growth processes, and other properties such as health effects of ultrafine aerosol particles at various places in Budapest including different central urban sites, a tunnel and an urban background site.

On-line measurements have been performed using a differential mobility particle sizer (DMPS) for determining particle number concentrations in 30 bins in the mobility diameter range of 6–1000 nm. A meteorological station was also used for recording basic parameters such as air temperature, wind speed and direction, global radiation, etc. Time resolution of all measurements is ca. 10 min. The instruments were first set up near central Budapest, and later in the Castle District Tunnel.

Number size distributions were inverted from the DMPS data. These data were fitted by lognormal distribution functions to determine modal concentrations and number median mobility diameters (NMMDs). At the same time, concentrations in selected size ranges were also calculated, to allocate their contributions to the total number concentration, and to identify their time series. Temporal evolution of and changes in the nucleation mode, Aitken mode and accumulation mode were utilised for classifying the days and for the identification of new particle formation events.

Diurnal variation of concentrations was compared for different microenvironments. During this evaluation, several aspects were taken into consideration including workdays and weekends, as well as days with and without new particle formation. There were significant differences between the sites and distributions.

Daily median number concentration of particles in the measured size range varied from 3.8×10^3 to 29×10^3 cm^{-3} with a median value of 11.8×10^3 cm^{-3} near the city centre. For the tunnel site, it ranged from 5.1×10^3 to 465×10^3 cm^{-3} with a median of 143×10^3 cm^{-3}. Variability is related to micrometeorological conditions, traffic flow, vehicular emission as well as formation (source) and sink (coagulation and condensation) processes.

For the central site, contribution of ultrafine particles to the total particle number varied from 58 to 92% with a mean ratio and standard deviation of (79±6)%, while in the tunnel site, these values ranged from 61% to 98% with a mean and standard deviation of (85±1)%, which is slightly larger than for the urban ambient air.

Overall mean for the NMMD of the Aitken and accumulation modes were 26 and 93 nm, and 33 and 86 nm for the central and the tunnel site, respectively. All these values are substantially smaller than for rural or background environments. The reason is that the smallest particles are affected by coagulation and wall losses more extensively than the larger ones, and these effects can shift the modes to larger median diameters. Semi-volatile compounds that are present in larger concentrations in the Tunnel can condense on the surface of the particles, which also contributes to the shift.

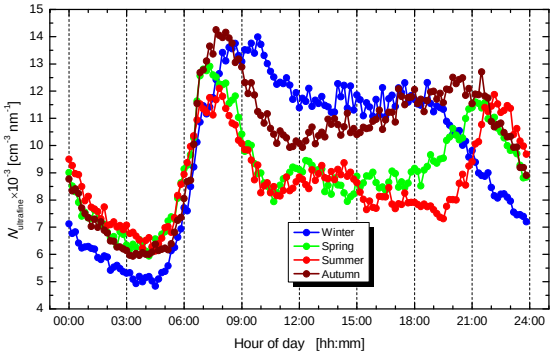

Figure 1. Diurnal variation of ultrafine particle concentrations for the four seasons in central Budapest.

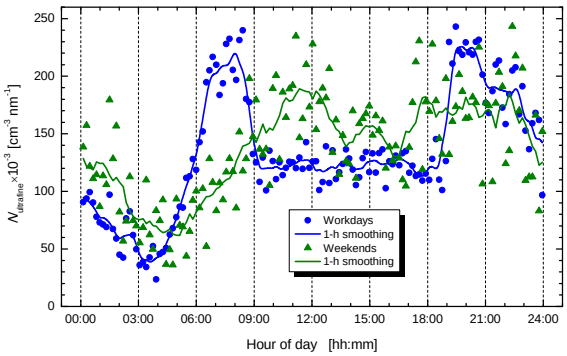

Figure 2. Diurnal variation of ultrafine particle number concentration for workdays and weekends in the Castle District Tunnel.

This work was supported by the Hungarian Scientific Research Fund under grant K84091.

Salma, I., Borsós, T., Aalto, P. & Kulmala, M. (2011) Boreal Env. Res., accepted for publication.

Analysing roadside Particle Number Concentrations using Boosted Regression Trees (BRT).

N.Z.Yahaya, J.E. Tate and M.R.Tight

[1]Institute for Transport Studies, University of Leeds, UNITED KINGDOM
Keywords: particle number concentration, street canyon, stochastic boosted regression trees, wind factors
Presenting author email: tsnzy@leeds.ac.uk

The influence of traffic flow and wind factors on roadside Particle Number Concentration [PNC] have been continuously surveyed for a 12 month period around a congested urban traffic signal controlled junction intersection in the suburb of Headingley, City of Leeds, UK. The experimental work was conducted at the semi-permanent 'Instrumented Junction' research site. Instrumentation includes: traffic flow and speed sensors, above roof-top and in-street sonic anemometers and four air quality stations measuring ultra-fine PNC.

Analysis has demonstrated significant variations in PNC between the stations, largely influenced by the prevailing and in-street winds, building geometries, background concentrations and tidal traffic flows. There is strong evidence of along canyon flow channelling at the sites located in irregular street canyon environments, with air-flows commonly parallel to the street axis. Across-canyon air-flows were also observed, which led to elevated concentrations on the leeward side of the street canyon at two of the monitoring stations as shown in Figure 1.

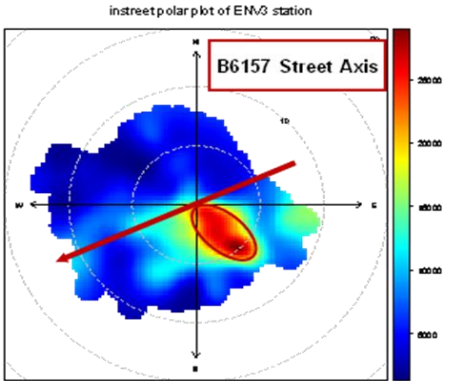

Figure 1. Bivariate polar-plot of [PNC] at ENV3

An new approach methodology to analyse PNC, Stochastic Gradient Boosting, or Boosted Regression Trees (BRTs) (Friedman, 2001, Friedman, 2002) is used to explore the relative influence of a variety of source and meteorological variables on PNC at the urban roadside locations. BRTs differ substantially from traditional regression-based approaches. Simple regression models only provide a single relationship between response and predictor variables BRTs are constructed of multiple regressions models. The BRTs were fitted using the 'gbm' package (R Development Core Team, 2008 and Ridgeway, 2007). Sensitivity testing of model parameters has been carried out (e.g. learning rates (0.005-0.5), number of trees (1000-10000) and interaction depth (1-10)) to identify the optimal parameterisation.

The BRT analysis has provided an importance rank of predictor (relative influence) variables expressed as a percentage. Figure 2 illustrates the relative influence results for site ENV1. It was found that the most important variable was the roof-top wind direction, followed by the traffic flow and vehicle speed. The roof-top wind speed was also found to be a significant influence on PNC concentration. These phenomena are in line with expectations as wind direction and speed are known to strongly influence dispersing air-flows and concentrations in street canyons.

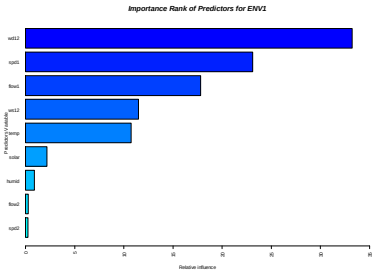

Figure 2. Relative importance of the PNC predictors at ENV1.

A clear benefit of BRTs for air pollution applications in particular PNC study, is their ability to model complex variable interactions and non-linear effects, which are the norm in air pollution research and can be difficult to determine using traditional statistical approaches.

Street-to-street variations in PM, PNC and BC in a motorway-dominated urban neighbourhood

I.D. Longley[1], W. Pattinson[2], S.Kingham[2], L. Reddish[1], G.Olivares[1], G.Coulson[1]

[1] National Institute of Water & Atmospheric Research Ltd, Auckland 1010, New Zealand

Introduction

Recent international research shows that the air quality impact of major roads is significant up to a 250 m distance and possibly further (Zhou & Levy, 2007). Negative health outcomes are increasingly being related to a traffic emission source. In New Zealand, as elsewhere, exceedence of National Environmental Standards for air quality (and WHO guidelines) based on short-term concentration peaks may occur alongside major roads. However, many observed health impacts are associated with chronic long-term exposure at times when standards are not breached (e.g. Brugge *et al.*, 2007). Ignoring this burden, as is currently the norm, leads to an undervaluation of the resulting health-care costs attributable to traffic (Künzli *et al*., 2008). Management is complicated by the multi-source nature of urban air pollution and whether road traffic sources are a major or significant source at any given location. A rational judgment of the cost-benefit of mitigation of traffic emission exposure requires that its full impact be quantified.

Methods

An observational campaign (lasting 5 months in total) has been conducted in Auckland (New Zealand) within an urban residential neighbourhood, of a scale of approximately 1 km^2, which is strongly affected by a major road. Three modes of monitoring have been employed. As well as three conventional fixed-site monitoring sites (including measurements of PM_{10} using beta-attenuation monitors, and one site equipped with an SMPS), mobile measurements of PM, black carbon and particle number concentrations have been made by cycle and car.

The fixed sites were deployed to represent 'background', 'kerbside' and 'setback' locations with respect to the motorway in the prevailing wind direction. The data generated is designed to be used to train a range of models aimed at capturing the spatio-temporal variation in concentrations across the study area.

The mobile monitoring was conducted to provide temporally limited but spatially detailed information on the finer-scale variation across the study area, as well as investigate the location and impact of emission sources other than the motorway (local roads, motorway intersection, woodsmoke from domestic heating, etc). Spatially dense passive monitoring of NO_2 was also conducted across the Study Area to further inform an understanding of long-term (persistent) fine-scale variation in the impacts of traffic emissions.

Results

Although analysis is still ongoing, early results indicate that the motorway (which carries 6 lanes of traffic and approximately 100,000 vehicles per day) contributes relatively little to PM_{10} concentrations across the Study Area compared to other (background) sources (which may include other, non-local traffic sources). However, the contribution of the motorway to concentrations of NO_x and NO_2 (and, by implication, long-term variations in all other traffic-related pollutants) within 0 – 200 m of the motorway is substantial. Data captured by mobile survey is strongly influenced by close encounters with vehicle plumes. However, when these encounters are filtered from the data significant fine-scale variations in particle and black carbon concentrations are revealed.

The spatial and temporal variation of selected aerosol and gas phase parameters is assessed in longterm measurements for the Karlsruhe (Germany) area with an automated self calibrating mobile laboratory. As measurement platform a tramway (AERO-TRAM) operating in the public transport is used. For the year 2010 measurements on more then 2300 runs are obtained resulting in an extraordinary dataset for ground based mobile applications. The AERO-TRAM operates on two selected lines. Both lines connecting the rural and suburban hinterland of Karlsruhe with the city centre. They are crossing areas with high concentrations of particles and trace gases and areas where only background concentrations are expected. Therefore, the obtained comprehensive dataset is useful for determining regional variation of particles and trace gases as well as for the identification of source areas. The differences in regional particle number concentrations, particle size distribution and also in the NO and NO_2 concentrations, which are important precursors for particles, will be presented for the year 2010 (figure 1 shows concentration differences for selected regions in May 2010). The obtained concentration distributions will be discussed focussing on different surrounding parameters, which are characterising rural, suburban and urban regions and also under consideration of meteorological conditions. An interesting feature of the mobile system is the use of analysers with high response times leading in a high spatial resolution of the measurements. This gives the possibility to study the impact of emission hot spots (e.g. crossroads with high traffic amount) on the closed surrounding based on a high resolved dataset. In figure 2 the particle number and the NO and NO_2 concentrations as a mean for May 2010 along an inner city street canyon are shown. Two emission hot spots exist along the street canyon (fig. 2, A and D) influencing the shown concentration profiles. Profiles along the AERO-TRAM track at different hot spots will be discussed in detail.

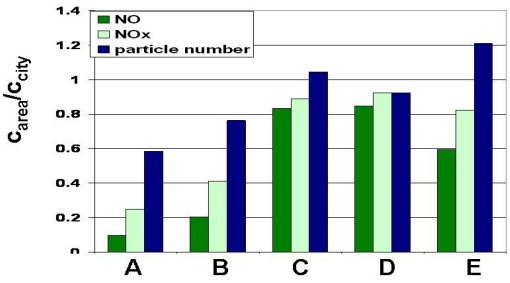

Figure 1. Regional particle number and NO, NO_x concentrations relative to the inner city region (mean values over all drives for May 2010 for A rural area, B suburban area C pedestrian area, D main station, E motorway).

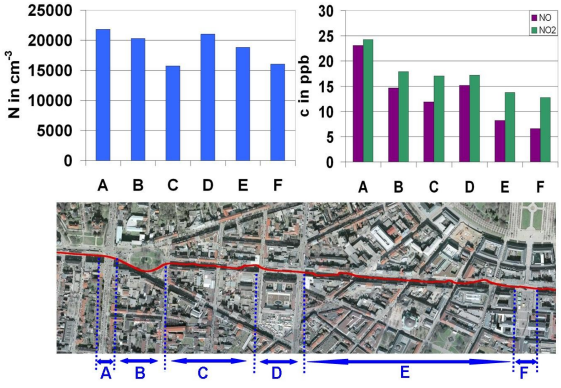

Figure 2. Particle number (left) and NO, NO_2 concentrations (right) for an inner city street canyon as mean over all drives for May 2010 and over the areas A crossroad with high traffic amount, B place next a crossroad, C road with low traffic amount, D crossroad, E pedestrian area and F market place.

Particle area and number concentrations influenced by local sources at an urban background station in Germany

Keywords: particle area, car traffic, asphalt grinding, gas-fired CHP, airport

The European Union defined a daily average PM_{10}-limit of 50 µg · m^{-3} for the protection of human health (2008/50/EC). Epidemiological and toxicological studies give evidence that ultrafine particles (< 100 nm, UFP) show negative health effects (Knol *et al.*, 2009).

Reduction limits for diesel cars are fixed (EURO VI). To control the results of reducing emitted particle numbers from cars and especially trucks, governmental agencies in Germany started to measure ultrafine particles on a routine base (Birmili *et al.* 2009 and Löschau *et al.* 2010).

Table 1 1-h av. tracheobronchial particle area and particle conc. 09-09-2009 – 14-06-2010

	NSAM	UCPC	SMPS
	µm²/cm³	p / cm³	p / cm³
nm	10 - 1000	3 - 1000	10 - 500
Median	5.0	9 900	8 600
Std	3.1	6 100	6 000
5 Perc	1.9	4 600	3 700
95 Perc	11.7	22 500	21 000

The urban background station was situated in Langen, Germany: 15 km south of Frankfurt a. M. and 5 km south east of the airport in the Rhine-Main-Area. Three different particle measuring instruments (TSI Inc.) were running continuously (09-09 – 06-11, 1 min av. and SMPS 6 min av.) on a rooftop at 14 m above ground with cut of at 1 µm. NSAM measures the deposited tracheobronchial (= tb) particle area within particle diameter of 10 - 1000 nm. With UCPC 3776 particle number concentration from 3 - 1000 nm was measured. With SMPS 3936 and CPC 3010 particle number size distributions between 10 – 500 nm were detected. 6 size classes were calculated from SPMS data (10 |30 |50 |70 |100 |200 |500). The difference of UCPC and total SMPS was expected to be size class 3 – 10 nm Offsets between both instruments cannot be excluded.

Temperature, humidity, wind speed, wind direction, precipitation was collected by WS600 (LUFFT GmbH). Only complete datasets of 1 h av. were used for evaluation (85 % of time period). For diurnal Mo-Fr variations data from official holidays and from 23-12-09 until 03-01-10 were excluded.

During the measuring period the median of the tb particle area concentration was 5 µm²/cm³, particle number concentration from 10 to 500 nm was about 8 600 p · cm^{-3}. 1 300 p · cm^{-3} more particles were found from 3 to 1 000 nm range (s. Tab. 1). The temperature was between -15 and +30°C, wind speed up to 14 m · s^{-1}.

For diurnal variations from Monday to Friday 2 different shapes were detected (Fig 1). Shape A: Tb particle area and particles 30 – 500 nm showed a 1st min. around 4:00, max. at 9:00 and 2nd min. at 15:00, similar to previous observations at an urban background during UFIPOLNET (Wehner *et al.*, 2008). Shape B: Particles 3 – 10 nm showed 1st max between 13 – 15:00 probably caused by particle nucleation events and a 2nd max at 7:00. Particles 10 – 30 nm show almost the same diurnal variation as shape A except for afternoon, were the second min. looks as if overlayed by effects responsible for shape B.

Grinding up asphalt and other road construction work in 10 to 100 m distance caused raised particle area and number concentrations. Elevated particle concentration occurred with winds from a nearby combined heat and power gas-fired power plant (CHP). The influence of the airport will be evaluated. The influence of fireworks is described elsewhere (Gerwig *et al.*, 2011).

In November 2010, the measurement campaign CARRIBA2010 (Clouds, Aerosol, Radiation, and tuRbulence in the tRade wInd regime over BArbados) took place in the Caribbean (Barbados), during which ground-based and airborne measurements were done.

Measurement that we want to report about here aimed at the examination of aerosol cloud interactions for the cumulus clouds typical for the trade wind regions. For that, on the ground, particle number size distributions and the activation of particles to cloud droplets were measured. The latter was done using two different CCNc (Cloud Condensation Nucleus counters), the one available from DMT (Droplet Measurement Technologies), which was used for size segregated measurements, and a miniaturized CCNc (mini-CCNc, designed following Roberts and Nenes (2005)), used to measure the number concentration of CCN (N_{CCN}) while scanning the supersaturation. The measurement platform ACTOS (Airborne Cloud Turbulence Observation System, Siebert *et al.* (2006)) was flown at altitudes up to 2500m, being carried by a helicopter. ACTOS carried instrumentation for the characterization of meteorological parameters, turbulence, cloud droplets and aerosol particles. The airborne aerosol characterization consisted of instruments measuring particle number concentration (N_{CN}), number size distribution and particle activation, where for the latter a mini-CCNc was used.

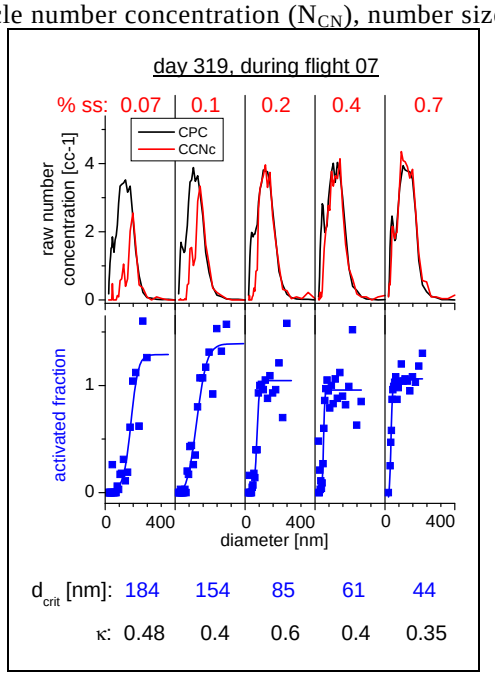

Figure 1. Ground based measurements taken during one of the ACTOS-flights.

On ground, measurements were performed continuously for 22 days. Cumulus clouds were almost always present, short rain showers (lasting for some minutes only) occurred on some days. N_{CN} measured on ground ranged from around 200 to 800 cc^{-1}, while N_{CCN} at a supersaturation of 0.3% was measured to be about 50 to 400 cc^{-1}. From the size segregated CCNc measurements done on ground, a particle hygroscopicity parameter κ (Petters and Kreidenweis, 2007) can be derived – as shown exemplarily in Figure 1. κ varied with time but also with dry particle size, however was consistently larger than generally found for continental aerosol, with κ of about 0.5 to 0.6 on average, a value similar to the one modelled as an annual mean by Pringle *et al.* (2010) for the Caribbean region.

During the campaign, 17 research flights were done. N_{CCN} was always measured at a supersaturation of 0.3%, at least during one profile. Additionally, during some flights the supersaturation was scanned during level flight legs. A first comparison of N_{CCN} measured on ground with those measured on ACTOS within the boundary layer (below 500m) showed good agreement, besides for times with increased rainfall intensity, when N_{CCN} measured on ground was lower than that derived from the airborne measurements. Besides for lofted aerosol layers that were observed seldom, a decrease in N_{CCN} was seen above the boundary layer.

With our study we aim at a thorough characterization of the marine aerosol as it occurs in the Caribbean, with respect to N_{CN}, particle size distributions and particle hygroscopicity, at the variation of these parameters both, with time and height, and at the link between these aerosol parameters with the cloud properties.

We thank Joe Prospero for providing the infrastructure at his monitoring station on Barbados, the CIMH for help prior to and during the campaign, and the people at the Concord Center for providing us the office space. This project was funded by DFG-grant SI 1534/3-1 and the IfT.

Keywords: Heterogeneous ice nucleation, Ice nuclei, volcanic particles
Presenting author email: karinard@tau.ac.il

The effectiveness of volcanic ash as ice nuclei has been debated in the past. Some reported that volcanic ash particles are very effective as ice nuclei, while others reported just the opposite. In this work we show that the volcanic ash particles from Eyjafjallajökull are very effective ice nuclei (IN). We observe that in some cases these particles are as effective as or even more so than mineral dust particles.

Measurements of IN concentrations have been carried out at Tel Aviv University (TAU) in Israel and at the Taunus Observatory (TO) in central Germany on a daily basis using the same methods and identical instruments.

The aerosols were collected on 47mm diameter silicon substrates using a specially designed electrostatic precipitator (Klein et al., 2010). All the samples were collected at a flow rate of 2 liters min^{-1} with 10 liters and 5 liters sampled at TO and TAU, respectively. Substrates were analyzed in the isothermal static vapor diffusion chamber FRIDGE (Klein et al., 2010). Ice nuclei concentrations were measured at three different temperatures between −8ºC to −18ºC and RH_{ICE} between 103% and 119%. The ice crystals were observed by a CCD camera and were counted automatically.

In this research we show that the plume of the volcanic ash from Iceland passed over Germany and even more interesting, it reached Israel, which is located about 5000 km away from the source (Fig 1).

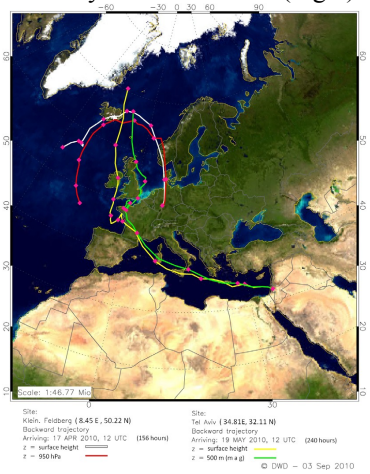

Figure 1.Backward trajectories from Eyjafjallajökull volcano arriving at Germany in April 2010 and at Israel in May 2010. Trajectories were calculated by the German Weather Service DWD.

High concentration of IN were found as the plume passed over Germany and over Israel. The concentrations of IN were higher than those measured during a dust storm that passed over Germany (Bingemer et al., 2011). They were of similar to those measured during dust storms passing over Israel (see Fig. 2)

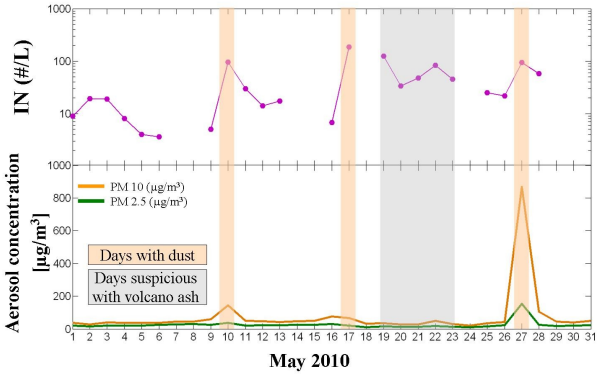

Figure 2.Number concentration of ice nuclei (at −18°C and water saturation) and concentration of PM_{10} and $PM_{2.5}$ at TAU during May 2010. A dust storm is defined when PM_{10} increases above 100 µg/m^3.

Such high concentrations of ice nuclei and high activation temperatures (forming ice at warmer temperatures) point to the potential impact of volcanic ash on microphysical and radiative properties of tropospheric clouds.

This work was supported by Deutsche Forschungsgemeinschaft (DFG) under the Collaborative Research Centre 641, the German Israeli Foundation for Scientific Research and Development (GIF), and the Virtual Institute “Aerosol-Cloud-Interactions” of the Helmholtz-Gemeinschaft. We thank the German Weather Service DWD for providing the trajectory analysis.

Single particle depolarization studies: Unraveling the mysteries of Paris Fog

Darrel Baumgardner[1], Neda Boyouk[2], and Martial Haeffelin[2]

As part of the Paris Fog campaign, conducted from October, 2010 to March 15, 2011, measurements were made with the Aerosol Particle Spectrometer with Depolarization (APSD), an optical particle counter that measures single particle light scattering. Side scattered light collected at an angle of 90° ± 53° is used to derive particle diameter between 0.5 and 10μm. Back scattered light collected at 160° ± 13° gives information on composition when compared with the side scattering and depolarized light collected at 160° ± 13° is proportional to shape and surface roughness.

The measurements were evaluated to study the evolution of aerosol from the period before fog formation, then during the fog events, and following the dissipation of fog. We create maps of the relationship between size, backscattering and depolarization to derive unique "fingerprints" related to the aerosol properties and the air mass origins.

Figure 1 illustrates one set of fingerprints that relate the ratio of backscattering to side scattering to the depolarization to side scattering. The three maps are for the three hour period before fog, then the period in fog, followed by the three hour post fog period. These three were created for all fog events when the air was in the 180-270° quadrant three hours previously. The fingerprints are distinctly different showing the result of fog processing of the particles. Additional fingerprints have been created for those fog events when the air mass came from the other three quadrants.

This presentation will describe the fingerprints in the context of their physical significance as they relate to the optical, chemical and morphological characteristics of the particles and how these are modified when fog forms.

In the example shown in Fig. 1, the most frequent events, denoted by the red color, occur at a relative backscatter ratio (arbitrary units) around 15 with no clear correlation with depolarization ratio. In the cloud this pattern changes to a clear positive correlation between the two ratios followed by another pattern, also correlated but with a different slope after the fog.

Factors affecting the molecular flux during evaporation and condensation of water on an aqueous droplet surface

R. E. H. Miles[1], T. Yli-Juuti[2], I. Riipinen[2,3] and J. P. Reid[1]

Keywords: mass accommodation, heat and mass transfer, Raman spectroscopy.
Presenting author email: j.p.reid@bristol.ac.uk

The rate at which the equilibrium state of an aerosol is achieved depends on both the kinetics of mass transfer between the droplet surface and surrounding gas phase, and the coupling between heat and mass transfer. An understanding of mass transfer to and from particles is important for determining the number of activated cloud condensation nuclei (CCN) in cloud physics models. Treating particles as existing at equilibrium when their size is kinetically controlled could give uncertainties in the number of activated CCN, compromising the accuracy of aerosol indirect effect predictions (Chuang *et al*., 1997; Davidovits *et al*., 2004). Here we present direct measurements of the molecular flux of water at the surface of aqueous aerosol particles as a function of pressure, particle size, solute concentration and solute type.

In this work, an optically tweezed aqueous droplet several micrometers in diameter is periodically illuminated with a second laser beam of the same wavelength, 532 nm. When exposed to the secondary heating beam the droplet temperature rises, increasing its vapour pressure and leading to droplet evaporation as the solute effect seeks to re-establish equilibrium with the surrounding relative humidity. Upon removal of the heating beam, the droplet temperature falls, decreasing the droplet vapour pressure and initiating droplet growth. Changes in particle size caused by the droplet temperature fluctuations can be monitored using Cavity Enhanced Raman Scattering, with time resolution down to 0.06 s and a sizing accuracy of < 1 nm in radius (Figure 1).

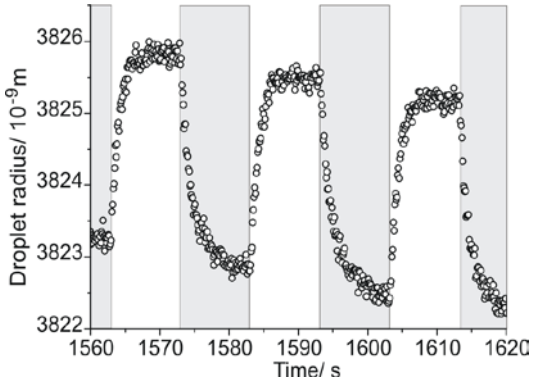

Figure 1. Change in droplet radius with time. Grey shaded regions show when the heating beam is on.

By fitting a first order exponential to the condensation and evaporation events an experimental time constant can be determined, providing information on the rates of the two processes. Measurements can be taken at pressures down to ~ 3 kPa by partially evacuating the sealed trapping cell, allowing the effect of gas phase diffusion on the mass flux to be investigated. Preliminary results (Miles *et al.*, 2010) show a clear pressure dependence of the measured molecular flux during condensation events at the droplet surface. Representative data for water condensing on a ~ 0.36 M aqueous sodium chloride droplet is shown in Figure 2.

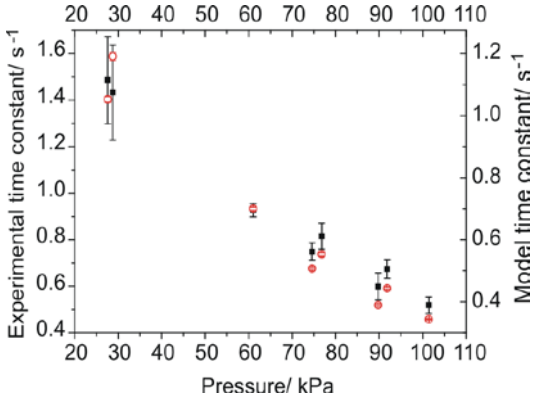

Figure 2. Experimentally measured pressure dependence of the condensational growth time constant (squares) compared with model predictions (circles) for $\alpha_m = \alpha_t = 1$ using the model of Kulmala *et al.* (1993). Proportional change on each axis is the same.

Measurements have been performed on aqueous sodium chloride particles with radii in the range 3000 nm to 4400 nm and concentrations varying between 0.36 M and 0.91 M. When pressure, temperature and latent heat effects are taken into account, striking agreement is seen between rate data collected from different droplets. Measurements are currently underway to investigate the effect of the inorganic solute type on the molecular flux. Future work will look at the effect of organic thin films on the rate of condensation and evaporation.

In situ measurement of cloud droplet activation behaviour of black carbon particles

M. Gysel, M. Laborde, N. Bukowiecki, Z. Jurányi, E. Hammer, P. Zieger, U. Baltensperger and E. Weingartner

Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland
Keywords: black carbon, aerosol cloud interaction, mixing state, CCN.
Presenting author email: martin.gysel@psi.ch

Black carbon (BC) emitted from combustion sources is the major absorbing component of atmospheric aerosols. The Earth's climate can be influenced by BC particles in several ways, for example by absorption of solar radiation or by decreased surface albedo of glaciers through deposition of BC particles. Cloud droplets only form on cloud condensation nuclei (CCN). The CCN properties of BC particles are important for their atmospheric life cycle as wet removal is an important sink. Several laboratory and field studies have shown that BC particles are less hygroscopic and less CCN active than inorganic or water-soluble organic aerosol components. The aim of this study is to compare the activation behaviour of BC particles in real clouds with the activation behaviour of non-BC particles.

In-situ measurements of the cloud droplet activation behaviour of aerosol particles were done at the high alpine research station Jungfraujoch (3580 m asl), Switzerland. Two different inlets were employed to selectively collect the interstitial aerosol (all particles that did not form cloud droplets) as well as the total aerosol (interstitial aerosol plus cloud droplet residuals) during cloud episodes. Both aerosol samples were characterized using a Single Particle Soot Photometer (SP2), which provides quantitative detection of BC mass in individual particles as well as optical sizing, and a Scanning Particle Mobility Sizer (SMPS), which measures the particle number size distribution. Comparison of the aerosol samples from the two inlets makes it possible the characterize both CCN active and inactive particles.

Results from a cloud event on the 29/07/2010 with a condensed water content of ~0.2 g/m^3 are discussed here. The SMPS measurement reveals a 50% activation diameter of 95 nm, and the activated fraction reaches a plateau value of 80% at diameters >200 nm (Fig. 1). A plateau value of less than 100% up to a diameter of 550 nm (not shown) in this particular example is likely due to the Bergeron-Findeisen mechanism or entrainment. The SP2 makes it possible to distinguish between BC containing (BC core mass >0.3 fg BC) and "purely scattering" particles (BC core mass <0.3 fg BC). The activation behaviour measured by the SP2 for both purely scattering particles (red line) and BC containing particles (black circles) is equal to that of the whole particle ensemble as measured by the SMPS.

The BC mass in single particles is reliably detected down to ~0.3 fg BC, corresponding to a mass equivalent BC core diameter of D_{core}≈70 nm. The black line in Fig. 2 shows the fraction of activated BC particles as a function of D_{core}. The activated fraction of BC particles is ~80% for D_{core}>200 nm and drops down to 50% at D_{core}≈90 nm. Most BC particles with a core diameter of 90 nm must have a total diameter larger than 95 nm, which is the 50% activation cut-off of the whole aerosol ensemble, since the SP2 indicated that the BC particles generally had substantial coatings of variable thickness. This provides evidence that BC particles require a larger diameter for cloud droplet activation than the reminder of the aerosol. The drop of the activation curve of all BC particles with small BC core diameters (Fig. 2, black line, D_{core}<180 nm) is not seen in the activation curve of optically sized BC particles (Fig. 1, black circles) due to different lower detection limits.

The orange line in Fig. 2 shows the activation curve of the subset representing the most thickly coated BC particles. The orange line is above the black line, thus indicating preferential activation of the most thickly coated BC particles in the range of small core diameters (D_{core}<180 nm). This provides evidence that the mixing state of BC particles matters for their CCN activation.

The results from further cloud events indicate considerable variability. Sometimes BC activation was insensitive to mixing state down to BC core diameters D_{core}<100 nm. In other cases an influence of coating thickness on CCN activation of BC particles was still observed at overall diameters as large as D_{opt}>180 nm.

A more comprehensive analysis of numerous cloud events and a discussion of results in the context of previous literature will be presented.

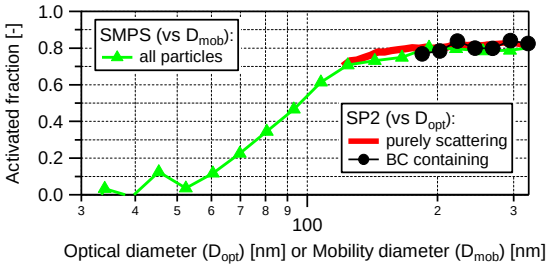

Figure 1. Activation as measured by SMPS and SP2.

Aerosol Cloud Interactions in a deep tropical convective storm, Hector

P.J. Connolly[1], C. Dearden[2] and T. Choularton[2]
[1]School of Earth, Atmospheric and Environmental Science, University of Manchester, Manchester, M13 9PL, United Kingdom
Keywords: ice, storm, aerosol, intensity
Presenting author email: p.connolly@manchester.ac.uk

Model studies have shown that convective clouds are sensitive to the amount of aerosol entrained into them (Connolly et al., 2007; Khain et al., 2005). The study by Connolly et al. (2007) simulated a deep tropical storm known as Hector, which occurs daily during the transition to and the break period from the Australian monsoon over a group of islands known as the Tiwi Islands. The findings of their study was that aerosols in the form of Cloud Condensation Nuclei (CCN) were able to affect the amount of precipitation from the storm due to the effect they had on both the liquid and ice microphysics within the storm.

In summary:

- When CCN concentrations were relatively low (below 200 cm^{-3}) the warm rain process (i.e. Collision and coalescence of drops) was very efficient and resulted in removal of condensate from the cloud.
- When CCN values were relatively high (above 400 cm^{-3}) liquid water did not precipitate initially, but this created regions of high supercooled liquid water content (LWC) in the upper regions of the cloud, following which hail generation was quite efficient.
- In between these two values the warm rain process was relatively inefficient and neither was hail generation. This resulted in effective transport of supercooled liquid water to temperatures lower that -35°C where the water froze homogeneously. This resulted is less precipitation and maximal anvil coverage.

During the Aerosol and Chemical Transport in Tropical Convection (ACTIVE) field campaign, radar observations were made with the C-POL radar at Gunn Point. This enabled quantification of the Hector storm during the transition from the dry to wet season in November and December 2005 and the break from the monsoon in February 2006. Aerosols were also measured using a suite of instruments: the Ultra High Sensitivity Aerosol Spectrometer (UHSAS), Condensation Particle Counter (CPC), Forward Scattering Spectrometer Probe (FSSP) and aerodyne Aerosol Mass Spectrometer (AMS) on board a Donier 228 aircraft. The composition and meteorology were sufficiently different to warrant classification into four distinct periods: a biomass burning period; a pre-monsoon period; the monsoon and the monsoon break as described by Allen et al. (2008). So the natural question that arose was *can observed differences in storm intensity be attributed to the differences in aerosol loading?*

In order to summarise the effects that the aerosols had on the number of cloud drops we applied the Aerosol-Cloud-Precipitation Interaction Model (ACPIM) in the configuration of a cloud parcel model. We then fitted curves to the relation of updraught speed against number of activated cloud drops, which unsurprisingly showed that clouds forming in the burning period had the most cloud drops and those in the break the least, having been cleaned by the effects of the monsoon (see Figure 1). These data were fitted to the model of Twomey and yielded curves of the form $N = Cs^k$ where N is the number of cloud drops, s the supersaturation and C and k are constants.

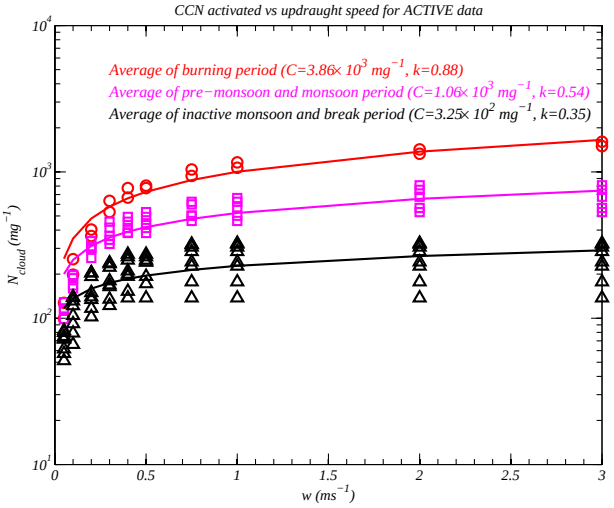

Figure 1: Model runs deriving the number of CCN vs the updraught speed.

In the presentation we will present an analysis that attempts to attribute the differences in observed storm intensity to the changes in aerosol throughout the period. Further results from Weather Research and Forecast Model (WRF) and the campaign data supporting it will be presented at the conference.

Anthropogenic Snowfall Events from Urban Fogs

G.J. Lloyd[1], T.W. Choularton [1]and P.Connolly[1]

During periods of anticyclonic weather, increasing numbers of Anthropogenic Snowfall Events (ASEs) from slightly supercooled fogs are being reported in the UK. The phenomenon was first recognised in the 1970s in America after work by Agee (1971) and Farn et al. (1978) noted a connection between industrial sources of aerosols created through combustion and inadvertent seeding of snowfall from fog. More recently work by Wood and Harrison (2009) described several events in the UK and striking satellite imagery provided by Van Den Berg (2008) revealed many patches of snow situated downwind of industrial areas after a period of freezing fog in the Netherlands.

In this paper we explain how the introduction of aerosol able to act as ice nuclei slightly below 0°C influences the microphysical processes that lead to these events. This is done through examination of reported ASEs, results from ice nucleation experiments using fly ash and other anthropogenic aerosol, together with analysis of meteorological data collected from the Whitworth Observatory during several events in Manchester, which for the first time provides valuable information obtained during the evolution of a number of ASEs.

A review of all reported ASEs reveals that these events occur in anticyclonic conditions in industrialised areas, close to potential sources of ice nuclei, when slightly supercooled fog is present at temperatures around -5°C. It is likely to be significant that these events occur within a temperature range where a known mechanism of secondary ice particle production occurs, as a few primary nucleated crystals fall through the supercooled fog (The Hallett-Mossop Process). Just one ASE at temperatures between -10°C to -14°C was reported by Farn et al. (1978) and in this temperature zone there is no known method of producing secondary ice particles hence it is very likely that all the snow crystals observed were produced through primary nucleation by aerosol.

The hypothesis, therefore, is that man made aerosol, is responsible for initiating the ice in these slightly supercooled fogs with, in many cases, secondary ice particle production enhancing the number of ice crystals leading to a detectable snowfall.

In order to investigate this, ice nucleation experiments using a cold stage and drops of deionised water polluted with fly ash confirmed the effective nature of this particular combustion product in triggering ice formation at higher temperatures, the average onset of ice nucleation being -3.4°C. Future ice nucleation experiments with man-made aerosol will be conducted to further investigate these preliminary findings and the results will be presented. This will identify whether an anthropogenic source of ice nuclei is able to cause ice formation in a temperature range where natural ice nuclei are very few.

Analysis of data obtained from the Whitworth Observatory Disdrometer reveals the precipitation types as an ASE on the 20th December in Manchester took place. Initially freezing drizzle is recorded before a transition to snow grains and eventually snowfall. Temperatures recorded at the beginning of this event were -2°C falling to -2.7°C. It is likely that further ASEs will be recorded by the observatory, providing the opportunity for detailed comparison of events, which will be crucial in the understanding of snowfall from urban fogs.

This sequence of precipitation provides one possible answer as to how an ASE may triggered. The introduction of efficient ice nuclei from a source of combustion, close to Manchester City Centre, will cause some of the fog droplets to freeze and as these fall they begin to sweep up other supercooled drops, growing by riming as they do so with the precipitation type making a transition to snow grains. As this riming takes place the Hallet-Mossop Process provides a powerful secondary ice production mechanism that is sufficient enough to cause the subsequent snowfall.

The significance of these results extends beyond that of the local importance of snowfall from radiation fog. The ability of certain man made aerosol to initiate snowfall from slightly supercooled layer cloud will substantially influence the water balance, water content and microphysics of these clouds. This will in turn shorten the lifetime of the clouds and their radiative properties. Hence this is potentially an important man made aerosol indirect effect in the atmosphere.

Session 1C: Molecular Characterisation of Aerosol Constituents

Measured O:C and H:C Elemental Ratios Constrain the Production Mechanisms of Biogenic Secondary Organic Material

In the atmospheric sciences, chemical mechanisms for the production of secondary organic material are derived in the context of environmental chambers and extrapolated to the more complex and dynamic context of the atmosphere. A stringent testing of mechanisms is therefore particularly important. A paradigm for doing so is presented herein for a C_5-C_{10}-C_{15} terpenoid sequence important in the atmosphere, derived from the photooxidation of isoprene, the dark ozonolysis of the α-pinene, and the dark ozonolysis of the β-caryophyllene.

The analysis paradigm compares measurements and model predictions in a multidimensional framework, including (1) particle mass yields, which depend on the thermodynamics of organic phase partitioning, and (2) particle composition, expressed as O:C and H:C elemental ratios. Secondary organic material (SOM) was produced in the Harvard Environmental Chamber over a range of organic particle mass concentrations. Elemental ratios of particle-phase SOM were measured by a high resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS). A chemically detailed model was applied, which couples the gas-phase oxidation scheme from the Master Chemical Mechanism (MCM v3.1) to an on-line gas-to-particle absorptive partitioning model using a group contribution method (SIMPOL) for the prediction of vapour pressure of organic compounds.

This study shows the importance of calibration of H_2O^+ peaks for accurate elemental analysis of AMS data, suggesting that the O:C and H:C ratios published in the last two years are systematically too low for laboratory-generated SOM. The measured ratios of SOM by using these calibrations are 0.75-0.97 (O:C) and 1.80-1.88 (H:C) for isoprene photooxidation, 0.33-0.52 and 1.47-1.56 for α-pinene ozonolysis, and 0.33-0.53 and 1.47-1.51 for β-caryophyllene ozonolysis.

With just information on particle mass yields, measurement and model were in good agreement, yet a higher dimensional comparison between the in situ O:C and H:C measurements and the values calculated from known products and their yields revealed important disagreement, in part because of unspeciated organic peroxides. In qualitative support, the MCM-SIMPOL model overpredicted the organic peroxides in the particle phase. While retaining the production of organic peroxides to an extent, the model had to be evolved by including pathways that moved the SOM composition in the direction of $\Delta(H:C) < 0$ and $\Delta(O:C) < 0$. In this light, the present study concludes that the model-measurement gap can be significantly reduced by a newly proposed reaction pathway: the particle-phase homolytic decomposition of organic peroxides and subsequent radical-promoted oligomerization (Fig. 1).

The presented paradigm of a stringent test and evolution of mechanism is important because climate-relevant chemical transport models use these mechanisms under the full domain of atmospheric conditions. The accuracy of the SOM production mechanisms, as a key component of biosphere-atmosphere-climate feedbacks, significantly affects the predictions of climate-related endpoints, both in today's world and in scenarios of future climate change.

Keywords: glyoxal, Secondary Organic Aerosols (SOA)
Presenting author email: barbara.noziere@ircelyon.univ-lyon1.fr

In recent years, atmospheric observations (Volkamer *et al*., 2007) and laboratory experiments (Kroll *et al*., 2005; Volkamer *et al*., 2009) have shown that glyoxal and its reactions in the aqueous phase of atmospheric particles (Carlton *et al*., 2007; Nozière *et al*., 2009; Galloway *et al*., 2009; Shapiro *et al*., 2009; Lim *et al*., 2010) are likely to contribute significantly to the mass of Secondary Organic Aerosols (SOA) in the atmosphere, at least in some regions. But while these reactions have been studied in laboratory, no evidence for their occurrence in atmospheric aerosols has been reported until now. In this work, we report the identification of reaction products of glyoxal in aerosols from different origins (Aspvreten, Sweden; Paris France…), confirming the contribution of glyoxal chemistry to these aerosols.

Prior to analyzing atmospheric aerosol samples the products from different reactions of glyoxal were studied in laboratory and in smog chamber. The laboratory experiments focused on the liquid-phase reactions of glyoxal in differentes solutions, corresponding to different reaction mechanisms: water exposed to UV light (OH-radical mechanisms), ammonium sulfate solutions in the dark (ionic mechanisms), persulfate solutions in the dark (sulfate-radical mechanisms) and ammonium sulfate exposed to UV light. The smog chamber experiments were performed at the Paul Scherrer Institut (PSI), Switzerland, and focused on the gas-phase photooxidation of acetylene, producing mostly gas-phase glyoxal. The secondary particles produced in the chamber were collected on Quartz filters for chemical analysis. Both the laboratory reaction mixtures and the secondary particles from the smog chamber were analyzed by the same method, using liquid chromatography/Q-tof tandem mass spectrometry (LC/MSMS). In all cases, the mass spectra obtained displayed a large number of products, among which where identified glyoxal oligomers and products specific to some reactions, such as imidazoles (reactions with NH_4^+ in the dark, cf. Galloway *et al*., 2009) or organosulfates.

Fine aerosols ($PM_{2.5}$) collected on Quartz filters in Aspvreten, Sweden, and in Paris, France during the MEGAPOLI campaign, were analyzed by the same method. A number of compounds were identified in the spectra obtained, which had been previously identified as glyoxal products in laboratory or the smog chamber (Figure 1).

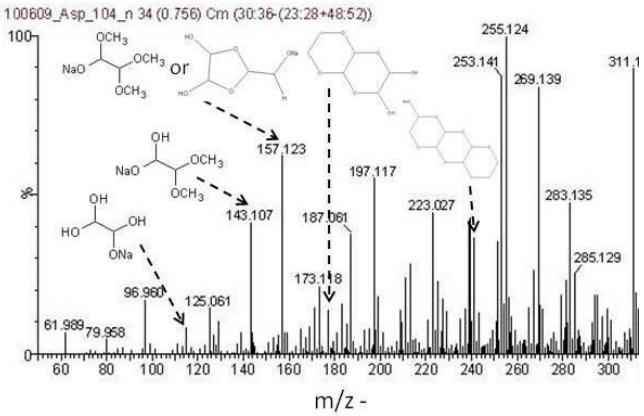

Figure 1. Examples of mass spectrum evidencing some products of glyoxal in aerosols from Aspvreten, Sweden.

So far, most of the products identified correspond to reactions involving ammonium sulfate salts (imidazoles, organosulfates…).

A significant fraction of the organic aerosols mass in the atmosphere originates from biomass burning sources such as wild fires, agricultural activities or residential heating and cooking. The fraction of biomass burning particle mass is not easily identified with conventional analytical techniques due to the highly complex compound mixtures in organic aerosols.
Here we will present results of ultra-high resolution mass spectrometry (UHR-MS) analyses, a technique, which has unique capabilities to characterize complex samples. UHR-MS allows identifying unambiguously the elemental composition of thousands of compounds in a single analysis and gaining information about the structure and formation mechanisms of organic compounds in aerosols (Reinhardt et al., 2007).

The unprecedented, very detailed picture of UHR-MS analyses of the thousands of organic compounds present in atmospheric aerosols reveals that the sample work up process is of critical importance to avoid artifacts introduced, e.g., by the reactions of aerosol components with solvents such as methanol. Such solvent-induced artifacts can change significantly the distribution of oxygenated functional groups, e.g., through formation of methyl esters when using methanol as solvent (Bateman et al., 2008) and can shift overall O/C atomic ratios, an indicator of atmospheric age often applied in aerosol field studies.
Different liquid extraction and separation conditions (methanol vs. acetonitrile) are compared in this study and we show that most of the reported artifacts in the literature can be avoided by carefully choosing ionization conditions during the MS measurement.
These solvent-extraction methods will be compared with direct measurement techniques from the filter surface, i.e., desorption electrospray ionization (DESI) and liquid extraction surface analysis (LESA).

Applying the improved sample work up conditions, several important types of biomass burning source samples from Central and Southern Europe and from South China will be compared. Using van Krevelen (i.e., distributions of elemental ratios) and Kedrick mass defect analysis (i.e., identification of homologous series) common pattern and source specific tracers are identified in the biomass burning samples. Mass spectral pattern of these source samples are also compared to ambient samples to identify the biomass burning signatures in the ambient samples. More highly oxidized compounds, including organo sulfates and organo nitrates are more abundant in ambient samples compared to source samples. Whereas in source samples the O:C ratio does mostly not exceed 1.2, in ambient samples the O:C ratio extends to 3 and possibly higher, which is consistent with organic aerosols aged in laboratory experiment.

Organic compounds are major constituents of fine continental aerosols. The understanding of their chemical composition, their properties and reactivity are important for assessing aerosol effects upon both global climate change and human health. Among organic aerosols, secondary organic aerosols (SOA) are predominant especially in summer due to the intense photochemical activity.
Here we compare the chemical composition of aerosols with particle diameters <1µm collected at an urban and rural site in the UK, Cambridge and Auchencorth Moss (EMP supersite), during summer 2009. We focus here in the organic components which contain sulfur as heteroatom in their elemental composition.

The water-soluble organic fraction of the filters was separated from inorganic ions (e.g., sulfate, nitrate) by a solid phase extraction step and re-dissolved in acetonitrile-water prior to the analysis. Ultra-high resolution mass spectrometry analyses were performed using an LTQ Orbitrap Velos, with an accuracy bellow 2ppm, using an electrospray ion source. Mass spectra were measured by direct infusion, in negative and positive polarities and recorded within the range of 50-1000m/z. Molecular formulas were assigned to the exact masses of the more than 5000 compounds in a single sample using the Xcalibur™ software. After subtraction of peaks present in blank samples, a series of criteria were used to determine the molecular formula of the compounds such as chemically reasonable atomic ratios. Visualization schemes, such as van Krevelen diagrams and Kendrick mass defect plots were used for data exploration. The main molecular signatures of products were established, by analysis of the functional group relationships among compounds and their relative intensity.

Summer samples from Cambridge generally have more components than samples from Auchencorth; however van Krevelen diagrams containing the entire data matrix exhibit qualitatively the same shape. Molecular series containing C_cH_h, $C_cH_hO_o$, $C_cH_hO_oS_s$, $C_cH_hO_oN_n$ and $C_cH_hO_oN_nS_s$ were observed. 90% of the data from Cambridge contains organic compounds with OSN heteroatoms; only 10% of the data contains compounds with C_cH_h and/or O_o. This value slightly decreases to 6% for Auchencorth samples. About 60% of components in both samples contain sulfur atoms.

Figure 1a and b shows the ratios O/C vs H/C for a subset of components containing $C_cH_hO_oS_s$. The data for Auchencorth sample is more scattered and contains more oxidized components with lower H/C. The average value for O/C and H/C ratio for Cambridge samples is 0.41 and 1.6 while for Auchencorth O/C increased to 0.52 and H/C decreased to 1.4. That is consistent with the evolution of the O/S ratio vs molecular mass, (not shown), where the Auchencorth samples exhibit higher values (average 3.3) than the Cambridge samples (average 2.7). In addition, only 9% of the components in Fig 1 have the same elemental composition. Based on our study, we infer that the samples collected in Auchencorth are the result of more aged organic aerosols while samples in Cambridge, collected in the city center, are the result of a mixture of fresh and aged aerosol.

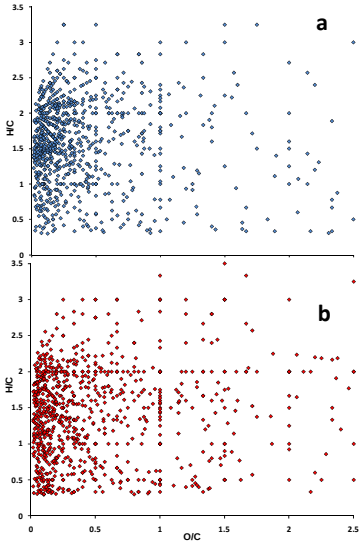

Fig 1. Van Krevelen diagram of S_sO_o-containing organics for a sample collected in Cambridge (a) and Auchencorth (b) in Summer 2009. $(M-H)^-$ ions were detected in a range of 70-1000Da.

Size resolved nanoparticle composition from SOA formation events

P.M. Winkler[1], J. Ortega[1], J. Zhao[1], H.R. Friedli[1] and J.N. Smith[1,2]

Keywords: Nanoparticle, secondary organic aerosol (SOA), TDCIMS, chemical composition.
Presenting author email: pwinkler@ucar.edu

The chemical composition of secondary organic nanoparticles is among the key issues to understand processes responsible for nucleation and subsequent growth. While aerosol mass spectrometry has typically been restricted to particle sizes above 100 nm due to the small amount of substance carried by the nanoparticles, only few techniques exist to investigate particle composition in a size range close to where nucleation and growth by organic vapours takes place. We employed the thermal desorption chemical ionization mass spectrometer (TDCIMS, Voisin *et al*., 2003) to investigate the chemical composition of particles in the size range from 10 nm to 80 nm. Ambient aerosol as well as aerosol formed in a biogenic aerosol chamber was used as source of particles.

TDCIMS comprises of a particle collection unit, an electrostatic precipitator, a ^{241}Am ion source and a triple quadrupole mass spectrometer. At the inlet, the aerosol is charged and size classified by three DMAs (McMurry *et al*., 2009) and subsequently collected on a platinum wire. After collection (typically in the order of ~10 minutes, depending on particle size) the wire is translated into the ion source where the collected material gets thermally desorbed and ionized. Positive and negative ion mass-to-charge ratio is alternatingly analysed in the mass spectrometer. It is notable that by ramping the temperature of the wire valuable information on the volatility of the substances is obtained (Smith and Rathbone, 2008).

SOA formation was studied at the NCAR biogenic aerosol chamber consisting of a 10 m^3 teflon FEP bag. Different kinds of monoterpenes of varying concentration as well as live tree emissions were oxidized by ozone under dark conditions. Running the chamber as a continuous flow system, we initiate particle formation after a steady state concentration of the organic vapour has been reached by subsequently adding ozone. Gas-phase and particles were analysed using gas chromatographs, scanning mobility particle spectrometers (SMPS), Cluster-CIMS and TDCIMS. For comparison, ambient measurements were taken at Manitou Forest Observatory operated by NCAR, BEACHON*, in the southern Rocky Mountains, Colorado. This site is located in a ponderosa pine dominated forest with expectedly high monoterpene emissions. Oxidation products of monoterpenes can thus be expected to play a crucial role in new particle formation and growth.

The system studied most intensely in the chamber was related to the ozonolysis of α-pinene. Typical concentrations were ~ 5ppb of α-pinene and ~ 50 ppb of ozone. In Figure 1, a corresponding mass spectrum of positive ions after collection of particles exhibiting 80 nm mean mobility diameter is illustrated. As can be seen, a distinct grouped pattern is observed up to ion masses of 200 amu. A similar behaviour was also found for negative ions. For high mass loadings on the wire (~200pg) this grouped pattern was observed even up to 250 amu suggesting high molecular weight compounds in the particles. Similar conclusions have been drawn recently by Hall and Johnston (2010) showing that oligomers account for 50% of the SOA mass. Preliminary results for 10 nm particles suggest, however, that these particles exhibit substantially different composition, indicating different vapours being responsible for particle growth at different sizes.

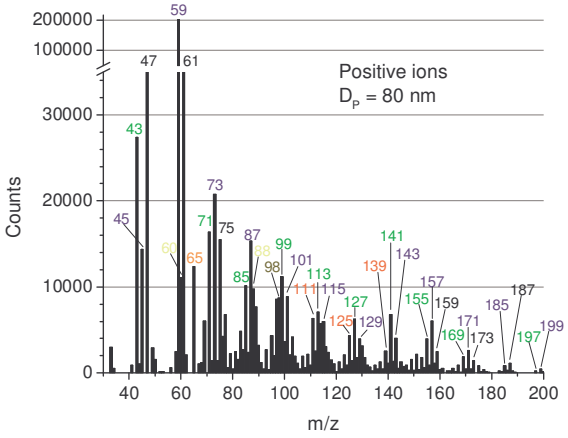

Figure 1. Positive ions measured from 80 nm particles formed from the dark ozonolysis of α-pinene.

Abstract:

To explore the properties and sources of polycyclic aromatic hydrocarbons (PAHs) contained in PM10 in Waliguan and Xining of Qinhai Province, China during summer, 10-group aerosol samples were installed at the Waliguan Atmospheric Background Observatory and Qinghai Station of Meteorology. Waliguan station (36° 17'N, 100° 54'E) is the highest GAW (Global Atmospheric Watch) station, and is located in a remote region on the northeastern boundary of the Qinghai-Tibetan plateau at a height of 3810 meters. Qinghai Station（36° 34'N, 101° 45'E）is located in the center of Xining city at a height of 2275 meters. Size-segregated particles were sampled using cascade impactors (Thermo) from May 24 to June 4, 2007. Size resolved chemical compositions of aerosol were investigated in order to characterize regional aerosol pollution. The meteorological conditions during the measurements maintained high temperatures and high RH. The mass concentration and size distribution of PM_{10}, and the spectral distributions of PAHs were analyzed. The daily mean concentration of PM_{10} was 24.85μg·m^{-3} and the particle size distribution exhibited three-modes in Waliguan; whereas the daily mean concentration of PM_{10} was 65.25μg·m^{-3} in Xining where the particle size distribution showed dual-modes.

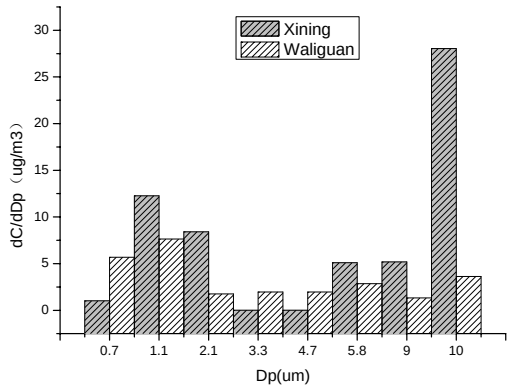

Figure 1. Mass size distribution of average PM_{10} mass concentration in sampling periods.

The percentage of accumulated particle mass in Waliguan was greater than in Xining. The concentration of PAHs in PM_{10} was 8.38ng·m-3 in Waliguan, much lower than Xining .

Due to the different photochemical pathways, the properties of PAHs and long-range transport of particles, PAHs with high molecular weight were mainly distributed in the fine particles and PAHs with lower molecular weight are relatively richer in the coarse particles at Waliguan. High molecular weight polycyclic aromatic hydrocarbons in the two sample sites were monodispersed in size. It is concluded that the PAHs pollution in Waliguan was associated with the seasonal transitions with the Asian monsoon system and transport from eastern/central China industrial emissions.

Simultaneous determination of water-soluble organic tracers in atmospheric aerosol using silyl-derivatization and GC-MS analysis

M.C. Pietrogrande, D. Bacco, S. Chiereghin

Department of Chemistry, University Ferrara, Ferrara, I44121, Italy

Keywords: water soluble organic compounds, dicarboxylic acids, sugars, chemical analysis.
Presenting author email: mpc@unife.it

This paper describes the development and application of a GC-MS method for the simultaneous analysis of a wide range of water-soluble molecular tracers in atmospheric aerosol, including short-chain dicarboxylic acids and sugars/sugar alcohols. Short-chain dicarboxylic acids are emitted directly into the atmosphere by a multiplicity of sources including power plants, vehicular circulation, meat cooking operations and biomass burning. They are also produced through the secondary organic aerosol (SOA) formation initiated by photochemical reactions with volatile hydrocarbons of both anthropogenic and biogenic nature [1].
Among the sugars, glucose and fructose may originate from plant pollens, microorganisms, and fragments of plants and animals, while arabitol and mannitol have been established as suitable markers for fungal spores [1]. Some sugars may also be produced by hydrolysis of the corresponding anhydrosugars when biomass is burned or emitted directly by thermal stripping during wildfires. This is the case of the anhydrosugars levoglucosan, mannosan and galactosan that are highly specific molecular tracers for biomass burning [2].

GC-MS analysis of carboxylic acids and saccharides requires a preliminary chemical derivatization to convert these polar compounds into volatilizable and stable derivatives.

With the aim of developing a multi-residue analytical method, that achieves simultaneous analysis of several molecular tracers in atmospheric PM samples, the silylation procedure using BSTFA (N,O-bis(trimethylsilyl)-trifluoroacetamide) as silylation reagent was investigated [3,4]. The response surface methodology (RSM) including central composite design (CCD) was applied to optimize the reaction operating conditions in order to achieve the highest response for a large number of dicarboxylic acids and sugars. The operative factors considered were: (i) reaction temperature (50°C-90°C), (ii) reaction duration (60 min-120 min), (iii) reagent concentrations (10%-100% of the total solution volume) and (iv) pyridine concentration (0%-50% of the derivatization reagent).

The CCD model makes it possible to investigate the interacting effect of the different operative parameters on the reaction yield. The highest BSTFA concentration maximizes the derivative yield with a pyridine concentration level close to the center value for acids (Fig. 1) and close to upper boundary for sugars. On the basis of the RSM model and experimental evidence, the optimum derivatization conditions were defined as reaction temperature of 75°C, reaction duration of 70 min, BSTFA reagent concentration of 55% and pyridine concentration of 35%.

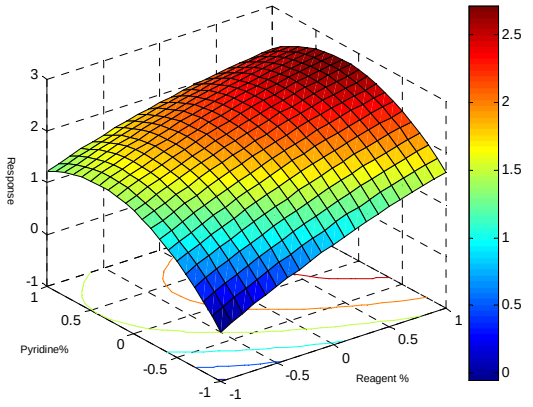

Figure 1: 3D plots of reaction yield of acids as a function of BSTFA and pyridine concentrations.

The optimized protocol was applied to 22 target analytes that are relevant chemical markers, i.e., 15 carboxylic acids and 7 sugars. The optimized procedure provides low detection limits ($\leq 2\ ngm^{-3}$) and satisfactory reproducibility (RSD%≤13%) suitable for environmental analysis.
The optimized procedure was applied to PM filters collected in a regional area close to Bologna, Northen Italy, under different conditions, i.e., different seasons (summer vs. winter), different sampling sites (urban vs. rural), different particle size dimensions ($PM_{2.5}$ vs. PM_1). The obtained results show that the developed method allows quantification of several molecular tracers suitable for source apportionment studies for evaluating contribution of specific primary emission sources and atmospheric photochemical reactions.

This work was in part financially supported by the Moniter project of the Environment Agency of Emilia Romagna region (ARPAER).

Traditionally, bulk mass methods have been used to monitor the long-term trends of PM_{10} and $PM_{2.5}$ aerosol mass. Bulk mass methods, however, provide limited information on the chemical speciation of aerosol. Recent epidemiological research has suggested that health effects of aerosol may be less closely linked to the total mass of PM_{10} or $PM_{2.5}$ aerosol than to the physicochemical characteristic of the aerosol. Long-term, high resolution monitoring of speciated aerosol is therefore required to further understand aerosol metrics on human health. In addition, secondary aerosols and their precursor gases are required to be monitored to understand atmospheric processes and to validate chemical transport models, which are used to inform policy, such as the UNECE Convention for Long-range Transboundary Air Pollution (CLRTAP) and the revised European Air Quality Framework Directive (Directive 2008/50/EC).

Long term monitoring of water soluble inorganic aerosols have been taking place in South East Scotland at a 'supersite' within the European Monitoring and Evaluation Program (EMEP). Hourly PM_{10} and $PM_{2.5}$ measurements of NO_3^-, Cl^-, SO_4^{2-}, Na^+, NH_4^+, K^+, Mg^{2+} and Ca^{2+} have been made since June 2006 using a Measurement of Aerosols and Reactive Gases Analyser (MARGA, Applikon, NL). The MARGA instrument is a wet chemistry technique which utilises a rotating wet denuder and steam jet aerosol collector (Khlystov *et al.* 1995) to capture water soluble gases and aerosol compounds, respectively. Analysis is then carried out by use of online ion chromatography. As a dual system this particular MARGA measures the aerosol chemical composition of both $PM_{2.5}$ and PM_{10}.

The data presented will be an overview of 4 years of measurements made by the MARGA at the Northern UK EMEP 'Supersite'.

Results

Long term monitoring at Auchencorth Moss has shown the site to be a relatively clean site, with a median PM_{10} SO_4^{2-} concentration of 0.75 µg m^{-3} from the years 2007 to 2009. Seasonal trends have been observed in aerosol, with both Cl^- and Na^+ having lower median concentrations during the months of May – July.

A large proportion of the aerosol measured by bulk mass methods can be explained by the MARGA. It was observed 67% of the PM_{10} aerosol measured by a TEOM FDMS could be explained by the chemical components resolved by the MARGA alone on average in 2008. The remaining unexplained mass is likely to be from organic and black carbon as well as unresolved crustal components.

Due to the high resolution of the MARGA it has been possible to investigate periods where air quality limits are exceeded. In March 2007, for example, a PM_{10} mass of 82 µg m^{-2} was measured by TEOM. The increase in concentration coincided with an increase in NH_4^+, SO_4^{2-}, NO_3^- and K^+ measured by the MARGA. Three day back trajectory analysis revealed that the origins were from Eastern Europe, where biomass burning had been observed.

Carrying out cluster back trajectory analysis has shown air masses from the Atlantic and Artic are associated to large contributions of Na^+ and Cl^- (Fig. 1) to the measured mass. The UK, Western Europe and Eastern Europe, on the otherhand, were associated to larger contributions of NH_4^+, NO_3^- and SO_4^{2-} to measured mass.

To summarise, the application of the MARGA system at the EMEP 'supersite' has furthered the understanding of atmospheric composition, large pollution events and long range transport in the South East Scotland.

Aerosol chemical mass closure in Corsica Island: towards a better understanding of the seasonal variation of aerosol sources in the Western Mediterranean

J. B. Nicolas[1], M.-D. Loÿe-Pilot[2], H. Cachier[1], J.Sciare[1], K. Oikonomou[1], N. Mihalopoulos[3], and F. Dulac[1]

[1]Laboratoire des Sciences du Climat et de l'Environnement (LSCE), CNRS-CEA, Gif-sur-Yvette, 91191, France

Keywords: Western Mediterranean, aerosol chemical mass closure, $PM_{2.5}$, black carbon.
Presenting author email: jose.nicolas@lsce.ipsl.fr

The Mediterranean population is expected to reach 550 million inhabitants within the next 30 years. This increasing anthropogenic pressure will be associated with higher emissions of atmospheric pollutants in a region holding already the highest PM (Particulate Matter) loadings in Europe. This increasing particulate pollution will induce climate changes at a regional scale that is still hardly predictable. In this context a better characterization of aerosols in this area is crucial and will comprise a better understanding of their sources, chemical composition, (trans)formation processes and impacts.

A 20-month field experiment (Aug 2001- Apr 2003) was performed in Corsica Island (France) within the EU-FP5 ADIOS project* (Atmospheric Deposition and Impact on the Mediterranean Sea) in order to better characterize the chemical composition of West Mediterranean aerosols. These results are presented here and compared (for Black Carbon (BC)) with recent measurements (2010-2011) performed in Corsica within ChArMEx (the Chemistry-Aerosol Mediterranean Experiment).

Methodology

Weekly aerosol sampling was performed at Ile Rousse in Corsica (2001-2003) for 2 size fractions having aerodynamic diameter below 2.5µm (Fine mode) and upper than 2.5µm (Coarse mode), respectively. Pre-fired quartz filters were used for carbon analyses (EC, OC) and pre-weighed nuclepore AOX filters for mass determination (PM) and major ion analyses (Cl, SO_4, NO_3, Na, NH_4, K, Mg, Ca). Weekly aerosol chemical mass closure was performed based on these chemical analyses. Co-located BC measurements were performed with an Aethalometer (Magee Scientific) and are compared with similar measurements performed 10 years after (2010-2011) at another site however.

Results

On a yearly basis, contrasted chemical compositions have been found in the two aerosol modes. In the Fine mode (Fig.1), Particulate Organic Matter (POM) contributed to almost half of the PM and ammonium sulfate about 40%. By contrast, the major part in the Coarse mode (75%) was composed from sea salts, dust and nitrate (Fig.2).

The seasonal variations of the major chemical components of Western Mediterranean aerosols will be presented here, providing new insights on the major aerosol sources in this region. Comparison will also be performed with similar measurements performed in Eastern Mediterranean (Crete Island, Finokalia) during the same period (Sciare *et al*, 2008) providing a unique characterization of the major aerosol sources in the whole Mediterranean.

Comparison of sectorized BC (seasonal) variations performed 10 years apart (2001 - 2011) will also be presented here providing insights of recent BC emission trends in the Western Mediterranean.

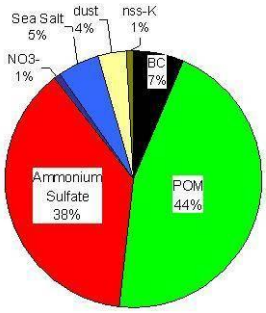

Figure 1. Mass closure in the Fine mode (< 2.5 µm), 2001-2003

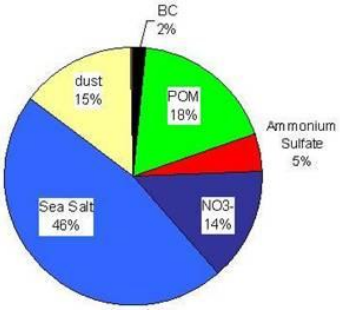

Figure 2. Mass closure in the Coarse mode (> 2.5 µm), 2001-2003

This research was funded by EU* (EVK3-2000-00604C), CNRS, CEA and ADEME. The Ersa semaphore French Navy staff is thanked here for hosting the Aethalometer since May 2010.

PAH in PM_{10} from tyre and pavement wear

M. Gustafsson[1], G. Blomqvist[1], and E. Brorström-Lundén[2]

[1]Swedish National Road and Transport Research Institute (VTI), Linköping, 581 95, Sweden
[2]Swedish Environmental Institute (IVL), Göteborg, 400 14, Sweden
Keywords: tyre, pavement, PM_{10}, PAH, road dust
Presenting author email: mats.gustafsson@vti.se

The interaction between pavement and tyre is an important traffic source to inhalable particles (PM_{10}). Especially in Nordic countries, where studded tyres are used, pavement wear contributes to high concentrations of PM_{10} during winter and spring. Except for minerals emanating in pavement stone material, the binder of the pavement and the tyres themselves contribute to inhalable PM. Both these particle sources contain polyaromatic hydrocarbons (PAH), some of which are classified as carcinogenic (Brorström-Lundén, 1995). The use of high aromatic (HA) oils in tyres is regulated by an EG directive (2005/69/EG).

At VTI, a road simulator (Figure 1) is used to study physical and chemical properties of particles formed from wear of pavements and tyres. Any desired pavement and wheels can be tested in different combinations in speeds up to 70 km/h.

Figure 1. The VTI Road Simulator

To study if tyres and bitumen contribute to PAH in PM_{10}, three studded winter tyres and three summer tyres were tested on one pavement in the road simulator. PM_{10} samples were taken using IVL low volume samplers (Ferm et al., 2001). PAH content of tyre rubber, bitumen and PM_{10} was analysed using soxhlet extraction and an HPLC (High Performance Liquid Chromatograph) fitted with a fluorescence detector (Varian Prostar363). The PAH analysed were the ones listed by the US Environmental Protection Agency as prioritised PAH.

The results show that for studded winter tyres, PAH in PM_{10} produced from pavement and tyre wear has a stronger correlation to PAH content in tyres than to that in bitumen (Figure 2). The tests with summer tyres show the same pattern but much lower correlation (R^2 = 0.17 and 0.01 for tyres and bitumen respectively).

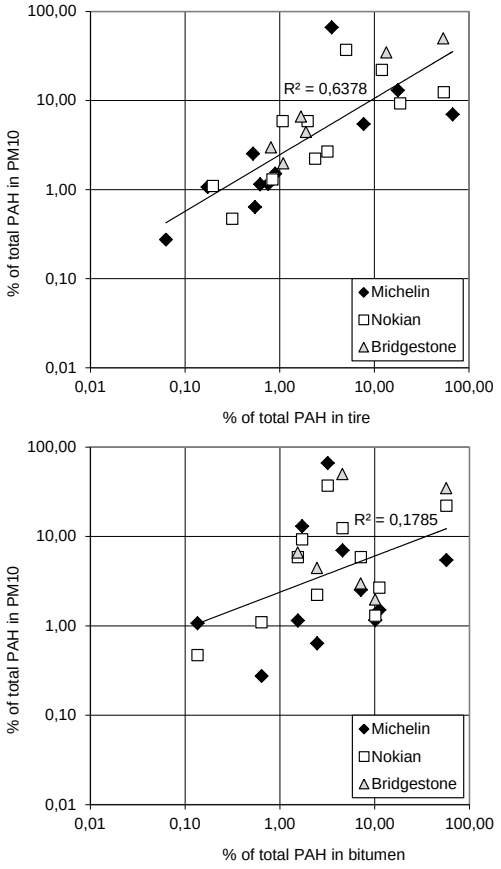

Figure 2. Percentage of total PAH in PM_{10} as related to percentage of total PAH in three studded winter tyres (makes in legend) and bitumen.

The results indicate that the winter tyres, although low in HA oils and following the EU directive on PAH, contribute to PAH content in PM_{10} from tyre and pavement wear, while bitumen is of less importance. Summer tyres seem to contribute in much lower degree to PAH in PM_{10}. It is hypothesised that the softer rubber in winter tyres are more prone to wear than summer tyres and therefore contribute more to PAH in PM_{10}.

Characterization of resuspended and respirable urban particulate matter

B. Turóczi[1], A. Hoffer[2], N. Kováts[1], A. Ács[1], A. Gelencsér[1]

[1]Institute of Environmental Sciences, University of Pannonia, Veszprém, Hungary
[2]Air Chemistry Group of the Hungarian Academy of Science, Veszprém, Hungary
Keywords: PM, resuspension, respirable aerosols, source apportionment, health effects of aerosols
Presenting author email: turoczi.beatrix@indamail.hu

Urban air quality has becoming increasingly affected by traffic related particulate matter, including direct emissions from exhaust, brake pad, tire wear and resuspended road dust. Road dust can be resuspended easily by passing vehicles and wind in urban street canyons. Resuspended dust may contribute up to about 30% to urban PM10 mass concentrations. Fugitive dust from paved and unpaved roads and bare grounds as well as construction and demolition works can also be important contributors to PM10 in urban aerosol. Prolonged exposure to emissions from road traffic has been associated with adverse health effects and linked to an increased risk of respiratory illnesses.

In previous studies resuspension of urban particulate matter was usually performed by sieving of collected road dust followed by separation through size selective inlets in the laboratory (Han *et al*, 2007, Zhao *et al*, 2006). These off-line procedures and sample handling may result in the loss of fine particles and distortion of particle size distribution.

A mobile resuspended road dust PM10 sampler was developed and constructed which collects PM10 samples directly from road surfaces. A PARTISOL-FRM MODEL 2000 sampler is fixed on the mobile sampling cart which collects the PM(10-1) fraction in a cyclone separator without filters. The collection of bulk PM(10-1) samples makes it possible to deploy analytical methods which are not suited for the analysis of filter samples. The lack of a filter substrate significantly reduces the analytical background. The Partisol sampler collects the PM1 fraction on a backup filter.

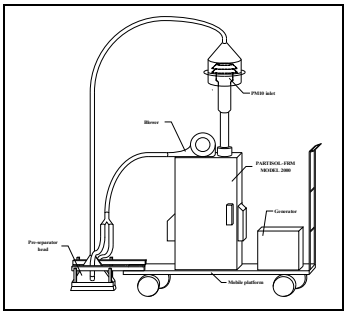

Figure 1. The mobile resuspended PM10 sampling unit

The sampler was tested by collecting resuspended particulate matter at kerbside locations in Veszprém, Hungary for 2 hours. The collected PM(10-1) fractions were weighted with a microbalance and PM10 mass concentrations in the duct were established. This simulates potential resuspension of particles under gusting wind conditions. The mean mass concentration of the resuspended and respirable particulate matter was 17.714 mg m^{-3} (standard deviation 2.147 mg m^{-3}).

The collected PM(10-1) fractions were analyzed by various analytical methods to establish mass balance and get insight into the contribution of possible sources to deposited dust. The main constituents of the resuspended urban particulate matter are the crustal elements. It was also possible to determine mineral phase composition of PM(10-1) dust which is generally not possible from samples collected on filter substrate. The major mineral phases were dolomite, calcite, clinochlore, muscovite, quartz, albite, orthoclase and gypsum. The major water-soluble inorganic ions in the resuspended road dust were Ca^{2+}, K^{+}, Na^{+}, Mg^{2+}, Cl^{-}, NO_3^{-} and SO_4^{2-}. PAHs were analyzed which are key tracers in different combustion processes.

The results indicate that the major components of the resuspended PM10 are crustal minerals, but with the help of quantitative phase composition the contribution of individual primary sources can be assessed. A unique feature of bulk elemental analysis by X-ray fluorescence spectrometry is the capability of direct quantitative measurement of oxygen. This, together with the analysis of trace metals and soluble ions complements source apportionment and mass balance calculations. (Han *et al*, 2007).

The ecotoxicity of resuspended and respirable particulate matter was directly determined by *Vibrio fischeri* bioluminescence inhibition bioassay in a special instrument developed for the analysis of solid sediment samples (Lappalainen *et al*, 1999). The specific toxicity of the resuspended bulk PM(10-1) and PM1 filter samples were compared with those obtained for urban PM10 and special emission samples.

Personal Monitoring of Exposure to Particulate Matter with a High Temporal Resolution

A.V. Broich[1], L.E. Gerharz[2] and O.Klemm[1]

[1]Climatology Working Group, Westfälische-Wilhelms-Universität, Münster, 48149, Germany
[2]Institute for Geoinformatics, Westfälische-Wilhelms-Universität, Münster, 48151, Germany
Keywords: particulate matter, individual behaviour, GPS, personal exposure, mobile measurements, indoor air
Anna.Broich@gmail.com

Air pollution with particulate matter is one of the key environmental health problems today. Several studies reported that long-term exposure to aerosol particles potentially leads to a number of cardiovascular diseases and premature deaths every year (Pope et al. 2002, Hoek et al. 2002). Continuous monitoring of air quality is implemented by governmental institutions at ambient fixed sites. These measurements only represent distinct outdoor locations in a city. However, humans in industrialized countries spent approximately 90 % of their time indoors (Klepeis et al. 2001).

In the present study we measured the personal exposure to particulate matter of sixteen individual persons during their daily routine. This was realized by an equipped measurement backpack, containing the Grimm Aerosol Spectrometer model 1.109, a GPS tracker, and a video camera.

Table 1: Comparison between 24-hour-mean concentrations of ambient fixed site measurements and personal monitoring of PM_{10}

Profiles	Ambient fixed site measurement ($\mu g\ m^{-3}$)	Personal monitoring ($\mu g\ m^{-3}$)
P1	41.5	41.0
P2	31.8	65.7
P3	31.6	28.5
P4	26.0	83.9
P5	23.8	117
P6	16.6	322
P7	13.0	114
P8	28.2	70.6
P9	24.2	28.7
P10	33.8	42.0
P11	22.2	36.6
P12	33.8	42.8
P13	28.5	27.0
P14	33.9	122
P15	30.0	33.5
P16	18.4	27.6

Novel in this study was the set-up allowing portable measurements indoors and outdoors with a high temporal resolution. The test persons carried the backpack for a time period of 24 hours. The time resolution was set to six seconds to identify variability in short-term exposure related to the persons' activities, as tracked and logged by camera and GPS.

Table 1 shows the comparison between ambient fixed site measurements and personal monitoring. It becomes evident that fixed site measurements alone do not describe the real concentration of PM an individual is exposed to over the day. Furthermore, the individual exposure is highly dependent on personal activity and lifestyle, leading to large differences between individuals.

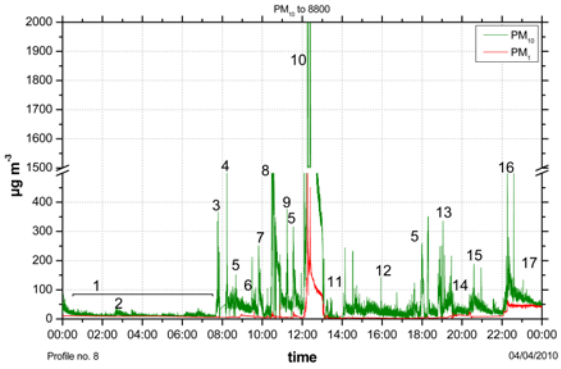

Figure 1: Diurnal course of 6-sec-measurements of PM_1 and PM_{10} during 24 hours from profile of a single test person; with: 1 sleeping ; 2 bathroom visit; 3 dressing; 4 take down laundry; 5 cellar room, 6 breakfast, 7 vacuuming, 8 changing bedcover, 9 changing clothes, 10 frying cutlets, 11 go for a walk outside; 12 coffee and cake time with guests; 13 relight wood stove; 14 dinner; 15 sweeping (open windows); 16 closing bedroom door; 17 sleeping with windows open (Easter Fire outside).

Figure 1 shows the course of PM_{10} and PM_1 of one single profile (P8) of a test person. The variability of PM_{10} was mostly related to indoor activities such as food preparing or just dressing or vacuuming. Night concentrations and concentration while going for a walk outside were distinctly lower.

We suggest that studies of this nature should be conducted in larger dimension and include biometric parameters as well. In this way, the exposure of individual persons, age groups, professional groups, and lifestyles towards PM can be quantified more representatively. Eventually, exposure models (Gerharz et al., 2009) can be parameterized more realistically.

Session 1E: Engineered Nanoparticle Release from Nanostructured Materials into the Air

Exposure to nanostructured particles during powder handling and mixing, sanding nanoparticle-doped paints and grinding windmill blades

K.A. Jensen and I.K. Koponen

National Research Centre for the Working Environment, Copenhagen, DK-2100, Denmark
Keywords: engineered nanoparticles, workplace, exposure, risk.
email: kaj@nrcwe.dk

Currently there is intensive focus on the potential health risk of exposure to engineered nanoparticles. The risk may be ascribed to small particle size, higher chemical reactivity per mass and/or even special nano-scale properties. However, very little is currently known about the actual or potential exposure levels as well as the characteristics of this exposure. Airborne engineered nanoparticles may occur as free single particles as well as in aggregates and agglomerates. The different types of nanostructured particulates may have formed already in the source material (eg, powders, slurries and composites), as a consequence of work-processes or due to aerosol dynamic processes (coagulation and scavenging). Consequently it is often difficult to determine the fraction of engineered nanoparticles from on-line monitoring in workplace measurements. Such data are crucial to enable a proper risk assessment. Improved assessments can be obtained by more detailed of-line analysis using e.g., electron microscopy and chemical analysis.

In this paper, we present the characteristics of real and potential workplace exposures to engineered nanoparticles based on a number of case studies. The investigations comprise both workplace measurements and measurements during simulated work-processes in the laboratory.

Workplace measurements were done using a TSI Fast Mobility Particle Sizer (FMPS; 5.6-560 nm) and a GRIMM Dust Monitor Model 1.109 (0.28-30ɛm) in the activity zone (< 2 m from the source). Background measurements were done in the workplace areas using a CPC Model 2022 (TSI) and a GRIMM Dust Monitor. PM_1 and Total Suspended Particulates (TSP) was collected on cellulose and Teflon filters filters at the activity and background measurement positions as well as on the operator using Conical Inhalable Samplers (CIS) and Millipore TSP samplers. In laboratory studies, an FMPS was used for nanoparticle measurements. Coarser particles were measured using TSI Aerodynamic Particle Sizer Model 3321 (0.523-20 μm). Dust particles were characterized by analytical Scanning (Quanta 200 FEG MKII) and Transmission Electron Microscopy (Tecnai G20) both from FEI Company, Hillsboro, Oregon, USA.

The case-studies are briefly summarized below emphasizing some of the major general conclusions.

Laboratory handling of nanoparticle powders: There is a potential risk of exposure to nanoparticles even when working in fume hoods. The level of exposure risk is related to type of fume hood and worker behaviour. Here we investigated the exposure during handling of very low-mass powder and during simulated accidental loss of up to 100 g nanoparticulate powder in a fume hood. The result showed that no particle release could be measured to the air outside of the fume-hood at 1 sec. time-resolution in either of the cases. Short-term bursts were detected inside the fume-hood and visual observations showed that powder jets may be released from the fume hood during accidents.

Industrial scale pouring and mixing of nanoparticles powders: Pouring and mixing was found to be the most typical activity in the workplaces visited. Our current examples include companies compounding nanoparticles and pigments into plastic and companies producing paints and lacquers. Workplace exposure during nanoparticle mixing and dosing for twin-screw extrusion was studied in a research and development company and at a large-scale industrial plant. All exposures related to the paint and lacquer factories were studied at industrial workplaces. These studies strongly suggest that the airborne nanoparticles are dominated by aggregates and agglomerates. Moreover, exposure levels are not necessarily linked to the amount of material used. The work procedure, the design of the workplace and use of local exhaust ventilation plays a major role in reducing the risk of exposure.

Sanding and grinding surfaces with and without nanoparticles-based coatings: Finishing and repair is another potential source of exposure to nanostructured dust particles. Our cases include a laboratory study of the emission characteristics of dust particles generated during sanding of paint and lacquer products with and without engineered nanoparticles and a workplace study of particle exposures during grinding a glasfiber-based windmill wing for repair. Carbon nanotube re-enforced epoxy-paints for windmill wings are currently in the R&D phase. Both studies revealed high concentrations of small nm-size particles in the air. Some of these are ascribed to the electrical motors in the power-tools. However, at least in some cases, a fraction of the dust particles consists of free engineered nanoparticles and larger pigments or agglomerates and aggregates thereof. We conclude that mechanical reworking may be associated with very high exposure concentrations in particle numbers.

Investigations on (Nano-) Particle Release during Mechanical Treatment of Different Composite Materials

B. Stahlmecke[1], J. Romazanov[1], C. Asbach[1], H. Fissan[1,2], T.A.J. Kuhlbusch[1,2]

Air Quality & Sustainable Nanotechnology Division, Institute of Energy and Environmental Technology, Bliersheimer Strasse 60, 47229 Duisburg, Germany
[2]CeNIDE, Center for Nanointegration Duisburg-Essen, 47229 Duisburg, Germany
Keywords: Nanoparticles, Nanotubes, Release Scenarios, Measurements, Size Distribution
Presenting author email: stahlmecke@iuta.de

Due to the increasing use of nanomaterials and especially nanoparticles in different composite materials there is an enhanced likelihood of unwanted particle release, which may cause adverse health effects. Besides the unknown amount of released particles during different treatments the origin (release from composite, machinery or other sources) and composition of the released particles is also often unknown.

In order to characterize possible releases from a composite material, the emission of particles during different treatments of the composite has to be investigated in a first step. In a second step a further analysis is required to investigate the degree of separation of the original particles from the surrounding matrix material. This step requires particle sampling and consecutive analysis, e.g. by using electron-microscopy. In many cases the released particles consist of a mixture of nanoparticle and matrix material (e.g. Vorbau et al., 2009).

We will present results from two different studies. The first study aimed at the investigation of a possible particle release from composite building materials made of matrix material and aerogel particles under realistic conditions. The term realistic condition indicates conditions for handling of the composites which are present in the DIY sector. Handling includes e.g. drilling into the composite materials or polishing of the surface of the material. The number size distribution of released particles was measured using a fast mobility particle sizer (FMPS, TSI model 3091) and an aerodynamic particle sizer (APS, TSI model 3321). Furthermore, particles were sampled on glassy carbon substrates by applying a nanometer aerosol sampler (NAS, TSI model 3089).

Different types of composite materials (with and without aerogel particles) were examined by applying several handling procedures ranging from simple dropping to grinding of the materials. Using this approach the energy input, and thus the likeliness of particle release from the material, was increased. Special emphasis was laid on the distinction of particles stemming from the actual working process and particles stemming from other activities.

The main advantage of this approach is the assessment of particles emitted under realistic conditions, thus providing at least information on possible particle emissions in the private sector, where usually no or little measures are taken to inhibit a particle release. The main drawback is the complicated calculation of the different particle fractions: Particle release from the composites has to be quantified versus a background of particles from other sources (e.g. from outside, originating from the process or from the machines used).

The second study was conducted on composite materials containing multiwalled carbon nanotubes. These experiments were conducted in a clean enclosure, where the material was disintegrated by a shredder. No background particles where present during the experiments, so that any measured particles could only stem from the shredding process, which may also include motor emission from the shredder. This study aimed on the simulation of a typical recycling process to assess the number and size distribution of the released particles, especially in view of a possible release of carbon nanotubes.

We will present the rationale of data analysis and the results of the abovementioned experiments conducted for a realistic appraisement of the released particles. Furthermore, we will discuss the advantages and drawbacks of the two different applied approaches. Special emphasis will be given to the comparability of such studies, including the minimum data set that should be presented along with additional information on experimental conditions which may affect the measurements.

This work is partly funded by the German Federal Ministry of Education and Research (BMBF) within the CarboSafe project as part of the Inno.CNT initiative by Grant No. 03X0043D.

Sanding induced nanoparticle release into air from artificially aged/weathered surface coatings

D. Göhler, L. Hillemann and M. Stintz

Institute of Process Engineering and Environmental Technology - Research Group Mechanical Process Engineering, Technische Universität Dresden, 01062 Dresden
Keywords: nanoparticle release, aged surface coatings, sanding process, engineered nanoparticle additives
Presenting author email: daniel.goehler@tu-dresden.de

Nanoparticle additives (NPA) and nanoscaled pigments (NSP) are increasingly used in surface coatings and composite materials to achieve customized product properties. After appropriate processing, the NPAs and NSPs should be firmly embedded in the matrix material. However, since their possible risks to health, safety and environment are still under discussion, it is necessary to investigate their (possible) release from coatings and composites.

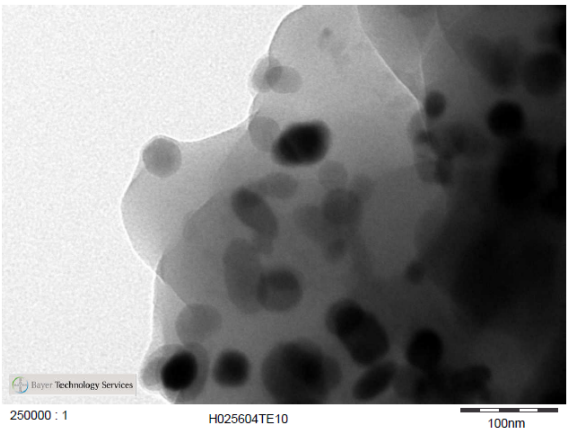

Figure 1: TEM-image of a electrostatic-precipitated polyurethan swarf particle with firmly embedded ZnO NPAs

The release of NPAs and NSPs into air, has already been analyzed in several studies. Weak, but long-term abrasion processes on surface coatings containing and not containing NPAs were simulated by Vorbau et al. (2009) and Guiot et al. (2009). Both studies showed only a slight release of particles. Even more, thorough analyzes of the wear particles with electron microscopy could not confirm the existence of free NPAs. Similar results are given by Hsu & Chein (2007), who investigated the abrasive effect of sunlight, wind and human contact. Koponen et al. (2009 & 2010) and Göhler et al. (2010) characterized the nanoparticle release due to the sanding of coatings with and without NPAs, while cutting and drill processes on CNT-composite materials were simulated by Bello et al. (2009 & 2010). The last mentioned studies based on a relatively high energy input which leads in each case to a considerable generation of nanoparticles, whether NPAs or NSPs were added to the matrix material or not. Nearly all studies have shown, that no free NPA were observed.

External impacts like sunlight, moisture or temperature fluctuations can destruct the matrix material of coatings and composites. This can lead to a denudation of the NPAs and NSPs, which is probably associated with a higher release risk. To our knowledge, no study has been reported the possible nanoparticle release of samples with partially or completely degenerated matrix material.

Based on the sanding test apparatus presented by Göhler et al. (2010) artificially aged/weathered samples of surface coatings and composites were exposed to a defined sanding process. A fast mobility particle sizer (FMPS) and an optical particle size spectrometer (OPS) were employed for the determination of the particle size distribution in a size range of 5.6 nm - 20 µm, while a condensation particle counter (CPC) was chosen to measure the total particle number concentration. Additionally, samples of the swarf aerosol were electrostatic precipitated for subsequent scanning electron microscopy (SEM), transmission electron microscopy (TEM) and energy dispersive X-ray spectroscopy (EDX).

First results on artificially UV-light aged surface coatings show an increase of the nanoparticle release, possibly caused by embrittlement of the matrix material, since no free NPAs were observed during TEM analyses. In addition to the results of this study, the presentation will discuss the experimental apparatus, setup and procedure in detail. Furthermore, measurement results in terms of particle size distributions and numbers of released particles will be presented.

Release of nanoparticles from composite materials under abrasive stress

M.W. Meier[1], M. Mertler[1] and W. Wohlleben[2]

[1]Dust Separation and Aerosol Technology GCP/TP, BASF SE, 67056 Ludwigshafen, Germany
[2]Experimental Toxicology GV/T, BASF SE, 67056 Ludwigshafen, Germany

1. Introduction

Nanocomposites are internally nanostructured materials [1], generated spontaneously or by nanofillers (nano-particles, -platelets, -fibers) dispersed in a continuous matrix material. Consumer contact with nanocomposites has generally been considered as low risk, but substantiation is missing.

In this study, the release of selected nanocomposite materials upon abrasive stressing is characterized. The amount and particle size distribution of released particles is measured, and the released particles were collected for further (toxicological) investigations.

2. Experiments

For the abrasion test rig, a setup similar to that of Vorbau et al (2009) has been used (see Fig. 1). The entire test rig is standing in a housing that is supplied with filtered air, in order to reduce the background particle concentration from the ambient air. A stamp equipped with a sanding paper is pressed with a defined force onto a sample of the studied composite material rotating on a plate. Via a suction cap located above the stamp, an air flow containing released particles is drawn from the housing. The concentration and size distribution of the aerosol is measured by a Scanning Mobility Particle Sizer (SMPS). Particles are collected on a membrane filter for further investigations (SEM, particle size, surface chemistry by XPS and SIMS).

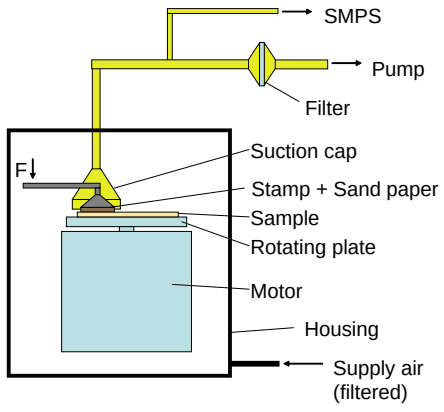

Figure 1: Test rig for abrasion experiments

Studied materials were two polymers and two cementitious materials, with and without nanofillers added.

3. Results

From the abrasion tests it was found that the major fraction of abraded material consists of relatively coarse particles between 10 µm and 80 µm. Only around 5% of the abraded polymeric material and 20% of the abraded cementitious material was found to be smaller than 2 µm. The surface chemistry of the abraded particles was assessed by XPS and SIMS, in order to check whether free nanofillers might adhere to the surfaces of larger particles. For the materials studied here, no release of free nanofillers could be detected.

A closer look is taken at the finest particle fraction in the gas phase by using an SMPS. Particle number concentrations between 500 and 100 000 #/cm³ were found, depending on the material. It was also material-dependent whether an addition of nanofillers led to a higher concentration of released submicron particles or not. For example, an increase was found for SiO_2 particles in polyamide, while no increase in concentration was found for carbon nanotubes in polyoxymethylene. A strong scatter of the data is found especially when higher particle concentrations were measured, which is mainly due to an unsteady dispersion process of abraded material from the stamp surface into the surroundings. Similar observations regarding this scatter were made by Göhler et al. (2010) and Vorbau et al. (2009).

4. Conclusions

Upon abrasion experiments on composite materials containing nanofillers, the release of nanoparticles was investigated. In some cases, an increase of particle release was found in the presence of nanofillers, in others not. No indications were found that free nanofillers were released during the abrasive stressing.

The interest in nanocomposites including nanoparticles with a scale below 100 nm is still of rising interest in industry. The physical and chemical properties of the respective nanocomposites can be adjusted very nicely via using the right nanoparticles as well as the right matrix (polymer, metal, ceramic).

A still open question of those nanocomposites is the potential toxicity during industrial use, because harmful nanoparticles might be released by thermal and mechanical stresses.

The focus of our work is on the mechanical treatment, like drilling, cutting and grinding. Therefore it is essential to know which and how many nanoparticles will be generated in view of the occupational health. An experimental setup was designed to characterize the released particles. The setup for the experiments is shown in figure 1.

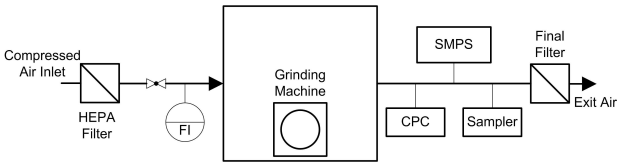

Figure 1. Scheme of the experimental setup with a grinding machine.

The test rig is equipped with a common grinding machine in which a nanocomposite can be handled under realistic conditions. Measurements will be performed with a Condensation Particle Counter (CPC), Scanning Mobility Particle Sizer (SMPS) and Electrical Low Pressure Impactor (ELPI).

Common polymeric materials, nanocomposites, have been chosen with and without nanoparticles. All materials were produced specially for this purpose. An example for an epoxy resin is shown in figure 2 with a volume percentage of 0.5 % of MWCNTs.

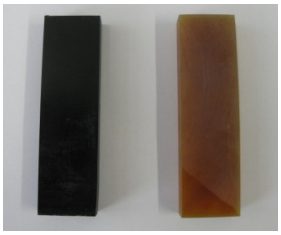

Figure 2. Example of a composite including (left) and excluding (right) Carbon Nano Tubes (CNT).

The results of measurements and the collected particles will be presented and compared. One of the first results is shown in figure 3.

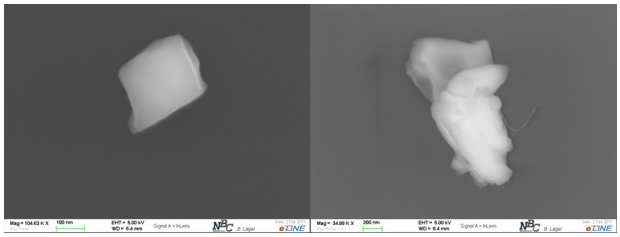

Figure 3. Generated particles of a composite including (right) and excluding (left) Carbon Nano Tubes (CNT).

Keywords: nanostructured materials, handling processes, nanoparticle release testing standardisation

There is an increasing interest in making use of nanoobjects to take advantage of their properties to improve the functionality of powders and composite materials. Those nanoobjects can occur in form of nanoparticles and fibers (e.g. CNT) (NP) as well as their agglomerates and are used either as powders or dispersed in liquids or solids. A discussion about the possibility of negative health effects of NPs and their agglomerates/ aggregates in air has started. However, negative effects in human beings and nature can only occur, if NPs and their agglomerates/aggregates are emitted, e.g. during synthesis, from products during their lifetime and recycling or after littering in the environment. The latter case is not considered here. To reduce the chances for NP emission, the following topic areas have to be addressed: control of emission and exposure including adequate measurement techniques, abatement strategies and standardized procedures to assess the probability of nanoparticle-release from nanomaterials into the environment.

To form nanostructured materials, NPs are produced in form of powders and suspended into liquid and most often in solid materials. Different methods under different conditions trying to simulate the real world activities like in case of handling of composite material, sawing and drilling have been used thus far.The approach thus far taken to investigate the NP-release from all kinds of materials containing NPs and the different handling processes, however, is extremely time consuming. An understanding of the underlying basic processes and their representation by a limited number of test methods is needed. It should be based on determining the release probabilities of NPs for different materials. This is depending in a first step on the easiness to separate the matrix material from the NPs, which may become airborne in a second step.

Besides the complex environmental stress, two types of stress can be differentiated for the NP containing materials: mechanical and thermal stress. Almost all treatment processes (like drilling, sawing and so on) start with mechanical stress forming chunks of matrix materials containing NPs. Except in cases where the particles are loosely bound to surfaces with direct access to the environment – actually they are already matrix material free – there is no real chance to liberate the NPs, because the achievable smallest chunk size is still too big. To get to smaller and smaller dimensions of these blocks, one has to locally introduce more and more mechanical energy into the material, which becomes increasingly difficult. In case of powders existing dustiness tests may be modified to especially concentrate on NP-release. For liquids very small droplets are produced with electrospray containing just one particle each.
In case of composites the mechanical energy input causes a (local) heating of the material.
The thermal energy input leads to evaporation and oxidation processes, which transfer material into the gas phase. In cases where the needed evaporation and /or oxidation energy for the matrix material is lower than for the NPs, there will be free NPs without matrix material. The knowledge of the basic physics and chemistry already allows for setting up a list of separation probabilities for different nanostructured materials, based on the thermal properties of the matrix material.

Since thermal energy input is the most likely relevant process to separate matrix material and NPs in case of composites, which is the first, but needed step to release NPs into air, the determination of the separation probability should be based on a thermal process, which finally can be standardized. The Thermo-Gravimetric Analysis (TGA) is a well defined and representative process, which allows the determination of the release of the matrix material into the air in comparison to nanoparticle combustion or sintering as a function of temperature.
Starting with a matrix containing a systematic order of the different forms of nanostructured materials and the list of different handling procedures, the handling procedures will be sorted according to different stress situations. Possible standard processes for different stress situations will be identified and described. Available first results for different stress situations will be discussed. It will be demonstrated how the tremendous work needed for investigating all possible handling procedures for all existing and expected nanostructured materials can be reduced by concentrating on representative processes for different stress situations, which may become standards in the future.

Session 1F: Aerosol Nucleation

Rethinking the first nucleation theorem in atmospheric nucleation

H. Vehkamäki[1], M. J. McGrath[1], T. Kurten[1,2], K. Lehtinen[3], and M. Kulmala[1]

The first nucleation theorem is a very useful tool in experimental studies of vapor–liquid nucleation, as it relates the derivative of the nucleation rate with respect to saturation ratio to the critical cluster size of the system. In other words, one can measure the nucleation rate of a system at various saturation ratios (holding all other variables, e.g temperature, constant), and learn information concerning the structure of the critical nucleus. This is an invaluable tool, as it is quite difficult to probe the structure of the critical nucleus directly. It has been well-established that the theorem is accurate for systems with a single maximum in the free energy profile. In the case of systems which have a local minimum on the free energy surface in addition to the maximum, the situation is not as clear. This is the case in ion-induced nucleation under moderate saturation ratios, where the addition of multiple neutral molecules (such as water) serve to stabilize the ion before the free energy barrier to nucleation. In addition, quantum chemical calculations indicate that such a local minima also exists for the case of sulfuric acid-base molecule nucleation, e.g. the amine-containing SA dimer evaporates much more slowly than the amine-containing SA trimer. It has been argued that the first nucleation theorem can still be used in this case, either without modification or with a minor systematic modification, although in-depth exploration is lacking in the literature.

Through the use of the Atmospheric Cluster Dynamics Code (ACDC), a collection of Perl and MATLAB scripts, we have solved the birth-death equations (the system of differential equations describing the cluster interactions) for various fictitious free energy profiles displaying a free energy maximum and one (or zero) free energy minimums, including one directly applicable for ion-induced nucleation. Here, "fictitious" means that all of the physical properties of the system are taken to be that of water (mass, vapor pressure, etc.), but the free energy profile has been arbitrarily changed to display a local minimum at small cluster sizes. The ion-induced case uses the free energy curves computed by classical theory for the quasi-one-component water + ion nucleation system. In addition to the first nucleation theorem, a generalization of the first nucleation theorem derived by McGraw and Wu was also used. Given that these versions of the nucleation theorem were both derived under the assumption that only monomers can collide and evaporate from clusters, and given that this same restriction is not present in explicit solution of the differential equations governing the system, both cases (allowing only monomer collisions/evaporations, and allowing all collisions/evaporations) were tested by ACDC.

In order to compare to the experimental case, we explored the possibility of holding various concentrations constant while computing the derivative of the nucleation rate with respect to the saturation ratio: the monomer concentration, the concentration of the cluster at the free energy minimum, and the total concentration of molecules in the system. We have found that the first nucleation theorem holds true for the case where there is no free energy minimum (as expected). For the fictitious free energy profile with one free energy minimum, the first nucleation theorem predicts incorrect results, regardless of the quantity held constant. For a curve produced by considering the ion-induced nucleation of water, the first nucleation theorem was found to give decent results when the concentration of the cluster located at the free energy minimum or the total number of ions was held constant, but not in the case of holding the naked ion concentration constant. These results have a significant impact on the determination of critical cluster composition from field studies and laboratory experiments related to atmospheric nucleation.

Aerosol nucleation induced by a high energy particle beam

M.B. Enghoff[1], J.O.P. Pedersen[1], U.I. Uggerhøj[2], S:M: Paling[3], and H. Svensmark[1]

[1]National Space Institute, Technical University of Denmark, Copenhagen, Denmark

[2]Department of Physics and Astronomy, University of Sheffield, Sheffield S10 2TN, U.K.
Keywords: ion-induced nucleation
Presenting author email: jopp@space.dtu.dk

The importance of ion-induced nucleation for the Earth' atmosphere is a subject of intense discussions which is being studied both in field measurements and in modeling work. Previous laboratory studies using gamma rays have found a positive correlation between ionizing radiation intensity and aerosol concentration in air (Raes and Janssens (1985), Svensmark *et al.* (2007), Enghoff *et al.* (2008)), but systematic laboratory experiments on aerosol nucleation with ionizing particle radiation have so far only been performed with very high radiation doses far above natural atmospheric levels using radioactive sources or high intensity electron and proton beams. Preliminary measurements with a more realistic 3.5 GeV/c pion beam have been reported to show indications of ion-induced nucleation, but suffered from unstable conditions in the reaction chamber (Duplissy *et al.* (2010)). A new experimental facility dedicated to these studies is under commissioning at the CERN Proton Synchrotron (PS) and is likely to resolve these problems.

The present experiments took place in a 50 L cylindrical, elec-tropolished stainless steel reactor, previously used by Enghoff *et al.* (2008). A mixture of pure humidified synthetic air is continuously flowed through the vessel at a rate of 3.1 L/min together with trace amounts of (typically 2 ppb) sulfur dioxide and approximately 55 ppb ozone with the relative humidity held at about 50\%. UV light was used to initiate the photochemistry in the chamber leading to an in situ production of sulfuric acid. The temperature was kept at 21.2^{o}C and the pressure at 1-2 mbar above room pressure.

A low-intensity beam of 580 MeV electrons from the Aarhus Storage Ring ASTRID at the University of Aarhus was used as the ionizing source. The energy of the electron beam falls within the main part of the natural cosmic ray spectrum and the induced ion concentrations cover the full range of atmospheric values.

Production of aerosols was measured using a condensation particle counter (CPC) with a nominal 50 % cutoff diameter of 4 nm. The chamber volume could be ionized using the 580 MeV electrons going coaxially through the chamber. The ionization level from the beam was adjustable by changing the amount of beam extracted and the electrons pass through the volume of air almost undisturbed. Alternatively a 33.5 MBq Na-22 gamma source could be used.

The procedure for each experiment involved turning the UV lamps on for 10 minutes giving a burst of sulfuric acid and then recording the resulting particle number. The time between UV bursts was 60 minutes, in order to allow the aerosol concentration (as measured by the CPC) to reach zero by the end of each burst, with the aerosols being lost to walls and by dilution.

We found a clear and significant contribution from ion-induced nucleation and consider this to be the first unambiguous observation of the ion-effect on aerosol nucleation using a particle beam under conditions that resemble the Earth's atmosphere. By comparison with ionization using a gamma source we further found that the nature of the ionizing particles is not important for the ion-induced component of the nucleation (Enghoff *et al.* (2011)).

Keywords: CLOUD experiment, ion-induced nucleation, ions, sulfuric acid, smog chamber.

The possible influence of cosmic rays on aerosols and clouds is of considerable interest (Carslaw, 2009). The CLOUD experiment at CERN aims to study under controlled conditions the effects of cosmic rays on nucleation. CLOUD was installed at CERN in 2009 and three successful campaigns were carried out in 2009 and 2010 to study ion-induced and neutral binary nucleation of H_2SO_4 and H_2O, for tropospheric and stratospheric conditions. Here we present the nucleation data obtain in the CLOUD chamber together with the result of the new model including ion-induced nucleation mechanism.

Methods

Technical input for the CLOUD design was obtained in a pilot experiment in 2006 (Duplissy *et al.*, 2010). The chamber is a 3m-diameter electro-polished stainless-steel cylinder (26.1 m^3). A field cage is installed inside the chamber to allow the removal of ions, when required. The contents of the chamber are irradiated by UV light in the range 250-400 nm. Experimental runs can be performed at stable temperatures between 40°C and -90°C.

The chamber is exposed to a 3.5 GeV/c secondary pion beam from the CERN PS, corresponding to the characteristic energies and ionization densities of cosmic ray muons in the lower troposphere. The beam intensity can be adjusted to cover the natural range from ground level to the stratosphere. Ultra-pure air is obtained from the evaporation of cryogenic liquid N_2 and liquid O_2. The air is humidified with a Nafion humidifier. Ozone is added to the air by UV irradiation. Trace gases such as SO_2 are added from gas cylinders containing pressurised N_2 as the carrier.

The chamber instrumentation includes PTRMS, CIMS, Nano-SMPS, CPC battery, PSM, API-ToF, NAIS, Gerdien, LOPAP, dew point sensor, SO_2 and O_3 analyser, as well as T, P and UV sensors.

Model

The classical nucleation theory including the hydrate interaction model and the ion-induced nucleation will be merged into one model. From this improved model an extension of the parameterisation from Kulmala et al., (1998) and Vehkamäki et al. (2002) will be developed, and compared with the CLOUD data.

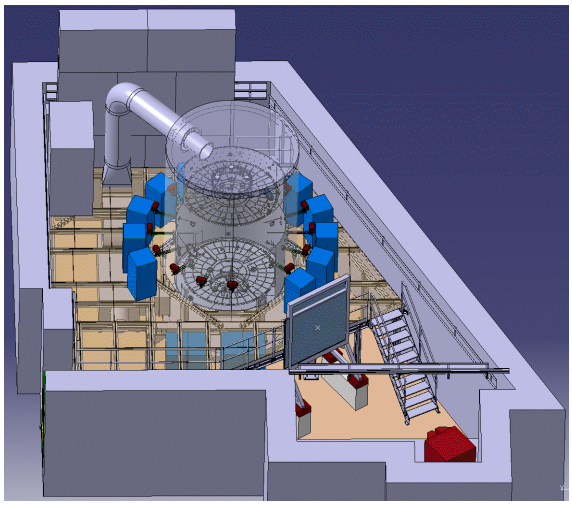

Figure 1. An illustration of CLOUD in the experimental zone at the CERN PS. The de-focused particle beam exits a dipole magnet (bottom right), crosses the hodoscope counter (middle) and then traverses the 3m-diameter CLOUD chamber. The instruments (blue boxes) analyse the contents of the chamber via sampling probes fitted with valves.

We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. This research has received funding from the EC's Seventh Framework Programme under grant agreement no. 215072 (Marie Curie Initial Training Network "CLOUD-ITN"), from the German Federal Ministry of Education and Research (project no. 01LK0902A), from the Swiss National Science Foundation, and from the Academy of Finland Center of Excellence program (project no. 1118615).

Formation of Zn and ZnO nanoparticles by homogeneous nucleation

B. Steer[1], V. Ranganathan[2], H. Gnewuch[2], B. Gorbunov[2] and F. Larner[3]

[1]University of Kent at Canterbury, University Road, Canterbury CT2 7NJ, UK
[2]Naneum Ltd., CIC, University Road, Canterbury CT2 7FG, UK
[3]Department of Earth Science and Engineering, Imperial College London, London SW7 2AZ, UK
Keywords: homogeneous nucleation, Zn nanoparticles, engineered nanoparticles.
Presenting author email: brian.steer@naneum.com

Zn and ZnO nanoparticles are widely used for many applications in nanotechnology. Mechanisms of Zn and ZnO nanoparticles formation are not fully understood. A novel system for the generation of engineered nanoparticles (ENPs) was developed. This system was based on vapour to particle conversion technique and it was used to generate Zn nanoparticles over the size range from 5 nm to 500 nm (diameter). These particles can subsequently be oxidized to ZnO. Freshly produced Zn nanoparticles generated in the gas phase were characterised using a range of state-of-the-art-techniques.

Homogeneous nucleation of Zn ENPs was observed in clean nitrogen and argon at atmospheric pressure at flow rate from 0.3 to 3 l/min and oven temperatures 300 to 700°C. Nanoparticles number size distributions obtained with an NPS500 SMPS were influenced by the oven temperature and by the flow rate of the carrier gas. Two distinct modes were observed at about 6nm and 75nm in size distributions recorded with an NPS500. Variation of the oven temperature slightly affects the median diameter of the modes. Temperature variation changes relative heights of the modes in the size distributions. TEM images of the nanoparticles collected with a thermal precipitator show two distinct particle shapes that indicates two mechanisms of nanoparticle formation. The first mechanism of Zn formation takes place at the lower temperatures of the oven when rectangular shaped particles of about 50nm were observed. Therefore, these particles were formed directly by vapour to solid phase mechanism (similar to sublimation).

At higher temperatures spherical particles were the dominant morphology in TEM photographs. This indicates the formation of Zn particles via a stage where liquid droplets were formed. Therefore, Zn ENPs might be generated in two stages: first formation of liquid droplets from the vapour, and second crystallisation of these droplets.

Theoretical modelling of homogeneous nucleation was performed using self-consistent classical nucleation theory modified by Gorbunov (1999). The free energy of embryo formation was calculated for spherical embryos in the case of liquid particle formation from vapour (Abraham, 1974). The Zeldovich factor was introduced according to Pruppacher and Klett (1997).

In the case of vapour to solid Zn particle formation it was assumed that embryos were of equilibrium crystalline shape. Supersaturation in the Zn generator was calculated using the commercially available finite element software COMSOL. The modelling confirmed that at lower temperatures, vapour to solid ENPs formation is the dominant process. At higher temperatures, solid Zn particles are formed via an intermediate stage of liquid particles: vapour – liquid-solid. Thus modelling confirms observed formation of spherical particles at higher temperatures.

The generator was modified by adding another oven with an air inlet of 0.5 to 2 l/min flow rate where Zn aerosol particles were oxidised to ZnO. Regimes were found to generate ZnO particles in the size range from 10 to 300 nm.

This enables the morphology of Zn and ZnO ENPs as well as the size of particles to be controlled in a flow system. The findings in this work can be used for production of ENPs with predetermined sizes and shapes for various nanotechnology applications.

A Shape Independent Collision Kernel Valid for All Knudsen Numbers

Ranganathan Gopalakrishnan[1], Thaseem Thajudeen[1], Christopher J. Hogan Jr.[1]

[1]Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN, USA
Keywords: condensation, coagulation, brownian dynamics
Presenting author email: Hogan@me.umn.edu

Aerosol particle growth is invariably driven by either particle-gas molecule collisions (condensation) or particle-particle collisions (coagulation/agglomeration). Aerosol systems are typically dilute, thus collisional growth can be modelled by only considering the motion of the two colliding entities. Therefore, the collision rate between two entities in the gas phase can be calculated as the product of the number concentrations of the entities in question multiplied by the collision kernel. For neutral aerosol particles, collision kernel determination is simplified by the fact that the force between colliding entities in this situation is often negligibly small. However, as characteristic aerosol particle sizes are typically similar in magnitude to the mean persistence distance of colliding entities (particles or gas molecules), thus neither a continuum approach (Smoluchowski's analysis) nor a free molecular approach (from gas dynamics) to collision kernel calculation is appropriate for aerosol particles.

While a number of "transition regime" collision kernels have been developed for both condensation and coagulation processes, there a several pending issues with modelling transition regime collisions. First, while condensation and coagulation have typically been modelled using distinctly different equations, the collision of a fast moving vapor molecule with a particle is simply a limiting case of more general particle-particle collisions. Therefore, there should be a single collision kernel valid for both condensation and coagulation. Second, all previously developed transition regime collision kernels apply for spherical particles only. In this presentation, we show that through Langevin equation (Ermak & Buckholz 1980) modelling and mean hitting calculations, a collision kernel which accurately describes both condensation and coagulation can be constructed. Through dimensionless analysis of the collision process and further mean hitting time calculations we show that this collision kernel is valid for aerosol particles of arbitrary shape across the transition regime (the entire Knudsen number range).

Theoretical Approach

Dimensionless analysis of the collision process reveals that for colliding entities at thermal energy kT, with radii a_1 and a_2, masses m_1 and m_2, and friction factors f_1 and f_2, the collision kernel, β, can be written is dimensionless form as:

$$H = \phi(Kn_D) \qquad (1)$$

where $H = (\beta\mu)/(f_{red}[a_1+a_2]^3)$ (dimensionless collision kernel), $Kn_D = (kT\mu)^{1/2}/((f_{red}[a_1+a_2]^3)$ (diffusive Knudsen number), $f_{red} = (f_1 f_2)/(f_1+f_2)$ (the reduced friction factor), and $\mu = (m_1 m_2)/(m_1+m_2)$ (the reduced mass). Regardless of whether the collision is between particle and vapour molecule or particle with particle, the relation $H(Kn_D)$ should describe the collision process in the transition regime.

Results

Langevin based mean hitting time calculations are used to determine $H(Kn_D)$ for both condensation (where a gas molecule moves around a stationary aerosol particle) and coagulation (where two particles move relative to each other. In addition, we redefine H and Kn_D for non-spherical by appropriately replacing the particle radius (the collision size parameters) in H and Kn_D with appropriate functions of their continuum radius and orientationally averaged projected surface area. We then use mean hitting time calculations to also determine $H(Kn_D)$ for condensation onto nonspherical particles. Results of all computations are shown in Figure 1.

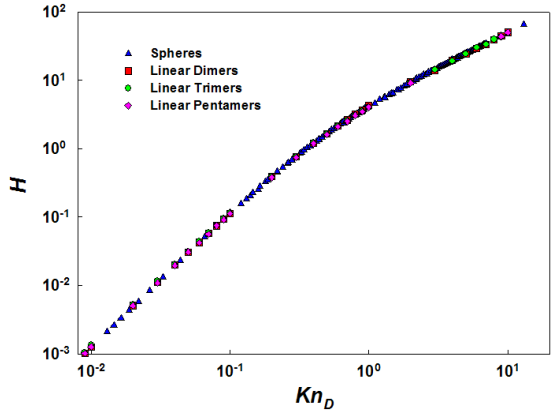

Figure 1. $H(Kn_D)$ relation from mean hitting time calculations. Particles of all shape collapse to a single curve.

The single $H(Kn_D)$ relationship found for both condensation and coagulation, and for non-spherical particles suggest that the combined approach of dimensionless analysis and mean hitting calculations can be employed to construct a universal collision kernel across the entire Knudsen number range.

Nucleation rates and parametrisation in the CLOUD experiment

Almeida-Simões, João[1,2], Curtius, Joachim[1], Kirkby, Jasper[2], and the CLOUD collaboration

[1] Goethe-University of Frankfurt am Main, 60438 Frankfurt am Main, Germany
[2] Physics Department, CERN, CH1211, Geneva, Switzerland

Keywords: CLOUD experiment, cosmic rays, atmospheric nucleation, nucleation rate, parametrisation.

The possible influence of cosmic rays on aerosols and clouds is of considerable interest (Carslaw, 2009). The CLOUD experiment at CERN aims to study under controlled conditions the effects of cosmic rays on nucleation, cloud droplets and ice particles.

The CLOUD experiment involves a 3m stainless steel aerosol chamber exposed to a pion beam from the CERN Proton Synchrotron. A suite of instruments continuously analyse the contents of the chamber via sampling probes. Each instrument has its own data acquisition system which delivers data in real-time to the CLOUD server. The CLOUD chamber is able to reproduce a wide range of well-controlled atmospheric conditions, including temperatures -90°C to 100°C, ion-pair concentrations 1-4000 cm^{-3} and relative humidities, RH, 0-100%. The nucleation and growth of new particles has been studied in the presence of various trace gases, including H_2SO_4 (10^6-10^9 cm^{-3}), NH_3 (35pptv to 1ppbv), amines and organics.

One of the primary goals of CLOUD is a quantitative evaluation of the dependency of the nucleation rate, J, on variables such as [H_2SO_4], [NH_3], [IONS], RH, T, etc. We have developed an accurate, automated method to determine the nucleation rate of critical clusters from the time evolution of the particle number concentration measured by each of the particle counters attached to the CLOUD chamber (CPC, DEG-CPC or PSM). Each particle counter is characterised by certain detection size threshold, d_{50}. To obtain the nucleation rates at the critical size, a correction is required to account for losses before the particles are eventually detected at size d_{50}. The losses occur due to wall-losses, coagulation and chamber air dilution. A Monte-Carlo model (AeroCLOUD) was developed to calculate these corrections numerically (Fig.1). The output of the model has been verified by comparison with experimental measurements made near to the critical size using the Particle Size Magnifier (PSM).

Since 2009, CLOUD has measured the nucleation rate of new particles over a broad range of conditions relevant for the atmosphere. Using measurements from multiple instruments that analyse the CLOUD chamber, we have derived an empirical J parametrisation that combines the measured J values with current theoretical understanding. The parametrisation is tuned using a nonlinear numerical Levenberg-Marquardt algorithm. The parametrisation successfully predicts all nucleation rates measured so far by CLOUD and is designed to be well-behaved when extrapolating outside the experimentally-explored region.

The CLOUD parametrisation is based on the most rigorous laboratory measurements of ion-induced and neutral atmospheric nucleation achieved so far, and so constitutes an important new tool for evaluating the global contributions of nucleation in atmospheric models such as GLOMAP (Dunne, E.M., et al., this conference).

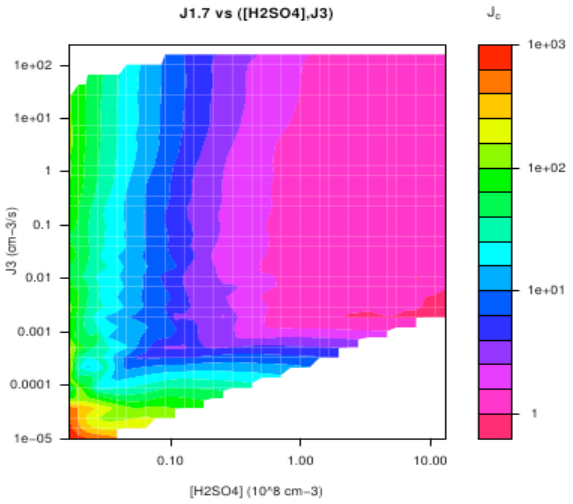

Figure 1. Example AeroCLOUD-calculated corrections for $J_{2.5}$ values (ie. detection with a 2.5nm-threshold CPC). The colour contours relate sulphuric acid concentration (x axis) and $J_{2.5}$ (y axis) with a correction factor that ranges from 1 (plotted in blue-magenta) for high [H_2SO_4] up to 1000 (plotted in orange-red) for low [H_2SO_4] and low $J_{2.5}$ values.

We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. This research has received funding from the EC's Seventh Framework Programme under the grant agreement no. 215072 (Marie Curie Initial Training Network "CLOUD-ITN"), from the German Federal Ministry of Education and Research (project no. 01LK0902A), and from the Swiss National Science Foundation, and from the Academy of Finland Center of Excellence Program (project no. 1118615).

Keywords: homogeneous nucleation, sulphuric acid, amine, flow tube.
kimmo.neitola@fmi.fi

Sulphuric acid is known to play a key role in atmospheric nucleation (gas to particle conversion). The attention has shifted lately towards a third nucleating species (ammonia, amines) in addition to sulphuric acid and water. This is due to recent quantum chemical calculations that suggest a third species to thermodynamically stabilize sulphuric acid-water molecular clusters.

Flow tube technique was used to study homogeneous nucleation of sulphuric acid and water with and without the presence of trimethylamine (TMA) in 2 different relative humidities (30% and 50%). Sulphuric acid was produced using a thermally controlled cylinder which is half filled with pure (97%) sulphuric acid. Dry, particle free compressed air is flown through the saturator with constant flow rate (0.1 lpm) to saturate the flow with sulphuric acid vapour. The concentration is controlled by the temperature of the saturator. The sulphuric acid concentration was measured with CIMS (Petäjä et al., 2009) or APi-TOF (Junninen et al., 2010).

The concentration of nucleated particles was monitored with Particle Size Magnifier (PSM, Vanhanen et al., 2009). The size of the particles was measured with DMPS system (HAUKE DMA, UCPC, TSI model 3025A) in the range of 3 to 200 nm.

Five different concentration levels of TMA was used (170, 480, 800, 1700 and 3600 ppt) with sulphuric acid concentration range between 10^5 and $5 \cdot 10^7$ mol./cm^3. The flow tube was operated is several hours in same conditions to ensure stable state. TMA concentration was changed only after a full cycle of saturator temperatures (0-45^{o}C) was done for both RH's separately.

Figure 1 shows DMPS size distribution (upper panel) and total count (lower panel) data without TMA for one saturator temperature cycle at RH 30%. Figure 2 shows data from DMPS (upper panel) and PSM (lower panel) for exactly similar conditions as in figure 1, except the addition of TMA. The sizes of the particles are similar in both figures before adding TMA. After the addition of TMA the size decreases out of the DMPS size range and concentration of particles decreases to 1/3 of the original concentration. Increasing the RH to 50% increases the concentration temporarily but after stable state is achieved concentration is decreased to about 800 cm^{-3}.

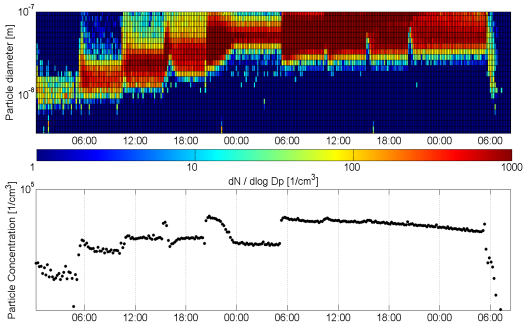

Figure 1. DMPS data for size distribution (upper panel) and total concentration (lower panel) for one saturator temperature cycle without TMA.

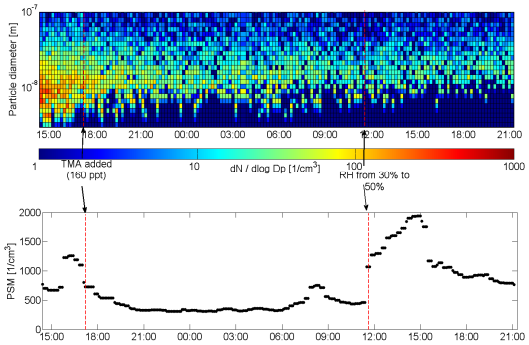

Figure 2. DMPS and PSM data over one cycle of saturator temperatures at RH 30% with lines when TMA (160ppt) was added and RH changed to 50%.

Results imply that TMA forms thermodynamically stable clusters with sulphuric acid with sizes below the detection limit of the PSM (~1.5 nm) suppressing the condensation of sulphuric acid to the surface of the particles and preventing the growth to detectable sizes. This was predicted by Anttila et al., (2005).

Session 2A: Bioaerosols

Bioaerosol analysis by a combined microarray / SERS (surface-enhanced Raman scattering) approach

K. R. Schwarzmeier, M. Knauer, R. Niessner, N. P. Ivleva and C. Haisch

Chair for Analytical Chemistry, Technische Universität München, Munich, D-81377, Germany
Keywords: Bioaerosols, Raman spectroscopy, SERS, microarray
Presenting author email: Christoph.Haisch@ch.tum.de

Bacterial contamination of indoor air is a serious threat to human health. Pathogenic germs can be transferred from the liquid to the aerosol phase for instance when the water is sprayed in air like in showers, air conditioners, or fountains. Existing analytical instruments for the of indoor air quality assessment and contamination monitoring are mostly time consuming as they generally require for a cultivation step. The need for a rapid, sensitive and selective detection method of bioaerosols is evident. We developed a new method, which allows for a direct measurement of the microorganisms.

Our approach is based on the combination of a commercial wet particle sampler (Coriolis µ, Bertin Technology, France), an immunologic capture of the specific microorganisms in the detection liquid and a consecutive detection, characterization, and quantification by surface-enhanced Raman scattering (SERS). The bacteria are impinged and collected into PBS buffer by the Coriolis µ sampler. The sampling liquid is pumped in a closed flow system over a microarray chip. Antibodies against the targeted microorganisms are bound to the surface of the chip (Fig. 1). They selectively collect the microorganisms from the liquid and immobilize them on the surface.

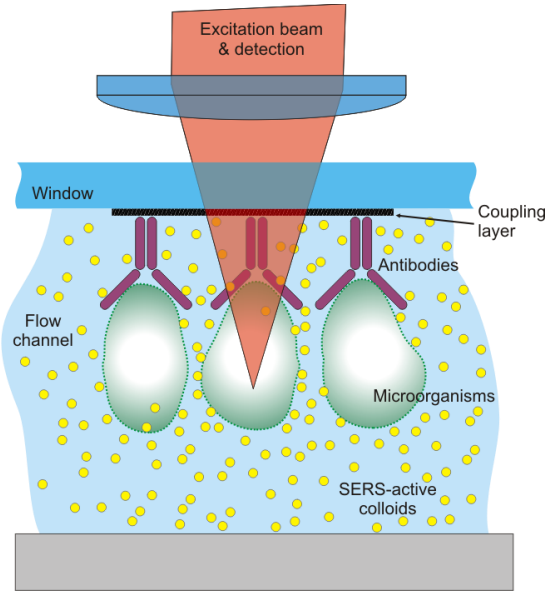

Figure 1. Principle of the SERS detection and characterization.

Quantification of the collected samples is carried out by SERS. The flow cell is installed underneath a Raman microscope, which stepwise scans over the chip surface. Quantification is not based on the signal intensity, but on the number of surface positions, where microorganisms are bound This approach was already demonstrated successfully for the detection of bacteria in water (Knauer *et al.* 2010a). The SERS effect is achieved by adding silver colloids into the flow system. It amplifies the signals by several orders of magnitude. Additionally, the information content of the spectra is increased by the chemical and electromagnetic interaction between the microorganism and the silver colloids (Knauer *et al.* 2010b).

The first tests of the system were carried out by placing the sampler onto, or alternatively into an aerosol chamber with a volume of 1 m^3. These first experiments we carried out with heat-inactivated E. coli and legionella bacteria. The bacteria were dispersed by a cross-flow nebulizer and depending on the experimental conditions, directly or after drying and discharging, lead into the chamber. Knowing the bacteria concentration in the dispersed liquid and its volume, the particle number concentration in the chamber could be calculated. Additionally, an Aerodynamic Particle Sizer (APS, model 3310a, TSI Inc., USA) was employed for reference analysis. Measurements in the chamber were carried out primarily in particle-free air, for later experiments, room air with a typical particle number concentration of about $6 \cdot 10^4$ cm^{-3} was in the chamber to simulate natural background contamination.

From these preliminary results we can deduce that a minimum number concentration of about 10^4 particles/m^3 can be detected by our system. Furthermore, we did not observe a significant influence of the natural background by ambient air in the lab on our measurements.

We believe that this combined approach has several advantages. The wet sampling by Coriolis effect is a rather efficient sampling approach for bioaerosols. Selective binding of the specific target microorganisms by the antibody reduced the analysis time significantly, particularly in case of high-load samples, as the SERS measurement of non-targeted particles is avoided. The SERS analysis, finally, reveals highly specific information on the collected organisms, which may even surpass the specificity of the antibody collection. Compared to conventional immunological microarray readout, SERS does not require for laborious labelling steps, and the SERS amplification allows for short measuring times.

Assessment of bacterial and fungal aerosol in hospital air

Viswanath Mula[1], Zaheer Ahmad Nasir[2], Ian Colbeck[2], Mark Loeffler[1]

[1]NHS Colchester Hospital University
[2]Department of Biological Sciences, University of Essex, Colchester, CO4 3SQ, U K

Keywords: bioaerosols, size distribution, hospitals

Airborne nosocomial infections in health care settings are often related to aerobiological sources. In order to reduce the dispersion of airborne biological particles in hospitals various air control measures are in practice and monitoring of airborne microorganism is generally carried out during epidemic outbreaks. However the regular assessment of microbial load in hospital air, especially in operation theatres, is of great importance to assess, not only, the air control efficiency but also to identify any introduction of airborne pathogens. This study aims to assess the levels of airborne bacteria and fungi in two different types of orthopaedic theatres (with and without laminar flow), a general ward and outdoors. The sampling was carried out with an Anderson 6 stage viable impactor over a period of 8 weeks. In both the theatres samples were collected in the morning and evening, while the samples in the ward and outdoors were taken at noon. The sampler was loaded with six Petri dishes containing either malt extract agar (Oxoid, UK), Nutrient agar (Oxoid, UK), or MacConkey Agar (Oxoid, UK), prior to sampling and the sampling interval was 5 minutes.

The highest mean concentration of total bacteria was found outdoors (1375 CFU/m^3) followed by the general ward (1265 CFU/m^3), an orthopaedic operation theatre without laminar flow (141 CFU/m^3) and an orthopaedic operation theatre with laminar flow (82 CFU/m^3). In general, higher concentrations were found in the operation theatre without laminar flow than the operation theatre with laminar flow. With reference to gram negative bacteria, the general ward had the highest mean concentration (130 CFU/m^3) followed by outdoors (91 CFU/m^3 at 20°C) and the operation theatre without laminar flow (2 CFU/m^3). No gram negative bacteria were detected in operation theatre with laminar flow. Similar to bacteria, the higher concentration of fungi was present outdoors and in the general ward as compared to the operation theatres. The mean concentration of fungi outdoors and in the general ward was 1318 CFU/m^3 and 1062 CFU/m^3, respectively. In the operation theatres the concentrations were higher in the evening than the morning. The mean concentration of fungi in operation theatres without laminar flow and with laminar flow, during morning and evening, was 22 CFU/m^3 and 38 CFU/m^3, 5 CFU/m^3 and 80 CFU/m^3, respectively (Table 1).

Table. 1 Mean, standard deviation, and % of less than 4.7μm of total culturable bacteria, gram –ve bacteria and fungal aerosol in different settings in a hospital.

OOT(M) Orthopaedic Operation Theatre without laminar flow (Morning), OOT(E) Orthopaedic Operation Theatre without laminar flow (Evening), LFOOT(M) Laminar Flow Orthopaedic Operation Theatre (Morning), LFOOT(E) Laminar Flow Orthopaedic Operation Theatre (Evening), Gen. Ward (General Ward).

Overall, lower concentrations of airborne microorganisms were found in the laminar flow theatre than non laminar flow theatre. However these levels were higher than suggested levels by The Department of Health. The concentrations in the ward were slightly lower than outdoors. This study not only provides an insight to microbial load of hospital air but also draws attention to the need of regular air sampling in heath care facilities in order to check that various systems and procedures to reduce microbial load are working effectively. Appropriate heating and ventilation systems, effective infection-control procedures and surveillance systems hold the key to limit airborne microbial load in hospitals.

Bioaerosols in the Earth System: Sources, Interactions and Effects

U. Pöschl

Max Planck Institute for Chemistry, Biogeochemistry Department, Mainz 55128, Germany

Keywords: PBAP, bioprecipitation, diversity, emission and transport, measurement and modeling
Presenting author email: u.poschl@mpic.de

Bioaerosols consisting of primary biological particles such as bacteria, spores and pollen are essential for the spread of organisms in the biosphere, and numerous studies have suggested that they may be important for atmospheric processes, including the formation of clouds and precipitation.

However, the sources and diversity, atmospheric abundance and transport, physicochemical properties and transformation of bioaerosols, including their activity as cloud condensation and ice nuclei (CCN, IN), are not well characterized. Thus, their actual influence on the evolution, present state and future development of the Earth system, the hydrological cycle and other biogeochemical cycles is poorly constrained.

Figure 1 illustrates the cycling of aerosols and water over pristine rainforest (bioprecipitation cycle) as observed during the wet season in the Amazon basin. Secondary organic aerosols (SOA) formed by photo-oxidation of volatile organic compounds (VOC) and primary biological aerosols (PBA) emitted from biota in the rainforest (plants and microorganisms) serve as CCN and IN, which induce warm or cold rain formation, precipitation, and wet deposition of gases and particles.

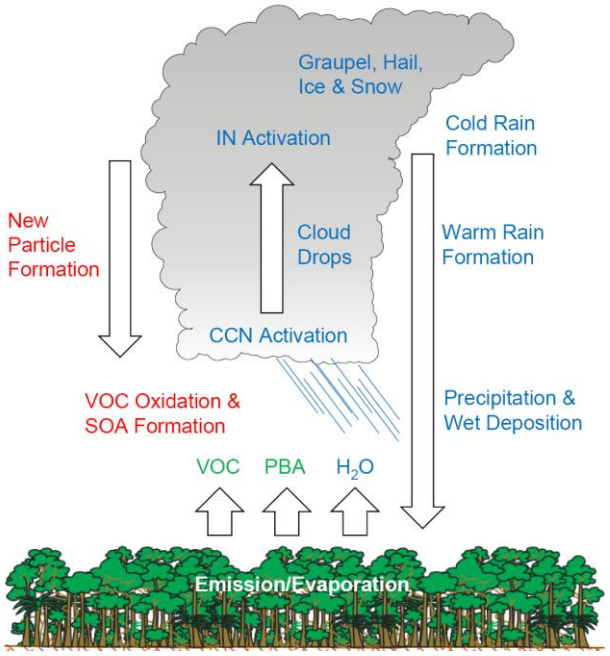

Figure 1. Aerosol and water cycle over pristine rainforest (Pöschl et al., 2010).

Clearly, bioaerosols are an important element of the Earth system. Their abundance and diversity, regional and temporal variability, and responses and feedbacks to climate change, however, are hardly quantified and not yet well understood.

The current state of knowledge of bioaerosol sources, interactions and effects will be outlined, recent advances will be presented and discussed, and major challenges and perspectives of future research will be explored.

The hygroscopicity of various pollen species of different phylogenies has been studied. Species investigated include the following genera: Artemisia, Betula, Cryptomeria, Iva, Juglans, Kochia, Narcissus, Salix, and Secale (Pope, 2010). The single pollen grains were investigated using both the electrodynamic balance (EDB) and environmental scanning electron microscope (ESEM) methodologies.

This is the first study to fully characterise the response of pollen mass, size and morphology to increases in environmental relative humidity. It was previously known that pollen grains swell internally at high humidity. The use of the EDB, in this study, quantified the mass growth of the pollen with respect to the environmental relative humidity. All investigated pollen grains exhibited remarkably similar hygroscopicities, with a mass increase of ~16% at 75% relative humidity when compared to dry conditions.

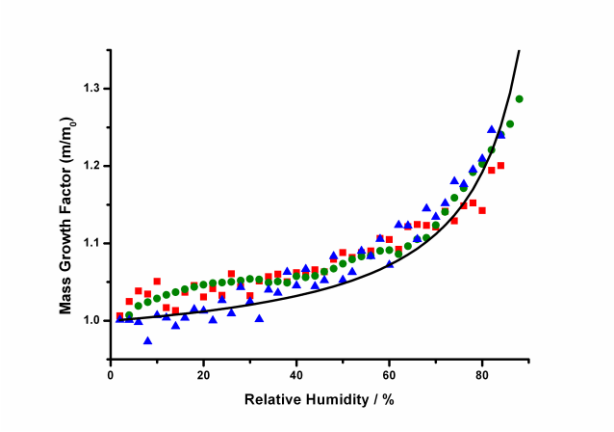

Figure 1. Humidograms of three pollen types measured in the EDB apparatus. Symbols: Red square – Narcissus, Green circle – Salix, Blue triangle – Betula. Line – modelled average humidogram of the three pollen species using κ-Köhler theory.

Studies using the ESEM indicate that the surface of the pollen grain is wettable, and so at least in part, some of the water uptake by the pollen grain is taken up externally. Low temperature studies in the ESEM investigated the ice nucleation ability of pollen via depositional freezing.

The hygroscopic response of the pollen to subsaturated relative humidities is parameterised using kappa-Köhler theory (Petters and Kreidenweis, 2007). It is found that whilst the pollen grains are only moderately hygroscopic, with kappa parameters = 0.05 – 0.1, their large size can allow activation at critical supersaturations of 0.001% and lower, and thus pollen will readily act as cloud condensation nuclei.

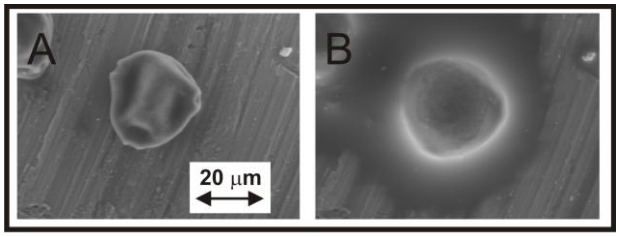

Figure 2. ESEM images of Betula occidentalis pollen at 68% (A) and 96% (B) relative humidity. Notice the internal swelling and external wetting of the particle in the high humidity environment.

The number density of pollen is too low to represent a significant global source of cloud condensation nuclei. However, the large sizes of pollen suggest that they will be an important source of giant cloud condensation nuclei (Johnson, 1982). By quantifying their size in a supersaturated environment, this study allows the effect of pollen, either as activated or as interstitial particles, on the autoconversion processes to be quantified. Current work is involved in incorporating the laboratory determined range of pollen critical supersaturations and hygroscopicities into a cloud resolving model. This will allow for the global and regional significance of this biospheric/atmospheric interaction to be assessed.

Development of a Lightweight, Simple and Efficient Exhaled Breath Condensate Collection Device and Method

Zhenqiang Xu and Maosheng Yao*

Principal Contact: Maosheng Yao, Professor, State Key Joint Laboratory for Environmental Simulation and Pollution Control, College of Environmental Sciences and Engineering, Peking University, Beijing 100871, China, Ph: +86 010 6276 7282, Email: yao@pku.edu.cn,

Abstract

Exhaled breath condensate (EBC) is increasingly being used as a non-invasive method for disease diagnosis in clinical settings. However, current available collectors often appear to be heavy, complex and to take longer time to get adequate amount of EBC. Here, a portable EBC collection device and method were developed and tested. The device consists four major parts: a trapezoidal cover with a round air inlet, a cuboid box, ultra-low temperature treated hydrophobic parafilm, and a layer of ice. During the EBC collection, the layer of ice was first placed onto the bottom of the cuboid box, followed by the hydrophobic parafilm, then tightly covered with the trapezoidal cover. In this study, seven volunteers were selected to exhale toward the device using a sterilized straw inserted into the air inlet of the trapezoidal cover for 5 min. The collected EBC appeared to be small water droplets formed on the surface of hydrophobic parafilm. When collecting the EBC, the trapezoidal cover was removed, and 10 μl of deionized water was pipetted onto the parafilm surface. Using a pipette tip, the deionized water drop was dragged over entire parafilm surface.

Due to the hydrophobic nature of the surface, the collected EBC on the surface was scavenged into the deionized water droplet, finally forming a droplet of 40-80 μl. The collected EBC was then analyzed using both culturing method and polymerase chain reaction (PCR) for culturable and total bacterial concentrations, respectively. Results indicated that the culturable bacterial concentrations ranged from 400 to 4000 CFU/ml with an average of 1452 CFU/ml of the EBC collected. Preliminary PCR tests showed that the EBC collected from some volunteers appeared to be bacteria positive with cycle threshold values of 20-26 with a bacterial DNA concentration of 0.5 to 1.5 ng/μl. While, for some volunteers the EBC was tested not positive, which was likely due to the inhibition problems. In this study, a simple and fast EBC collection device and method were developed and demonstrated. However, sample purification method needs to be developed for post-sample analysis using a variety of techniques for different bio-markers in diverse clinical settings. The developed EBC collection device and method would have great application potentials in early disease screening and diagnosis.

Allergens from Birch, Grass and Olive in ambient air deviate from pollen counts across Europe: the EU-HIALINE project

J.T.M. Buters[1] and the HIALINE working group[2]

Sofiev, Finland, S. Jäger and U. Berger, Austria, I. Sauliene, Lithuania, R. Albertini and L. Cecchi, Italy

Keywords: biogenic particles, health effects of aerosols, outdoor aerosols, PM10, PM2.5, allergens.

Background The developed world is confronted with an epidemic of allergic diseases. Allergic disease is now affecting 20% of the European population, up from 3% in the 1950`s. Exposure to allergens is one of several factors determining allergic disease and symptoms in individuals. The major aeroallergens in Europe originate from house dust mite, grass, cat, birch and olive (in this sequence). Of these, all outdoor allergens stem from pollen. Exposure to aeroallergens from pollen is assessed by counting pollen in ambient air. However, several publications show that pollen count is not representative for allergen exposure[1], and allergen from pollen could be influenced by climate change independently from pollen numbers. We therefore monitored simultaneously pollen count and the major allergens from pollen in different size fractions of ambient air in 10 countries in the EU-HIALINE (Health Impacts of Airborne Allergen Information Network).

Methods Ambient air was sampled at 800l/min with a Chemvol high-volume cascade impactor equipped with stages PM>10µm, 10 µm>PM>2.5µm, and in Munich also 2.5 µm>PM>0.12µm. The polyurethane impacting substrate was extracted with 0.1M NH_4HCO_3, pH8.1. The major pollen allergens from birch Bet v 1, grass Phl p 5 and olive Ole e 1 were determined with allergen specific ELISA´s. Pollen counts were assessed with Burkard pollen traps.

Results We measured that we collected >99% of the airborne allergen in PM larger than 2.5µm. Our quality control showed that using antibodies as a detection method (ELISA) a 20-25% interassay-variation across Europe was observed. Pollen from birch correlated acceptable with allergen release for birch pollen (r^2 about 0.7). In contrast, pollen from grass released >100-200% more Phl p 5 in France and the UK than in other countries in Europe. In detail we could show that allergen release form all pollen depended strongly on the day, with days with very potent pollen being flanked by days with a weak allergen release. For olive, large amounts of allergen we detected at the end of the season when few pollen were airborne.

The effect of climate on allergen release is currently being evaluated by a computer simulation program SILAM of the Finnish Meteorological Institute. Aim is to determine which climatic factor influences allergen release.

Conclusions Aeroallergens were only found in PM>2.5µm, the fraction containing pollen. Pollen from different years, different trees, even different days and different countries could release up to 10-fold different amounts of allergen from the same amount of pollen. Thus exposure to allergen is poorly monitored by only monitoring pollen count. We think that monitoring the allergens itself in ambient air might be an improvement in allergen exposure assessment. In addition, airborne allergens could be a better indicator of climate change than pollen flight.

The research leading to these results has received funding from the EU public health project from the Executive Agency for Health and Consumers under grant agreement No 2008 11 07 and funding from Christine Kühne - Center of Allergy Research and Education-Munich (CK-CARE A).

Abstract

Exhaled breath condensate (EBC) is increasingly being used as a non-invasive method for disease diagnosis in clinical settings. However, current available collectors often appear to be heavy, complex and to take longer time to get adequate amount of EBC. Here, a portable EBC collection device and method were developed and tested. The device consists four major parts: a trapezoidal cover with a round air inlet, a cuboid box, ultra-low temperature treated hydrophobic parafilm, and a layer of ice. During the EBC collection, the layer of ice was first placed onto the bottom of the cuboid box, followed by the hydrophobic parafilm, then tightly covered with the trapezoidal cover. In this study, seven volunteers were selected to exhale toward the device using a sterilized straw inserted into the air inlet of the trapezoidal cover for 5 min. The collected EBC appeared to be small water droplets formed on the surface of hydrophobic parafilm. When collecting the EBC, the trapezoidal cover was removed, and 10 μl of deionized water was pipetted onto the parafilm surface. Using a pipette tip, the deionized water drop was dragged over entire parafilm surface.

Due to the hydrophobic nature of the surface, the collected EBC on the surface was scavenged into the deionized water droplet, finally forming a droplet of 40-80 μl. The collected EBC was then analyzed using both culturing method and polymerase chain reaction (PCR) for culturable and total bacterial concentrations, respectively. Results indicated that the culturable bacterial concentrations ranged from 400 to 4000 CFU/ml with an average of 1452 CFU/ml of the EBC collected. Preliminary PCR tests showed that the EBC collected from some volunteers appeared to be bacteria positive with cycle threshold values of 20-26 with a bacterial DNA concentration of 0.5 to 1.5 ng/μl. While, for some volunteers the EBC was tested not positive, which was likely due to the inhibition problems. In this study, a simple and fast EBC collection device and method were developed and demonstrated. However, sample purification method needs to be developed for post-sample analysis using a variety of techniques for different bio-markers in diverse clinical settings. The developed EBC collection device and method would have great application potentials in early disease screening and diagnosis.

Several proposed mechanisms link solar variability with changes in the climate through effects of cosmic rays on weather, aerosols and clouds (Carslaw *et al.*, 2002). However, the details, as well as the significance, of those mechanisms remain unclear.

The CLOUD (Cosmics Leaving OUtdoor Droplets) experiment aims at understanding the possible influence of cosmic rays on aerosol particles and clouds. It provides exceptionally clean and well-defined experimental conditions in an aerosol chamber of 26.1 m^3, together with the possibility of simulating cosmic rays "on demand" by making use of the CERN Proton Synchrotron's particle beam.

It has been well established that nucleation from gaseous precursors form an important source of particles in the atmosphere, and that sulfuric acid (H_2SO_4) plays a crucial role in atmospheric nucleation (e.g. Kulmala *et al.*, 2004, and Riipinen *et al.*, 2007). Hence, the focus was on the investigation of sulfuric acid nucleation under different conditions (e.g. varying beam intensity, concentrations of ammonia (NH_3), relative humidity, etc.).

The APi-TOF (Atmospheric Pressure interface Time-Of-Flight Mass Spectrometer) is a high-resolution mass spectrometer produced by Tofwerk AG, and Aerodyne Research, Inc. It is described in detail by Junninen *et al.* (2010). Sampling occurs from atmospheric pressure through a critical orifice. While passing through differentially pumped chambers, the sampled ions are focused and guided to the mass spectrometer. Note that no ionization of the sampled aerosol was performed, and only naturally charged ions are detected by this setup.

In the course of the experiments, sulfuric acid nucleation events were produced in the chamber. Depending on conditions, nucleation occurred either mainly by negative ions, or mainly by ions of both polarities. During those nucleation events, the ion species registered by the APi-TOF were almost exclusively sulfur-containing compounds or molecular clusters in both polarities. Their composition could be determined based on their exact masses and isotopic patterns, facilitated by the cleanliness of the chamber. Growing clusters of negative and positive polarity could be observed at a time resolution of less than 1 minute, starting at the single ion, up to 3300 Da (corresponding to mobility equivalent diameters of around 2 nm). The identified cluster ions were found to always contain H_2SO_4. Depending on the exact experimental conditions, they also contained NH_3, organic compounds (mainly amines), or both. A part of a typical spectrum during one experiment is shown in Figure 1. The appearance of the larger clusters coincides with the onset of particle formation as detected by other instruments. Clear correlations can be found between features of the steady-state cluster distributions and experimental variables, giving detailed insights into the early steps of new (charged) particle formation driven by sulfuric acid.

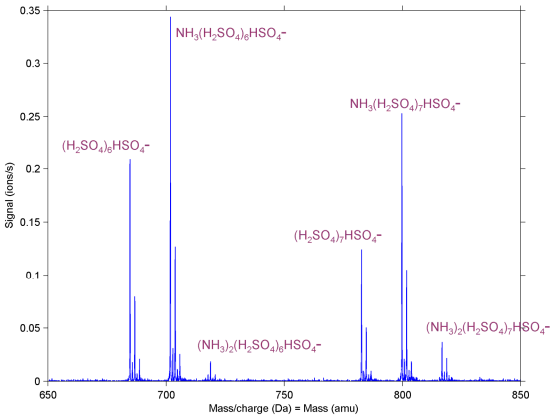

Figure 1. Part of a typical negative ion spectrum, and interpretations for the largest signals in this section.

Early stage particle growth rates during the CLOUD experiment

Riccobono, Francesco[1], Weingartner, Ernest[1], Baltensperger, Urs[1], and the CLOUD collaboration

[1]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland

Keywords: ion-induced nucleation, growth, CLOUD

Formation of atmospheric aerosol has been observed in a wide range of atmospheric conditions in many different locations and altitudes all over the globe (Kulmala *et al.*, 2004). Nucleation and subsequent condensational growth increase the total number of particles and modify the aerosol size distribution in the atmosphere, affecting the global radiation balance through both direct and indirect effects. Among the various nucleation mechanisms that occur in the atmosphere the ion induced nucleation mechanism is still poorly understood. One of the goals of the CLOUD experiments at CERN is to investigate to what extent the presence of ions in the atmosphere affects the formation of new particles (Kirkby, 2007).

Almost 200 experiments have been performed in the CLOUD aerosol chamber at CERN during the fall 2010 campaign. The CERN Proton Synchrotron provided an adjustable and precisely measurable beam of artificial cosmic rays, spanning the atmospheric ionization range from the upper troposphere to ground level (Kirkby *et al.*, 2011, submitted). Several particle formation events were observed following both neutral and charged pathways with a wide range of nucleation rates and growth rates at sulfuric acid concentrations comprised between 10^6 and 10^9 molecules per cm^3.

The early growth rates of the freshly nucleated particles determine which fraction of these particles can grow to CCN sizes and which fraction is lost by coagulation with larger pre-existing aerosol. In order to study the growth rate in different size ranges as function of the gas and ion concentrations we optimized different instruments. The Scanning Mobility Particle Sizer (SMPS) provides an accurate mean diameter measurement down to ~7 nm, but for particles smaller than this size the SMPS suffers from a poor size resolution due to the extremely low charging probability and to the high particle diffusion losses in the charger and in the DMA column. To retrieve the size information in the 2-10 nm size range we developed the Laminar Diffusion Tube (LDT). This instrument uses the 1.2 meter long sampling line of the CLOUD chamber as a diffusion tube, in which the particles are lost to the walls by diffusion as a function of the sample flowrate and of the particle diameter. Downstream of the LDT the particle concentration is determined with a Condensation Particle Counter (CPC, TSI 3786). By varying the flow rate through the sampling line (by changing the make-up air) the losses are controlled according to laminar diffusion theory.

In a next step, the mean diameter of the particle size distribution of particles with ~2 < *D* < ~10 nm is retrieved by a comparison of the diffusion losses at different make-up flow rates. This calculation does not require any assumption on the shape of the particle size distribution. Another advantage is that it does not depend on the specific detection efficiency curve of the CPC, it only assumes that the diffusion losses in the LDT do not depend on the particle composition.

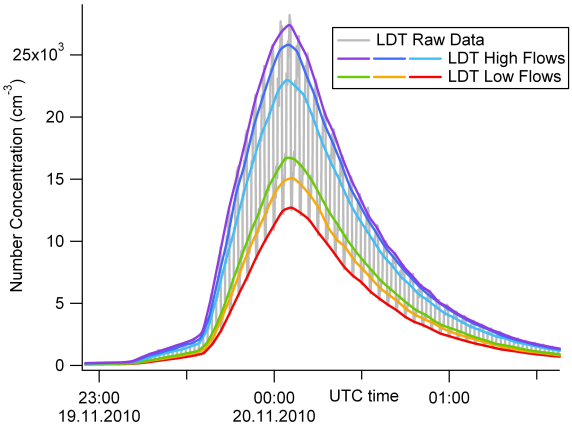

Figure 1. Laminar Diffusion Tube output during CLOUD run 318. The color curves correspond to different make-up flow rates and thereby different effective detection thresholds.

Growth rates enhancement factors obtained with the Laminar Diffusion Tube will be presented for various sets of gases (H2SO4, NH3) and ion concentrations.

A potential connection between cosmic ray intensity, low cloud cover and climate has been postulated (Marsh and Svensmark, 2000; Carslaw *et al*, 2002; Kirkby, 2007). Ion-induced nucleation could be the mechanism to explain such a connection due to the increased ion-production by galactic cosmic rays. Therefore a better understanding of nucleation mechanisms in general and ion induced nucleation as special case is of crucial importance.

To improve the scientific knowledge about ion-induced nucleation, the CLOUD-project (Cosmics Leaving OUtdoor Droplets) was established at CERN (European Organization for Nuclear Research). The experimental setup consists of an aerosol chamber into which a beam of particles is sent from a Proton Synchrotron to investigate the effects of ions on the aerosol production under controlled laboratory conditions. The chamber itself provides a nearly perfectly clean environment. Concentrations of possible third nucleation agents are almost negligible or are controlled in order to study these.

We modelled the binary sulphuric acid/water nucleation processes in the CLOUD-chamber based on earlier work (Lovejoy *et al*, 2004; Kazil, J., and Lovejoy, E. R., 2007). The models are based on uptake and loss of single sulphuric acid molecules and therefore span a range from a single molecule to particles with a few nanometer size. The special conditions of a chamber experiment makes certain adjustments to the model necessary for instance the main source of losses is the chamber wall. We present results for both steady state conditions and time evolution of nucleation processes. For the time evolution of nucleation we integrate the rate laws numerically using a similar approach to that of Lovejoy *et al*. The steady state solution is calculated with a direct iteration method, which is designed to be suitable to be extended to ternary systems.

The rate constants for charged nucleation are based on laboratory measurements, ab initio results and a smooth parameterisation to bulk phase properties as the particle size increases (Lovejoy te al, 2004). Neutral rate constants are currently based on the liquid drop model with corrections terms. These terms can be optimized with pure binary nucleation experiments. With appropriate parameterisation of neutral nucleation rates we expect to extend the current understanding of transitions from gas to condensed matter.

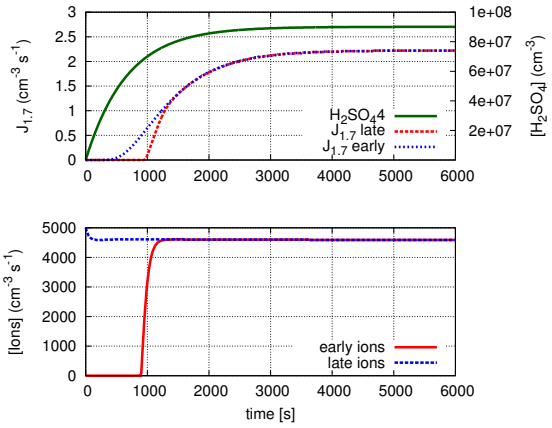

Figure 1: An example model result showing $J_{1.7nm}$ vs time (upper plot) with different starting concentrations of ions (lower plot). The sulphuric acid is shown as function of time (upper plot).

Numerical simulation of H2SO4 cycle and new particle formation in the Cern CLOUD chamber

J. Voigtländer[1], F. Stratmann[1], and the CLOUD collaboration

[1]Leibniz Institute for Tropospheric Research, Leipzig, Germany
Keywords: CLOUD-ITN, cloud chamber, modelling, mixing state, sulphuric acid, particle formation
Presenting author email: jensv@tropos.de

To study the effect of galactic cosmic rays on aerosols and clouds, the Cosmic Leaving OUtdoor Droplets (CLOUD) project was established. Within this project, experiments are carried out at a large volume cloud chamber (26m^2), located at Cern (Switzerland). In the chamber, aerosol particles, cloud droplets and ice crystals can be exposed to simulated atmospheric conditions and a particle beam provided by the Cern particle accelerator.

A big issue in large volume chambers like the CLOUD chamber at Cern is to achieve spatial homogeneity of thermodynamic conditions, gas composition and particle properties. Homogeneity in the tank becomes more complicated, if several parameters are changed during the experiments (e.g., UV-illumination system, particle nucleation, trace gas input, wall cooling). To achieve homogeneity, mixing fans are usually applied in such experiments. To check the mixing state, measurements are made at several selected points. However, it is not possible to check all relevant parameters continuously. Therefore, numerical simulations are carried out to evaluate the experimental configuration. For this study, the model was the commercially available fluid dynamics (CFD) model FLUENT (Ansys Inc., Canonsburg, PA, USA), fully coupled with the particle model FPM (Fine Particle Model, Particle Dynamics GmbH, Leipzig, Germany). The model provides the spatial and temporal distributions of all fluid (e.g., velocity, temperature) and particle dynamical (e.g., number, size, composition) properties resulting from the coupled processes of mass and heat transfer, flow and phase transition.

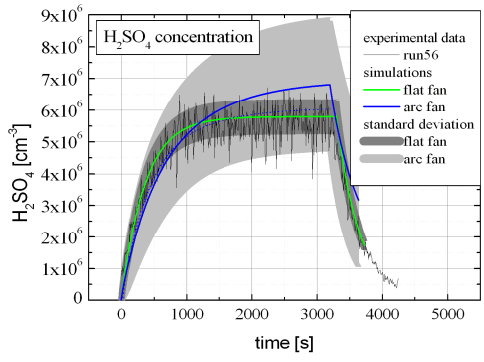

Figure 1: Simulated temporal evolution of the H_2SO_4 concentration in the CLOUD chamber compared to H_2SO_4 lifetime experiments. Simulations shown here were carried out for different fan shapes, but for equal H_2SO_4 production rates (4e5 cm^{-3}s^{-1}).

Due to the cylindrical shape of the CLOUD chamber, simulations were done on a 2-D grid. The mixing fans were described by zero thickness pressure jump layers. The actual parameters used to parameterize the mixing fans were derived by a comparison of calculated with measured H_2SO_4 concentrations of so-called H_2SO_4 lifetime experiments. In these experiments the temporal evolution of the H_2SO_4 concentration in the chamber, influenced by photolytic formation and wall loss of H2SO4, was investigated. A measured internal velocity profile was additionally included into the fitting procedure. Based on these results, the model was also applied to investigate 1/e mixing times of the tank to an instantaneous change of wall temperature and water mass fraction, and to study particle nucleation and growth.

Simulation results show that the mixing state of the tank's contents largely depends on the characteristics of the mixing fans. Simulations with a fan adjusted only to measured H_2SO_4 concentrations suggest that the tank's contents can be considered as homogeneously mixed (small standard deviations, Fig.1). In contrast, simulation results with boundary conditions giving results fitting both, a) temporal evolution of the H_2SO_4 concentration and b) measured internal velocity profile, indicate that a 1-fan configuration, as used in first experiments, is not sufficient to provide a homogeneously mixed chamber (large standard deviation, Fig.1). In particular, the mixing fan of such a configuration is only able to mix one half of the tank.

The 1/e response times for instantaneous changes of wall temperature and saturation ratio inside the chamber were found to be in the order of few minutes. A second fan reduces the time, dependent on fan shape, by a factor up to about 3. Particle number size distribution properties of the fresh nucleated particles (particle number, size, standard deviation of the assumed log-normal distribution) were found to be mixed over the tank's volume very similar to the gas species.

The investigations contribute to evaluate the experimental configuration of a tank like the CLOUD chamber and show that only 2 mixing fans, as already installed for actual and future experiments, can guarantee well mixed conditions inside the tank.

Sulphuric acid measurements by CIMS at the CLOUD chamber and cross-check with independent methods to derive [H_2SO_4]

Rondo, Linda[1] , Kürten, Andreas[1], Ehrhart, Sebastian[1], Curtius, Joachim[1] and the CLOUD collaboration
[1]Institute for Atmospheric and Environmental Sciences, University of Frankfurt am Main, Altenhöferallee 1, 60438, Frankfurt am Main, Germany
Keywords: CIMS, sulphuric acid, H_2SO_4 calibration system, CLOUD Experiment

Laboratory studies indicate that sulphuric acid vapor is the most important precursor gas responsible for the nucleation of aerosol particles (Kuang et al., 2008). However, huge discrepancies still exist between different studies trying to determine at what sulphuric acid concentrations the onset of atmospherically relevant nucleation rates occurs.

The CLOUD (Cosmics Leaving Outdoor Droplets) experiment (Duplissy et al., 2009) at the CERN Proton Synchrotron aims to resolve this discrepancy. Additionally, it is designed to investigate the possible link between galactic cosmic rays and aerosol formation.

An instrument based on CIMS (Chemical Ionization Mass Spectrometry) is used for the measurement of gaseous sulphuric acid produced in the CLOUD chamber. The principle of this measurement is based on the reaction between H_2SO_4 and NO_3^- primary ions and the subsequent detection of HSO_4^- ions by a mass spectrometer (Tanner and Eisele, 1993). Mainly due to uncertainties in the reaction rate coefficient and the reaction time in the ion drift region, it is necessary to calibrate the H_2SO_4-CIMS. This is crucial in order to provide the most accurate numbers for the sulfuric acid concentration and to reliably interpret the CLOUD data. Here we present different methods allowing to cross-check the measured concentrations which are based on the calibrated H_2SO_4-CIMS.

The calibration method is based on the production of H_2SO_4 through the reaction of known concentrations of OH and SO_2. OH is formed by the photo-dissociation of water vapor inside a quartz tube, which is illuminated by bandpass-filtered 185 nm light from a mercury lamp (Edwards, 2003). Independently to the calibration, the validity of the measured H_2SO_4 concentrations at CLOUD was cross-checked with two other methods. The first method is based on the measured depletion of SO_2 during the experimental runs when the UV light in the chamber was turned on and the photo chemistry lead to the conversion of SO_2 to H_2SO_4. The concentration of H_2SO_4 is related to the consumption rate of the SO_2 according to the following relation (when a steady-state between the production and the wall loss of H_2SO_4 is reached) : $[H_2SO_4] = d[SO_2] / (dt \cdot k_{wall\ loss})$.
This method, however, allows only a crude estimation of the H_2SO_4 concentrations due to the relatively small changes in $[SO_2]$.

The second method is based on the measurement of the aerosol growth rates which can be used to estimate the H_2SO_4 concentration. The dependence of the particle growth rate on vapour concentrations and its molecular composition is known from theory (Nieminen et al., 2010). Following this theory, the condensational growth rates of aerosol particles smaller than 10 nm are used to determine the concentrations of sulphuric acid.

Such analyses provide very useful indirect information on the concentration of sulphuric acid even in the absence of a direct measurement. It is also an excellent method to cross-check the validity of the measured values with a calibrated H_2SO_4-CIMS. For the experiments during 2009 and 2010, the data evaluation studies showed good agreement between the measured values and the values derived from the independent methods described above (see Fig. 1).

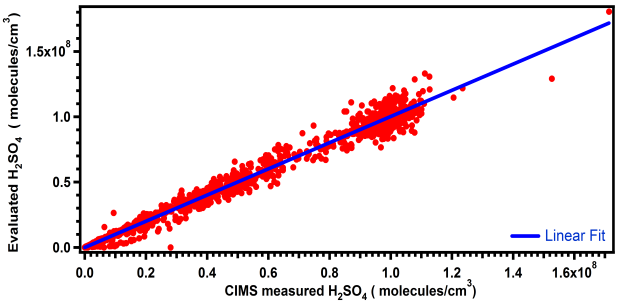

Figure 1. Example of the correlation between the evaluated [H_2SO_4] from the growth rate and the [H_2SO_4] measured by CIMS.

Presenting author email: alessandro.franchin@helsinki.fi

Nanoparticle formation in the boundary layer is a frequent phenomenon (Kulmala *et al.*, 2004). Sulfuric acid has been identified as a plausible candidate to participate in the nucleation (Weber et al. 1996). Ion-induced nucleation is one of the possible pathways for new particle formation in the atmosphere, but it is still unclear how important the contribution of ions is with respect to neutral pathways. Ion concentration and their size distribution are key quantities to understand ion-induced nucleation processes and dynamics.

During the CLOUD (Cosmics Leaving OUtdoor Droplets) 2010 fall campaign, several experiments of sulfuric acid-water neutral and ion-induced nucleation were performed in an aerosol chamber. In this experiment, Galactic Cosmic Rays (GCR) and the Proton Syncrotron (PS) accelerator at CERN were used as sources to generate ions in the 26.1 m^3 CLOUD aerosol chamber under precisely controlled conditions. Both GCR and the PS pion beam were constantly monitored by a GCR counter and by a hodoscope, respectively.

The ion concentration in the CLOUD chamber was measured with a Neutral cluster and Air Ion Spectrometer, (NAIS, Kulmala *et al.*, 2007). The NAIS is able to measure air ion number size distributions in the mobility equivalent diameter range of 0.8 to 40 nm and correspondingly neutral particle number size distributions from ~2 to 40 nm mobility diameter.

It was also possible to use a PSM (Particle Size Magnifier; Vanhanen e*t al. 2011*), a scanning CPC with a cut off varying from 1 to 2 nm, to retrieve the size distribution of the atmospheric ions created in the chamber and compare it to the NAIS in absence of neutral particles in the chamber (Figure 1).

Based on the measured GCR and beam intensities we were able to calculate the expected ion concentrations in the chamber as a function of beam intensity. The calculated ion concentrations were then compared with the measured values in the NAIS, therefore we retrieved the ion-ion recombination coefficient, performing a dedicated set of experiments at different conditions: in sulfuric acid free ($[H_2SO_4]$<5e5 cm^{-3}) and in sulfuric acid rich environment ($[H_2SO_4]$~3e6 cm^{-3}).

The ratio of formation rates of charged and total particles give information about the contribution of ion-induced nucleation. Charged nucleation rates were retrieved from the NAIS ion mode and from two CPCs one of which was equipped with a switchable ion trap both results will be compared.

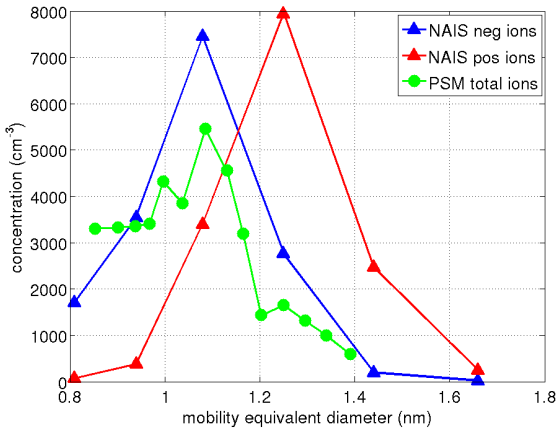

Figure 1. Comparison of number size distribution of ions from NAIS (blue for negative ions red for positive) and from PSM (green).

We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. This research has received funding from the EC's Seventh Framework Programme under grant agreement number 215072 (Marie Curie Initial Training Network "CLOUD-ITN"), from the German Federal Ministry of Education and Research (project number 01LK0902A), from the Swiss National Science Foundation and from the Academy of Finland Centre of Excellence program (project number 1118615).

Vegetation is the major source of biogenic volatile organic compounds (BVOC) in the troposphere. These BVOC impact atmospheric oxidation capacity and serve as precursors for secondary organic aerosols (SOA). In regions with low pre-existing particulate matter, BVOC oxidation by OH, ozone, and NO_3 can produce low volatile products which are involved in SOA formation.

Isoprene and monoterpene emissions from vegetation are well known. However, during and after stress situations plants emit many other BVOC. Sesquiterpenes (SQT) such as α- and β-farnesene, C_6-aldehydes and -alcohols produced within the octa-decanoid pathway (green leaf volatiles, GLV), or many different aromatic compounds originating from the phenylpropanoid pathway are typical BVOC emitted during biotic and abiotic stress.

In this study we measured the formation of secondary organic aerosols (SOA) from stress-induced BVOC emissions emitted from grey poplar seedlings (*Populus x canescens*). The experiments were conducted in the Jülich Plant Atmosphere Chamber (JPAC, Mentel *et al*., 2009). This system consists of two temperature controlled chambers, one housing the plants (plant chamber) and the second one was used for photochemical SOA production (reaction chamber). BVOC emitted from the poplar plants in the plant chamber were transferred into the reaction chamber where they were oxidized by ozone and by OH radicals. OH was produced by photolysis of ozone in presence of H_2O. OH concentrations were typically in the range of 3-8×10^7 cm^{-3}. Ambient conditions such as temperature, relative humidity, photosynthetic active radiation (PAR), CO_2, O_3, and NO_x levels were controlled.

We used 4-month-old wild type (WT) poplar plants that emit high amounts of isoprene and transgenic poplar lines down-regulated in isoprene emission (R-lines, Behnke *et al.*, 2007). Comparing particle formation from BVOC emitted from these plants enabled the characterization of the impact of isoprene on the SOA formation from plant emissions. Unstressed poplar plants emitted nearly exclusively isoprene whereby the emissions from the down regulated R-lines were more than an order of magnitude lower than those from the wild type. Using unstressed plants as BVOC sources for particle formation we found inefficient SOA formation with nucleation rates far below 1 cm^{-3} s^{-1}.

All lines showed strong additional emissions of sesquiterpenes and aromatic compounds after stressing the plants by short ozone pulses. Their emission rates and therefore the BVOC emission pattern changed on a time scale of several days after stress application, allowing to study SOA formation under nearly steady state conditions. Feeding BVOC mixes into the reaction chamber resulted in very strong SOA formation events with nucleation rates exceeding 3000 cm^{-3} s^{-1}. Normalized to the BVOC turnover the nucleation rates were generally lower for the isoprene emitting WT poplars compared to non-emitting mutants. This observation confirmed former findings of suppression of nucleation by isoprene (Kindler-Scharr *et al*., 2009).

Rapid variations of PAR in the plant chamber resulted in fast changes of isoprene emissions whereas the emissions of the other BVOC responded on a much longer time scale. Hence, switching off the lamps in the plant chamber allowed removing isoprene very fast while keeping the level of other BVOC concentrations high. Conducting this procedure during a particle formation event caused a fast decrease of isoprene concentration and a strong increase of OH concentrations in the reaction chamber followed by increases in particle number and mass. This also shows that suppression of OH concentrations by isoprene is the major reason for suppression of nucleation from non-isoprene BVOC.

Using a low isoprene emitting poplar plant as BVOC source and adding deuterated isoprene from a diffusion source we estimated isoprenes' contribution to the SOA mass formed from the BVOC emitted from poplar. While isoprene contributed to about 7% [C/C] to the BVOC in the gas phase the contribution to the particulate phase was only 1 %. Thus isoprene oxidation products partitioning into the SOA can not compete with that of oxidation products from the other BVOCs. However the SOA mass produced by isoprene oxidation products does not compensate the decrease of other BVOC particle precursors caused by the decrease of OH concentrations in the presence of isoprene.

Session 2C: Instrumentation for Chemical Characterisation of Aerosol

Development of a novel aerosol mass spectrometer for nucleation mode particles

S. G. Gonser[1] and A. Held[1]

[1]Bayreuth Centre of Ecology and Environmental Research (BayCEER), University of Bayreuth, 95448 Bayreuth, Germany

Keywords: Aerosol mass spectrometry, Nucleation mode, Secondary aerosol, Chemical composition.

Presenting author email: stefan.gonser@uni-bayreuth.de

Formation mechanisms and chemistry of secondary aerosol in the atmosphere are not fully understood today. This is due to the small number of instruments being able to analyze freshly nucleated particles with diameters smaller than 30 nm. In order to improve the fundamental understanding of the atmospheric aerosol, its formation mechanisms and chemistry we are developing a field portable aerosol mass spectrometer for particles smaller than 30 nm in diameter – CAChUP (Chemical Analyzer for Charged Ultrafine Particles).

CAChUP consists of an aerosol sizing and collection unit (similar to Voisin *et al* (2003)) coupled to a time of flight mass spectrometer (ToF-MS). The aerosol sizing and collection unit is composed of three major parts: (1) a unipolar corona discharge aerosol charger, (2) a radial differential mobility analyzer (rDMA) for the size separation of the particles, and (3) the actual collection unit. In the collection unit, the charged and sized aerosol particles are deposited on a filament. Once enough particles have been collected, the filament is heated gradually in order to evaporate the sample. The resulting gas phase is subsequently analyzed for its molecular composition in the ToF-MS.

A crucial part of CAChUP is the unipolar aerosol charger, since its charging efficiency determines the number of particles collected and eventually analyzed by the ToF-MS. For practical reasons regarding its transportability the charger design is based on corona discharge instead of using a radioactive source. The corona discharge is generated on bundles of carbon fibres, enabling the charger to be operated with voltages below 3 kV. These relatively low voltages minimize the production of ozone (Han *et al*, 2008), and consequently, the oxidation of the particles.

For the size separation of the particles, an rDMA was constructed (adapted from Zhang *et al* (1995)). The compact radial design allows to separate particles with diameters far below 10 nm, though our design limits the upper threshold to about 100 nm (Fig. 1). During preliminary tests our rDMA was able to separate nearly monodisperse aerosol distributions (geometric standard deviations of about 1.09) from broad distributions produced in a smog chamber.

To evaluate the performance of the collection unit in combination with the ToF-MS, molecular analysis of artificially produced secondary organic aerosol (SOA, with limonene as precursor) will be presented. After successful laboratory tests CAChUP will be ready for field experiments.

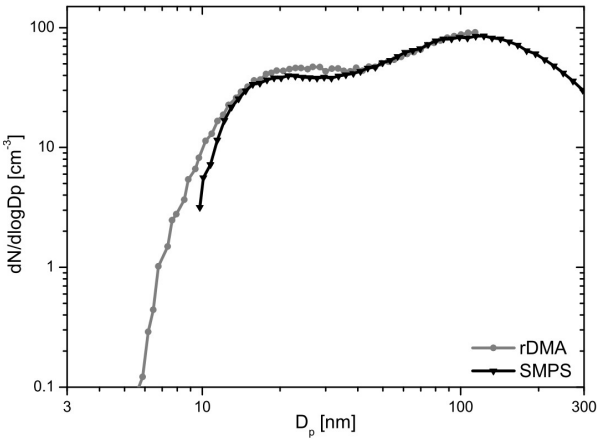

Figure 1. Preliminary intercomparison between our rDMA and a scanning mobility particle sizer (SMPS) at ambient air.

Presenting author email: Alexander.Laskin@pnl.gov

Understanding the molecular composition and fundamental chemical transformations of organic constituents of atmospheric aerosols during their formation and aging is both a major challenge and the area of great uncertainty in atmospheric and environmental research. Particularly, little is known about fundamental relationship between the chemical composition and physicochemical properties of organic aerosol (OA), their atmospheric history, evolution, and the impact on the environment.

Analysis of OA samples using soft-ionization methods combined with high-resolution mass spectrometry (HR-MS) analysis provide detailed information on the molecular content of OA that is pivotal for improving the understanding of their complex composition, multi-phase aging chemistry, direct (light absorption and scattering) and indirect (aerosol-cloud interactions) effects on atmospheric radiation and climate, health effects. The HR-MS methods can detect thousands of individual OA constituents at once, provide their elemental formulae from accurate mass measurements and structural information based on tandem mass spectrometry. Integration with additional analytical tools, such as chromatography and UV/Vis absorption spectroscopy, makes it possible to further separate OA compounds by their polarity and ability to absorb solar radiation.

This presentation will feature a summary of recent research projects focused on the detailed chemical characterization of OA, conducted in the groups of the co-authors. We will describe contemporary HR-MS methods (*Laskin, J. et al*, 2010; *Roach et al*, 2010), review recent applications in field and laboratory studies of OA (*Nizkorodov, Laskin, J., Laskin, A.*, 2011), and explain how the information obtained from HR-MS methods can be translated into an improved understanding of OA chemistry

Adverse health effects associated with aerosol particles in ambient air are well documented by epidemiological studies (e.g., increase in respiratory and cardiovascular diseases) and are supported by biological mechanistic animal and cell culture studies. On a cellular level, inflammation and oxidative stress reactions have been observed in cell culture experiments after exposure of aerosol particles to lung cells. However, due to the large variability in ambient particulate matter it is still unknown what physical or chemical properties are responsible for these negative health effects. Previous studies have highlighted reactive oxygen species (ROS) in components of organic particulate matter, as being potentially a major cause.

Most previous aerosol ROS studies have used off-line techniques to determine the concentration of these compounds, i.e., particles were collected on filters, extracted into a solvent and then analyzed for their ROS content. ROS are known to have often very short life times and time delay between particle sampling and ROS quantification using such offline techniques could allow for loss of reactive species, leading to a significant underestimation of ROS. Online ROS analysis has been developed to reduce this and also allows for more detailed time resolved analysis (Venkatachari *et al*, 2008).

An online measurement system was developed in the study presented here that collects water-soluble aerosol components and determined the ROS concentration by reaction with the fluorescent probe 2-7 dichlorofluorescein (DCFH). Particles were collected and continuously extracted on a wetted hydrophilic filter (Takeuchi *et al*, 2005). The particle collector samples air at up to 5 litres per minute (lpm) and collects particles larger than an aerodynamic diameter of 50 nm with greater than 95% efficiency. The particles are collected and extracted in a solution of horseradish peroxidase (HRP) (0.5 units per ml) that allows immediate reaction of ROS on collection. The concentration of ROS is characterised following subsequent reaction of the oxidised HRP with DCFH (5 µM) for 10 minutes at 37^{o}C, yielding the fluorescent product DCF in the continuous flow set-up. The concentration of DCF is measured using fluorescence spectroscopy in a flow-through cell and calibrated to ROS concentration with hydrogen peroxide. With a sampling rate of 5 lpm the detection limit of the system is approximately 10 nMoles of hydrogen peroxides per cubic meter of air.

This system was used to measure particle bound ROS concentrations during the ageing of primary moped combustion emissions in the presence of UV light and NOx in smog chamber experiments carried out at the Paul Scherrer Institut, Switzerland. During collection a charcoal denuder was used to remove oxidising gaseous species and the sensitivity aerosol free baseline was measured using an inline HEPA filter.

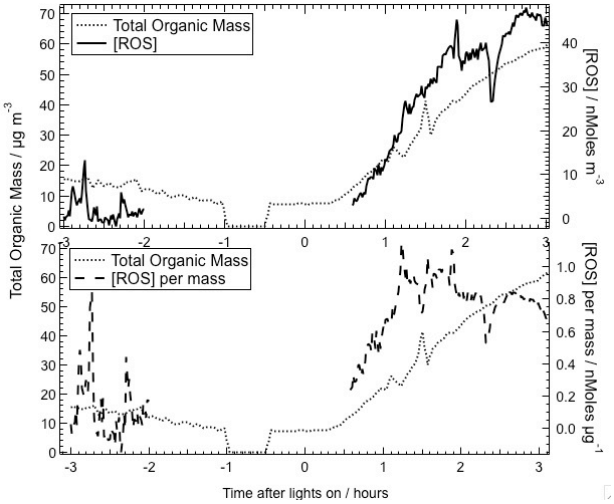

Figure 1 shows increasing ROS concentrations with increasing mass concentrations of SOA.

Primary moped emissions showed very low ROS concentrations per µg of aerosol. When the UV lights were turned on, at time zero in figure 1, the ROS concentrations increased with the concentration of SOA. ROS concentrations of up to 1 nMoles per µg of SOA were measured during the experiment. Un-aged primary emissions with mass concentrations of up to 200 µg/m^3 showed undetectable levels of ROS that were independent of mass concentration. This demonstrated that the reactivity seen during the ageing experiments was purely due to SOA.

Microchip Electrophoresis Interfaced to a Cloud Condensation Nuclei Collector for Online Monitoring of CCN Chemistry

Cloud condensation nuclei (CCN) are atmospheric aerosols that play critical roles in climate, specifically from their effects on the radiative budget and the hydrological cycle. Aerosols act as CCN when atmospheric water vapor spontaneously condenses on them, rapidly increasing their size. Each particle requires a specific water vapor supersaturation to activate, termed the critical supersaturation. Not all aerosols are CCN active, and the critical supersaturation depends on the size, morphology, and chemistry of the aerosol. Currently, direct measurement of CCN chemistry and its effect on CCN spectra has not been well characterized. This shortcoming is, in part, due to the difficulty in collecting a well-defined population of CCN with sufficient mass for conventional chemical analysis. Thus, improved methods for chemical analysis of aerosol are needed to understand the impact of chemistry and their origins on CCN activity.

Microchip electrophoresis (MCE) offers a promising new method for online monitoring of the chemical composition of CCN particles and possesses advantages over conventional monitoring equipment, including smaller instrumentation, shorter analysis times, increased portability, lower energy consumption, and the ability to make measurements from small liquid volumes. These attributes make MCE an attractive option for monitoring the chemistry of aerosol particles. MCE is particularly enticing for monitoring the chemistry of particles activated by CCN collectors because flow rates are very low (less than 1 L min^{-1}), resulting in the deposition of very low aerosol masses that cannot be adequately measured by ion chromatography (IC). Here, we present the coupling of MCE to a miniature CCN collector (Roberts and Nenes, 2005) for online monitoring of CCN chemistry at a single supersaturation. The outlet stream of the CCN system inertially impacts wetted CCN particles into a buffer-filled sample reservoir on a microchip for immediate electrophoretic analysis, which requires < 1 min per run. The instrument can operate unattended for at least two days. This approach is based upon an earlier instrument developed using a growth tube operating at very high supersaturation values to analyze the bulk composition of aerosols above a 10-nm diameter cutoff (Noblitt *et al.*, 2009). The integrated CCN-MCE system collects aerosols at ~50 mL min^{-1} and deposits them into ~20 µL of solution to provide detection limits of ~0.1 µg m^{-3} with 10 min of sampling. Concentrations are measured via differential analysis, and detection limits are inversely proportional to collection time, which can extend over an hour, further lowering detection limits. Currently, the system can monitor the anionic species chloride, sulfate, nitrate, and oxalate using existing separation chemistry (Noblitt *et al.*, 2009b). An example separation is shown in Figure 1. Inorganic cation species can also be analyzed with the instrument using chemistry that is currently in development. Here, we show the technical aspects of the instrument as well as anion data from preliminary ambient sampling.

This work was supported by the California Energy Commission (CEC 500-08-046) and the United States National Science Foundation (ATM-0737201).

Comprehensive GCxGC, a valuable technique for the screening and semiquantitation of different chemical compounds in ultrafine aerosol particles

J. Ruiz-Jimenez[1], J. Parshintsev[1], T. Laitinen[1,2], K. Hartonen[1], M.–L. Riekkola[1],T. Petäjä[2], M. Kulmala[2]
[1]Laboratory of Analytical Chemistry, Department of Chemistry, University of Helsinki, P.O. Box 55, FI-00014 Finland, [2]Division of Atmospheric Sciences, Department of Physics, University of Helsinki, P.O. Box 64, FI-00014, Finland

Keywords: Comprehensive gas chromatography, mass spectrometry, time-of-flight, ultrafine aerosol particles
Presenting author email: jose.ruiz-jimenez@helsinki.fi

Comprehensive two dimensional gas chromatography – time-of-flight mass spectrometry (GCxGC-TOF-MS) has been used for the screening and semi-quantitation of volatile organic compounds in aerosol particles. Because volatility was required, some compounds were transformed via derivatization such as silylation into volatile ones. The identification of the analytes was made by comparing the GC retention indices and the TOF mass spectra ,with the NIST and the Golm metabolome database reference libraries. The data treatment was simplified by exploiting a double classification of the identified compounds, namely the main functional group and the specific elements chemical groups present in the molecule (Table 1).

Table 1. Classification of the identified compounds was based on the main functional group or specific element present in the molecule

Hydroc	Alkanes, alkenes, cyclic, aromatic
Halogen	Fluorinated, chlorinated, brominated , iodinated
Nitrogen	Amino acids, nitro, amines, amides, nitriles, imides, urea deriv, amino acids-N-deriv, amino-sugars, heterocyclic
Sulphur	Suphonamides, mercapto, sulphonic, thio
Carboxyl	Free acids, hydroxyl-a, keto-a, esters, anhyd
Hydroxyl	Alcohols, polyols, ethers
Carbonyl	Aldehydes, ketones

This methodology was applied to the identification of compounds in 30 nm, 50 nm and total suspended particles (TSP) collected during spring and autumn 2009 and summer 2010 at the Station for Measuring Forest Ecosystem Atmosphere Relations (SMEAR II) at Hyytiälä (Finland).

Table 2. Number of identified compounds and relative peak areas in SMEAR II samples

	Number		Relative peak area (m^{-3})	
	Mean	Range	Mean	Range
TSP	444	380-560	2.110^{7}	$7.9\ 10^{6}$-$5.0\ 10^{7}$
50-nm	429	385-476	3.510^{7}	$1.2\ 10^{7}$-$8.3\ 10^{7}$
30-nm	441	395-511	1.210^{8}	$5.1\ 10^{7}$-$2.7\ 10^{8}$

The number of identified compounds was higher than 400 (Table 2), resulting in the concentrations of the most relevant compounds present in the samples.
Significant differences were found in the compound profiles of TS, 50-nm and 30-nm particles. The highest values in terms of the number of compounds and the relative peak area were found for 30-nm particles, collected in a different season of the year. It is clear that alkenes, thio compounds, amino acids, esters, simple alcohols and ketones were the most abundant compounds in the aerosol particles under study in terms of the number of compounds but it was not possible to find any clear correlation for halogenated compounds that together with sulphur containing compounds and acids existed as relatively high peak areas (concentrations).
The analysis of different sized, simultaneously collected aerosol particles, revealed that the number of compounds increased with the enhanced particle size but the concentrations decreased in the most of the cases, except aldehydes (Figure 1). The decrease is presumable linked to the formation of new low-volatile compounds.

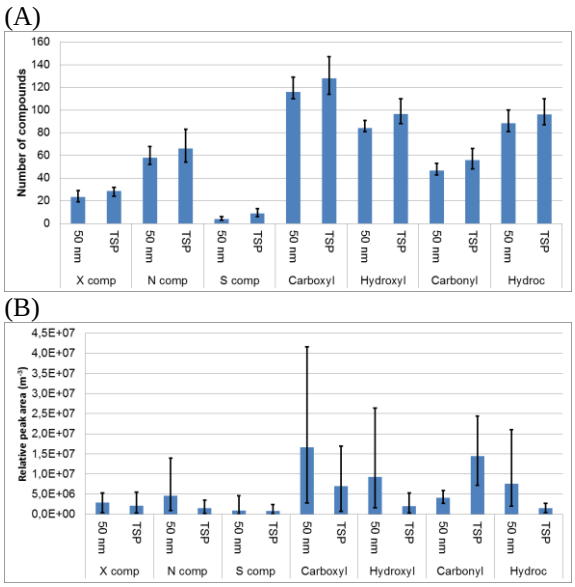

Figure 1. Chemical groups in different sized and TS particles as a function of A) number of compounds, B) relative peak areas

A new sensitive long-path absorption spectrometer for peroxide measurements in secondary organic aerosol

P. Mertes[1], J. Dommen[1], M. Kalberer[2], and U. Baltensperger[1]

[1]Laboratory of Atmospheric Chemistry, Paul Scherrer Institute, 5232, Villigen, Switzerland
[2]Centre for Atmospheric Science, Cambridge University, Cambridge, CB2 1EW, United Kingdom

Keywords: peroxides, smog chamber, SOA, spectrophotometry.
Presenting author email: peter.mertes@psi.ch

Beside their decisive role in atmospheric processes ambient fine and ultrafine particles have also an important impact on human health, predominantly on respiratory and cardiovascular systems (Pope and Dockery, 2006). Up to about 70% of these ambient particles are composed of organic material. However, the highly complex organic mixture is chemically still poorly characterized. The reaction of volatile organic compounds with ozone and OH radicals in the polluted troposphere mainly generates aldehydes, carboxylic acids and organic peroxides. The contribution of these peroxides to health risk is assumed to be especially important because of their high reactivity and oxidation potential (Morio *et al.*, 2001).

This project aims at developing an analytical method to determine the total amount of peroxides in secondary organic aerosol (SOA). Former studies indicate that the total amount of peroxides is considerably high in SOA (Ziemann, 2005). Using iodometry, quantification of peroxides in SOA was performed, and interesting time trends were observed (Gaschen *et al.*, 2008). However, due to insensitive spectrophotometry with 1-cm cuvettes, these experiments had to be performed at very high aerosol concentrations, and time resolution was rather low (2 hours).

In this study we describe a more sensitive method for peroxide quantification using a liquid core waveguide (LCW) in long pathlength absorbance spectroscopy (LPAS). According to Lambert-Beer's law, the sensitivity of spectrophotometry can be enhanced by increasing the optical path length. Absorbance is measured by a spectrophotometer (Ocean Optics, SD 2000). As detection cell we use a 50-cm Teflon AF 2400 LCW tube (DuPont, 0.6 mm i.d.). White light is supplied via a 200-μm glass fiber from a deuterium lamp (Avantes, AvaLight-DH-S). Solutions of hydrogen peroxide in 0.1 M $HCl_{(aq)}$/ethanol (1/1 by volume) were used for calibration. The reaction time was reduced to 40 min at an elevated temperature of 40°C. The detection limit was about 0.15 μM at 420 nm which is 80 times lower than reported by Gaschen *et al.* (2008).

We tested this instrument with aerosols produced in the PSI smog chamber. This is a 27-m^3 flexible teflon bag suspended in a temperature controlled wooden enclosure. Four xenon arc lamps combined with 80 black light lamps (SUN POWER Performance 100W) are used to simulate the solar light spectrum for photochemical aging. SOA was produced from α-pinene (biogenic precursor) or 1,3,5-trimethylbenzene (anthropogenic precursor). Aerosol particles were collected by impaction on stainless steel (A4) plates. The amount of peroxide functional groups was measured and normalized to the aerosol mass collected. Finally peroxide concentrations in SOA as a function of photochemical age and precursor were determined.

First measurements showed that SOA from the photooxidation of 1,3,5-trimethylbenzene contained between 30 and 250 pmol of peroxy-groups per μg collected aerosol. Assuming an average molecular weight of 150 Da for the peroxides this corresponds to 0.4 to 3.6 wt%. The peroxide content was highest within the first hour after experiment start and decreased during the experiment. In SOA from α-pinene we measured comparable amounts.

With our new setup using long pathlength absorbance spectroscopy to quantify peroxides in aerosol particles we find considerably lower amounts of peroxides than hitherto published studies have shown.

Emission of biogenic volatile organic compounds (BVOCs) by vegetation in the boreal forest and subsequently atmospheric oxidation leads to the formation of secondary organic aerosol (SOA). Oxidation of the BVOCs produces a variety of mostly unidentified organic species. Dependent on the volatility of the products, they partition between gas and particle phase. Seen from this perspective, organic acids are of particular importance for the particle phase, since the higher oxidation state and molecular mass, compared to the corresponding terpenes or aldehydes, is accompanied by a much lower volatility. However, very little is known about intermediate volatility organic compounds (IVOCs) which are residing almost entirely in the gas phase and generate efficiently lower volatility products by further reaction with atmospheric oxidants or by oligomerization (Donahue et al., 2006).

Here we show the high potential for gaining new insights into gas-to-particle-partitioning of individual organic acids by measuring them in both phases with the same instrument. This was achieved by coupling a miniature Versatile Aerosol Concentration Enrichment System (mVACES) as described by Geller et al. (2005) with an Atmospheric Pressure Chemical Ionization Ion Trap Mass Spectrometer (APCI-IT-MS; Hoffmann et al., 2002). The benefits of the on-line APCI-IT-MS are soft ionization with nearly no fragmentation, high time resolution and less sampling artifacts than in the common procedure of taking filter samples, extraction and detection with LC-MS. Furthermore the ion trap allows to perform MS/MS-experiments by isolation of single m/z ratios of particular ions. By subsequent addition of energy, the trapped ions form characteristic fragments which enable structural insight on the molecular level.

The sophisticated aerosol concentrator mVACES is a necessary unit for operation of the APCI-IT-MS in the field. It improves the limit of detection by concentrating particles without lowering the time resolution. Physical and chemical alteration of the particles, especially the change of gas-particle partitioning, was evaluated.

Field measurement during HUMPPA-COPEC10 campaign

The setup mVACES coupled to APCI-IT-MS was tested successfully in the laboratory and afterwards used during the large HUMPPA-COPEC field campaign at the SMEAR station in Hyytiälä, Finland in summer 2010. The comprehensive instrumental equipment of gas and particle phase measuring instruments during the campaign made it possible to compare the APCI-MS-data with a variety of different techniques. Especially the comparison between APCI-MS and the c-ToF-AMS (compact Time of Flight Aerosol Mass Spectrometer) of the University of Helsinki is predestinated, since these two instruments were connected to the same aerosol inlet line. Very good correlation coefficients between APCI-MS and AMS for sulfate (R^2=0.93) and for total organics (R^2=0.94) in particle phase have been determined. Furthermore organic acids were measured by filter sampling and subsequent analysis with LC-MS in order to resolve possible isobaric interference of the APCI-MS technique. For the first time in a field measurement in situ MS/MS-experiments for chemical characterization of the major abundant organic acids have been carried out. Results show similar pattern to those MS/MS-experiments in laboratory generated secondary organic aerosol.

However, not only comparison to different instruments and techniques revealed interesting results, but also the temporal behavior of specific compounds allows interpretation possibilities. For example fast mixing processes in the atmosphere (e.g. boundary layer processes) show a strong influence on the concentration levels of IVOCs. These short-term processes can only be monitored by an on-line technique. In addition we could show that gas-particle-partitioning of single organic compounds is not only driven by the molecular mass but most notably by the oxidation state of the regarded species. This means there exist highly oxidized organic acids with a relative small molecular mass which contribute more to particle mass than other organic acids with higher molecular masses.

Session 2D: Source Apportionment Studies

Source apportionments in a multi rural sites experiment in France (Particulair): Seasonality and regional specificities

Cozic J.[1], Piot C[2,1], Besombes JL[2], and Jaffrezo JL[1] and the Particul'air Team

[1] UJF-CNRS, LGGE, Rue Molière, BP 96, 38402 St Martin d'Hères Cedex, France.
[2] Université de Savoie - Polytech, LCME, Campus Scientifique, 73376 Le Bourget du Lac Cedex, France.

Keywords: aerosol chemistry, biomass emission, large scale characterization, rural environments, France.

There is an increasing concern all over Europe about a worsening of Air Quality due to domestic biomass combustion. Many studies showed over the last years that this source is responsible for a large share of particulate matter (PM) loading in very different types of environments (eg., large cities, alpine valleys, ..). However, there are still very few data available in order to evaluate the impact of this source in rural environments, particularly in France.

The program Particul'Air was design to investigate this aspect together with the impact of other sources (vehicle emission, marine emission...) simultaneously over a large portion of France. Nine sampling sites (cf figure 1) were selected in small rural villages (pop below 2500 inhabitants), spreading from the West (Brittany) to the East (Franche Comté) of the country.

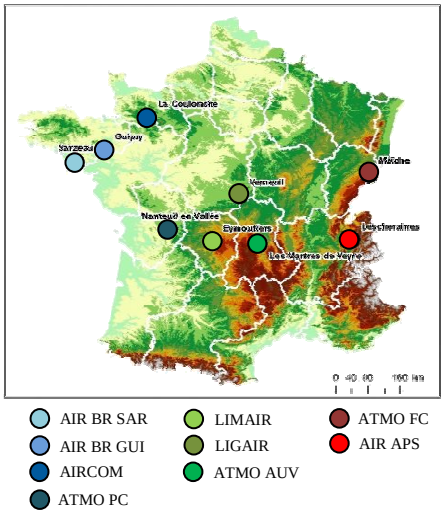

Figure 1. The 9 sampling sites.

Nine sampling periods of one week each (C1 to C9) were conducted simultaneously at the 9 sites, from March 2009 to February 2010, with daily sampling of PM10 at high flow rate. Additional measurements including PM mass (PM2.5 and PM10) and meteorological data were monitored. All filter samples were analyzed for EC/OC, major ionic species and LMW organic acids, levoglucosan, PAH, and trace metals. In addition, molecular speciation of organic matter (for about eighty compounds from different chemical families: hydrocarbons, PAH, organic acids…) was conducted on all samples of 5 of the campaigns.

The influence of the different sources can be estimated from different approaches, for instance by mono-tracer method using organic carbon (OC), levoglucosan and elemental carbon (EC) concentrations. Figure 2 presents the contribution of the different OM sources to OM for winter and summer depending of the region and shows that biomass combustion can indeed represent a very large share of the OM, with large variations according to the period and the site. Sites in mountainous areas (East) are more subjected to high concentrations and large impacts due to this source. However, sites close the Atlantic are far from being immune (West).

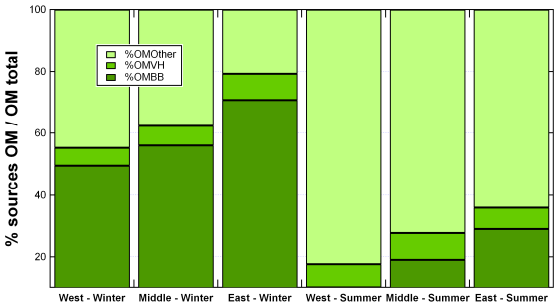

Figure 2. Contribution of the different OM sources to OM for Winter and Summer depending of the region.

This approach will be compared to the results obtained when using Molecular Marker - Chemical Mass Balance modeling (chemical aerosol composition and multiple tracers).

This work was supported by ADEME, CNRS, UJF and AASQA (AIRAPS, ATMO Poitou-Charentes, ATMO Auvergne, ATMO Franche-Comté, LIMAIR, LIGAIR, AIRBREIZH, AIRCOM).

A comprehensive study of the major sources of fine aerosols ($PM_{2.5}$) in the region of Paris (France): contribution of local versus imported emissions

M. Bressi[1], J. Sciare[1], V. Ghersi[2], N. Bonnaire[1], S. Moukhtar[2], J. Nicolas[1], A. Rosso[2], J.E. Petit[1], P. Lameloise[2], A. Féron[1], M. Artufel[1], and M. Reynaud[2]

Keywords: $PM_{2.5}$, Aerosol component composition, Chemical Mass closure, Source Apportionment, PMF
Presenting author email: michael.bressi@lsce.ipsl.fr

Paris is amongst the most populated urban zone in Europe with approximately 11 millions inhabitants (ca. 20% of the French population). With its specific meteorological conditions (oceanic versus continental air masses), this modern urbanized area represents a location of high interest for the investigation of Particulate Matter (PM).

Since 2007, the local air quality network AIRPARIF is monitoring particulate mass of fine aerosol with aerodynamic diameters below 2.5µm ($PM_{2.5}$) using a conventional on-line automatic system (R&P TEOM-FDMS). Since then, yearly averaged $PM_{2.5}$ levels have constantly been around 20µg/m^3 for urban background, which is the annual E.U. limit value of 2020. There is therefore a need to reduce $PM_{2.5}$ concentrations by applying efficient abatement strategies, which requires a comprehensive knowledge of this PM pollution. In particular, one needs to address the geographical origins of fine particles (local, regional or trans-frontier) as well as its main aerosol sources. These are the two main objectives of the AIRPARIF-AEROSOL project that will be discussed here.

Methodology

A large aerosol filter sampling network has been deployed in the region of Paris (ca. 120*100 km), composed by three rural, one suburban, one urban and one traffic stations. Daily (24h) sampling of $PM_{2.5}$ have been conducted at each station for a period of one year (11/09/2009–11/09/2010), using two Leckel low volume filter samplers (one for QMA, the other for PTFE filters) running at 2.3 m^3/h. After having determined their masses by gravimetry, the sampled filters have been thoroughly chemically characterized, by determining their content in carbon (EC, BC, OC, WSOC), major ions (NH_4^+, NO_3^-, SO_4^{2-}…), metals (Pb, Ti, Fe…) and specific tracers (levoglucosan, arabitol…).

Results

We will present here the $PM_{2.5}$ chemical characterization obtained at our 6 stations for the entire duration of the project (one year). We will first present the methodology developed to achieve the chemical mass closure on each station all along the year (See Figure 1.a). The temporal variability of $PM_{2.5}$ mass and its specific chemical components will be discussed, with an emphasis on pollution events.

Insights on the geographical origin of fine particles will be addressed by the "Lenshow" methodology (Lenshow et. al, 2001). It allows estimating the PM contribution of different geographical areas (long-range transport, rural, urban…) for each of the chemical constituent in $PM_{2.5}$.

Insights on the major aerosol sources of fine particles will be addressed from the results obtained by a source apportionment technique (PMF 3.0 model from EPA). Six major sources are likely to be at the origin of $PM_{2.5}$ over the Paris region (see Figure 1.b). A detailed chemical profile of each source, as well as their contributions (temporally resolved) to PM will be showed. These results will be compared with other European source apportionment studies (Viana et. al, 2008). Back-trajectory analyses (HYSPLIT trajectory model) will be used here to support our PMF factors identification. These different techniques are illustrated in Figure 1.

Sources of particulate matter and gaseous pollutants at some suburban sites in South East Queensland, Australia

A. Morrison[1], S.Law[1], G. A. Ayoko[1]* and H. Guo[2]

[1]Discipline of Chemistry, Queensland University of Technology, Brisbane, QLD 4001, Australia

Keywords: Source apportionment, PMF, PM10, gaseous pollutants.
Presenting author email: g.ayoko@qut.edu.au

Given the growing links between air quality and adverse environmental and human health effects (see, e.g., Chow, 2006; Teller and Levin, 2005), there has been an upsurge of interest in the spatial and temporal variations in the concentrations of airborne pollutants and use of receptor models for source identification and source apportionment.

In this paper we describe trends in air quality data obtained at two air monitoring stations in South East Queensland, and preliminary results on their source identification and apportionment. The goal of the work is to generate information that could aid the understanding of the source, transport and accumulation of pollutants in the region, and facilitate the formulation of mitigating measures.

The two sites examined in the paper are the Eagle Farm (EF) and Flinders View (FV) air monitoring stations, which were part of Queensland Environmental Protection Agency network of air monitoring sites within South-East Queensland. Their role was to monitor $PM_{10,}$ meteorological conditions and the concentrations of ozone, nitrogen oxides, sulphur dioxide, and visibility reducing particles. The Eagle Farm (EF) monitoring site was located in a light industrial area on Curtin Avenue (latitude -27.4383 and longitude 153.0798) the between 1998 and 2005 while FV monitoring site is located at Ipswich which is approximately 35 km south west of Brisbane. The site is located at latitude – 27.6528 and longitude 152.7741. It is bordered on the south by rural acreage blocks and located approximately 500 meters east of a highway and four kilometres east of the a power station, a landfill and a company that produces organic compounds..

The data collected between 2000 - 2004 at these site were pre-treated before Positive Matrix Factorisation (PMF) and other statistical analyses. Preliminary analysis of the data showed that the concentrations of the pollutants were generally below the Australian National Standards for each pollutant. However, there are a few days when the National Standards were exceeded by some pollutants. Further analysis of the data by advanced factor analytic methods revealed instructive details about the temporal and spatial variation, as well as the possible sources of the pollutants. Thus the main sources of the pollutants were identified as traffic and industrial emissions.

Conditional probability function (CPF) analysis identified the most likely sources of the pollutants measured at EF as the M1 motorway, Kingsford Smith drive, local traffic and the local industrial area, while the Cunningham highway, Swanbank power station and aircrafts operated by the Royal Australian Air Force were identified as the main sources at FV.

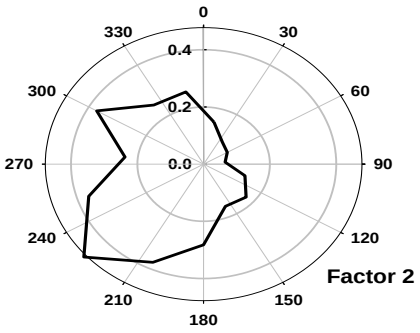

Fig 1: CPF plot for the highest 25% of the mass contribution for the PM factor.

The development of air quality management strategies and prioritisation of remedial action could greatly be enhanced by considering the resolved sources and the contributions of each source to the species measured at each of the sites.

We thank the former Queensland Environmental Protection agency for the data used for this work.

During a one year period (from August 2008 to July 2009) PM10 samples from different locations in Switzerland (urban kerbside, urban background, suburban and rural) were collected and analysed for inorganic ions, trace elements and the carbonaceous fraction. In addition, a detailed speciation of organic compounds was performed for selected PM10 samples. The data provide a detailed picture of the variation of the PM10 chemical composition between different site types, regions and seasons.

Ten years earlier, from January 1998 to March 1999, a similar study has been performed. As in the recent study, the data provided a detailed picture of the PM10 chemical composition at different Swiss sites (Hueglin et al. 2005) and allowed the identification and characterisation of the main emission sources.

During the last decades the concentrations of atmospheric PM10 slightly but steadily decreased in Switzerland (Barmpadimos *et al.*, 2010). PM10 concentrations measured in 1998/1999 and 2008/2009 reflect this trend (Fig. 1).

Between the two studies the most noticeable change in major PM10 constituents was observed for sulphate: at all sites average annual concentrations decreased between 1.1 and 1.5µg/m^3 (Fig, 1). Decreasing concentrations were also observed for elemental carbon (EC), ammonium and the sum of trace elements. Decreasing trace element concentrations were especially pronounced at the urban kerbside site, indicating declining trace element emissions from road traffic. Organic matter (OM) showed only decreasing concentrations at the urban kerbside site, the nitrate concentrations were slightly increasing at all sites. The average concentration of natural mineral dust as calculated from the concentrations of Al and Mg as well as from estimates of the crustal fractions of total measured Fe, K and Ca slightly decreased at the urban kerbside site, while at the other sites remained constant.

Both data sets were analysed (respectively re-analysed) by Positive Matrix Factorization (PMF). The main PM10 sources and components were identified as: road traffic, wood combustion, mineral dust, sulphate rich secondary aerosols, nitrate rich secondary aerosols, and a Na and Mg rich factor. It was found that wood combustion is an important source of PM10 at all sites. The estimated contribution of wood combustion related aerosols was highly correlated to the concentrations of levoglucosan. The results also revealed clear differences in properties of wood combustion emissions at the rural sites north and south of the Alps. The contribution of mineral dust as determined by PMF was in good agreement to the mineral dust concentration as calculated from the element concentrations. This gives us additional confidence in the reliability of the PMF results.

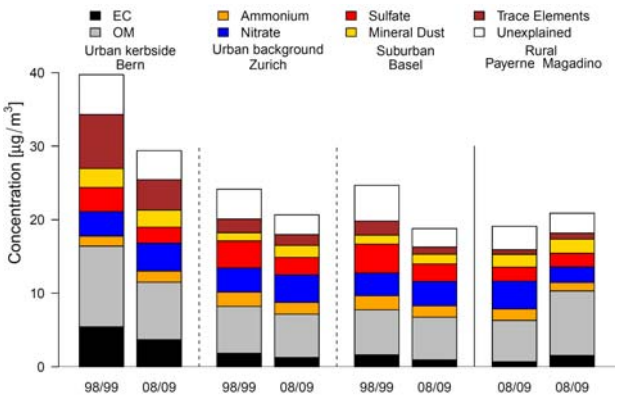

Figure 1: Chemical composition of atmospheric PM10 at urban kerbside, urban background ad suburban sites in 1998/1999 and 2008/2009 and at two rural sites in 2008/2009.

Spatial distribution of ambient particulate matter and source contributions in Augsburg, Germany

J. Schnelle-Kreis[1], J. Gu, G. Abbaszade[1], J. Diemer[2], R. Zimmermann[1,3]

[1]ICooperation Group Analysis of Complex Molecular Systems, Helmholtz Zentrum München, D-85764 Neuherberg, Germany
[2]Bavarian Environment Agency, 86179 Augsburg, Germany
[3]Analytical Chemistry, University Rostock, Dr.-Lorenz-Weg 1, D-18051 Rostock, Germany
Keywords: PM_{10}, PMF, source apportionment, spatial variability
Presenting author email: juergen.schnelle@helmholtz-muenchen.de

Ambient particulate matter (PM) has long been found to be associated with adverse health effect. In order to better understand and clarify the health impacts of different air pollution sources, there is a growing interest on the relationship between source-specific PM, spatial variability of PM and adverse health effects.

The aim of the study is to identify sources of urban PM_{10} in a winter season and to provide information on the temporal and spatial variability of PM composition and source contributions. The study location is Augsburg, a median sized city in southern Germany. In a previous study five sources of organic compounds have been identified using PMF based on concentrations of semi-volatile organic compounds (SVOC) in $PM_{2.5}$ (Schnelle-Kreis et al. 2007).

In the present study daily PM_{10} samples have been collected from November 14th 2007 to March 31st 2008 at a central, mainly traffic influenced site (Tr). In an intensified campaign from February 13th to March 12th parallel samples have been collected at 7 further sites. These sites are characterised as follows: industry (In), residential area with one-family dwellings (Re), urban background (Ub), tower in city centre with sampling site 100 m above ground (To), and three suburban sites (Su 1 to Su 3). Meteorological data including temperature, humidity, wind direction and speed as well as mixing layer height have been determined at a central site.

A total of 330 PM_{10} samples have been analysed for inorganic ions, elements, EC/OC and particulate organic compounds.

In the intensified campaign with 8 parallel sampling sites in operation the temporal variation of PM composition was determined by the Pearson correlation coefficients (r) of individual PM constituents. The spatial variation was characterised by means of coefficients of divergence (COD) (Wongphatarakul et al. 1998).

High correlations and medium to low COD values were found for most inorganic compounds including $NH4^+$, SO_4^{2-} and NO_3^-, EC and OC, and some organic compounds like PAH or levoglucosan. Some elements such as Ca, Mg, Na, Ti and Zn and most organic compounds including hopanes showed medium or weak correlations and higher COD values. These compounds are most probably influenced by local sources at the respective sites.

Positive matrix factorisation (PMF (Paatero 1997)) has been used for source apportionment analysis. Seven factors, associated with traffic emissions, biomass combustion, re-suspended dust, sodium chloride, Nitrate, and sulphate have been separated.

The PMF analysis strengthened the evidence of temporal and spatial variations of the PM composition. Factors with strong local impact like traffic and NaCl showed greatest differences between the different sites. Factors dominated by regional background or long distance transport like Nitrate or sulphate showed only very little spatial variation (Figure 1).

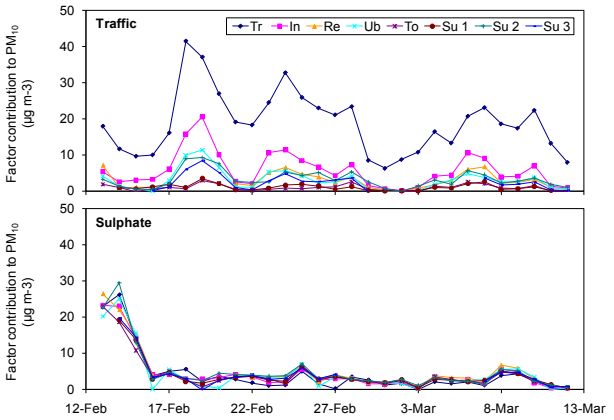

Figure 1: Contributions of source factors "Traffic" and "Sulphate" to ambient PM_{10} at the sampling 8 Sites in Augsburg.

Source apportionment modelling to quantify atmospheric particle emissions using tunnel measurements

Samantha Lawrence, Khaiwal Ravindra* and Ranjeet Sokhi

Centre for Atmospheric and Instrumentation Research (CAIR), University of Hertfordshire, Hatfield, Hertfordshire, AL10 9AB, United Kingdom
Keywords: PMx, metals, PAHs, non-exhaust emissions, emission factors.
Presenting author email: r.khaiwal@herts.ac.uk

Introduction: The link between increased particle pollution and health issues has prompted the introduction of strict exhaust emission standards. However, research has shown that non-exhaust emissions also contribute significantly to atmospheric particle concentrations. This highlights the need to chemically identify the non-exhaust emissions and their sources. Considering this, we quantified the exhaust / non-exhaust emissions by combining innovative motorway tunnel sampling and source apportionment receptor modelling.

Hatfield tunnel: The Hatfield Tunnel is located in Hatfield, Hertfordshire forming part of the A1(M) motorway between junctions 3 and 4; 0.8 km west of Hatfield town centre. The tunnel is 1115m in length, which provides sufficient distance for satisfactory gap between sampling sites. Furthermore, the dispersion is limited, providing an ideal location for sampling low concentration analytes.

Source apportionment: Analytical techniques ICP-AES and GC-MS were used to identify the metallic and organic composition of PM_{10}. Good correlation was observed between Fe, Cu, Mn, Ni, Pb and Sb and change in traffic volume. The concentration of polycyclic aromatic hydrocarbon and other organics varies significantly at the entrance and exit site of tunnel. Fluoranthene, pyrene, benzo[a]pyrene, chrysene and benzothiazole shows the highest incremented concentrations.

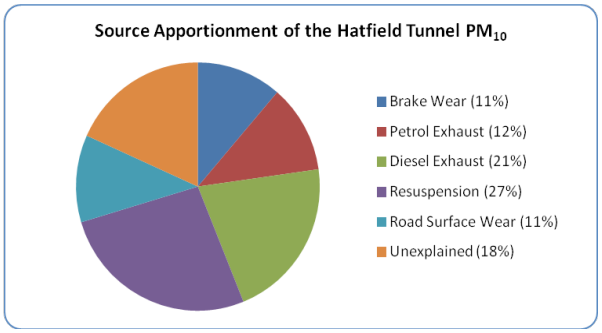

Figure 1. Source apportionment of PM_{10} using combined dataset.

The application of Principal Component Analysis and Multiple Linear Regression Analysis helped to identify the emission sources for 82% of the total PM_{10} mass inside the tunnel (Figure 1). These sources includes resuspension (27%), diesel exhaust emissions (21%), petrol exhaust emissions (12%), brake wear emissions (11%) and road surface wear (11%).

Atmospheric particle emissions: Road Tunnels are like large laboratories with known boundary conditions. The current work compares the High Volume, Dichotomous Stacked Filter Unit and Partisol Air Sampler for coarse, PM_{10} and $PM_{2.5}$ particle concentration measurement and found that they do not differ significantly (p= 95%). $PM_{2.5}$ fraction contributes 66% of PM_{10} proportions and significantly influenced by traffic (turbulence).The mean PM_{10} emission factors varies from 21.3±1.9 – 28.8±3.4 mg/vkm and composed of motorcycle, cars, LDVs, HDVs and buses as shown below:

Table 1. Comparison of mean PM_{10} mass emission factors (mg/km)

Fleet Type	Current Study	NAEI
Motorcycles	0.0003 - 0.001	0.002
Cars	26.1 - 33.4	33.0
LDVs	2.5 - 3.0	10.3
HDV	2.4 - 2.8	22.3
Buses	0.1 - 0.1	0.7

The source apportionment modelling identifies break wear (3.8-4.4 mg/vkm), petrol exhaust (3.9-4.5 mg/vkm), diesel exhaust (7.2-8.3 mg/vkm), resuspension (9-10.4 mg/vkm), road surface wear (3.9-4.5 mg/vkm), and unexplained (7.2 mg/vkm) as major sources of PM_{10} emissions. The current study shows that combined non-exhaust fleet PM_{10} emission factor (16.7-19.3 mg/vkm) is higher than the combined exhaust emission factor (11.1-12.8 mg/vkm).

This study shows that chemical components of PM_{10} linked to a number of health issues originate from exhaust and non-exhaust sources; signifying the need to mitigate not only exhaust but also non-exhaust emissions, as they will become major source of PM_{10}.

Session 2E: Gas-phase Synthesis of Nanoparticles

Flame-spray derived complex fluoride upconversion nanoparticles

A. Stepuk, D. Mohn and W.J. Stark

Institute for Chemical and Bioengineering, ETH Zurich, Zurich, 8093, Switzerland
Keywords: flame spray pyrolysis, upconversion nanoparticles, complex fluorides, luminescence.
Presenting author email alex.stepuk@chem.ethz.ch

Nowadays, various applications, such as bioimaging, solar cells (Shalav *et al*, 2005) and luminescent displays use upconversion phosphors. These materials consist of a host matrix filled with rare earth elements which are responsible for the visible emissions. The rare earth based upconversion phosphors are usually represented by oxysulfide, fluoride, gallate, and silicate types hosts, doped with Yb-Er and Yb-Tm couples (Auzel, 2004). One of the most efficient host matrices for the near-infrared (NIR) to visible upconversion phosphors is hexagonal sodium yttrium fluoride (Sommerdijk, 1973). Mass-produced upconversion phosphors $NaYF_4$: Yb, Tm are fabricated in bulk microcrystalline form by high-temperature solid-state synthesis. Recent reports demonstrated several novel approaches in mass-production of nanocrystalline UC phosphor materials: decomposition of multi-precursors, co-precipitation, hydrothermal and solvothermal methods (Martin *et al*, 1999). Nonetheless, those methods in the UC nanoparticles synthesis are limited to the predictable crystallites morphology, low production rate and complicated synthesis schemes.

In this study, flame spray technique (Grass and Stark, 2005) was applied to synthesize hexagonal $NaYF_4$ nanoparticles, doped with Yb^{3+} and Tm^{3+} ions. The prepared powders consisted of nanoparticles sized 20-40 nm. TEM analysis (Fig. 1a) of powders shows the presence of hexagonal particles in nanometric scale. The SEM micrographs of flame sprayed $NaYF_4$: Yb, Tm displayed the agglomerated uniformly sized nanoparticles (Fig. 1b).

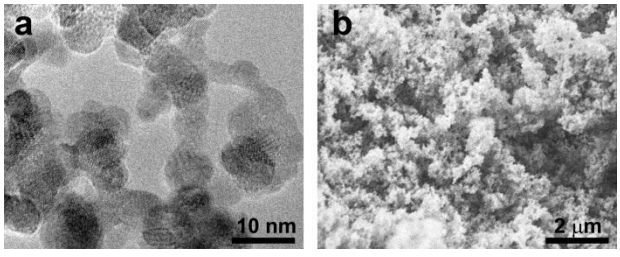

Figure 1. (a) TEM and (b) SEM images of $NaYF_4$:Yb,Tm nanoparticles.

Thermal treatment of the powders changed the phase composition, morphology and size of the particles (Fig. 2).

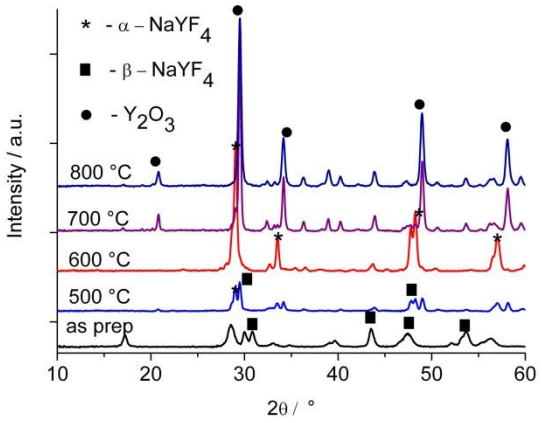

Figure 2. XRD patterns of the $NaYF_4$: Yb, Tm powders sintered at different temperatures.

Excitation by near-infrared (980 nm) laser revealed visible emissions formed by the particles, proving their upconversion properties. Upconversion luminescence of the materials strongly depends on the synthesis and sintering conditions.

Various flame regimes, doping by different rare-earth elements, variation of dopant concentration influenced the formation of cubic and hexagonal phases. Kinetics and thermodynamics, as critical factors of phase type, are to be discussed within the presentation. During this talk we will show, that aerosol processing is also applicable for non-oxidic nanoparticles, such as highly potential complex fluoride phosphors.

Presenting author email: c_meh@web.de

Nanocrystalline silicon is a promising material for the application in printable electronics (Holman et al, 2010). Silicon nanoparticles (SiNP) are typically synthesized via gas phase route by pyrolysis of diluted silane (SiH_4). These particles can be dispersed in organic liquids and deposited as thin functional films. As a prerequisite for the functionality of the film, good contacts between individual particles are necessary. It is difficult to sinter Si films due to the high melting point. A thin germanium layer around a silicon core might be a suitable composite material for improvement. Si and Ge are familiar from the electronic properties but Ge has a much lower melting point.

A reactor system with two consecutive hot-wall reactors was used in the experiments. The first reactor stage is operated at temperatures between 900°C and 1200°C for the synthesis of the SiNP with defined properties (Körmer et al, 2010). Silane, diluted in argon, is used as precursor mixture. After the first reactor the aerosol is quenched by additional argon. Prior to the second reactor stage, GeH_4 is fed into the system. In the second reactor stage Ge films are deposited on the SiNP aerosol at temperatures between 500°C and 700°C. At the reactor exit the aerosol is quenched by nitrogen. The particles are collected with a membrane filter or sampled with a low pressure impactor by deposition on TEM grids or silicon wafers.

The spherical silicon particles from the first reactor are characterized by a specific surface area of 90 m^2/g, which is equal to a mean diameter of about 29 nm. The average crystal size was determined from XRD analysis to 25 nm. The composite materials exhibit crystalline domains for Si as well as for Ge, which can be seen in the X-ray diffraction pattern in figure 1. The Ge shell thickness can be influenced by the temperature or the amount of GeH_4 added to SiNP aerosol.

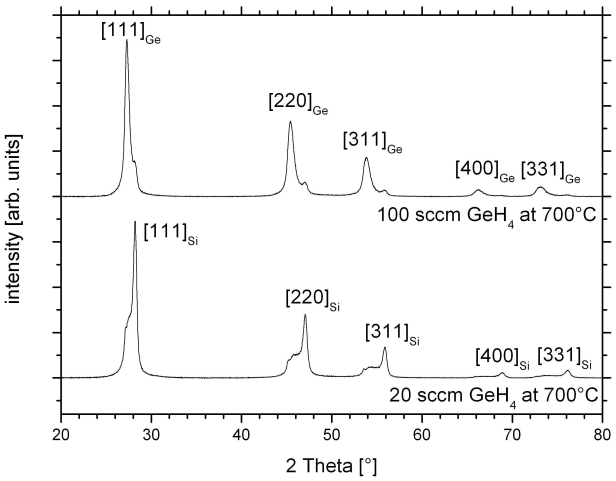

Figure 1. XRD data for Si-Ge composite material.

The core-shell structure was proven by STEM analysis. In figure 2 the z-contrast due to the different atomic weight of Si and Ge is visible. It shows representative particles synthesized at reaction conditions where thick Ge layers are formed. The deposition of Ge leads to varying shell thicknesses around the Si core and patchy particles are formed. This can be explained by energetically favoured sites for the initial island growth. Due to the slight misfit between the crystal lattices the Ge grows preferentially on itself and only partially around the Si core. The influence of the reaction conditions on the morphology of the hybrid particles will be discussed.

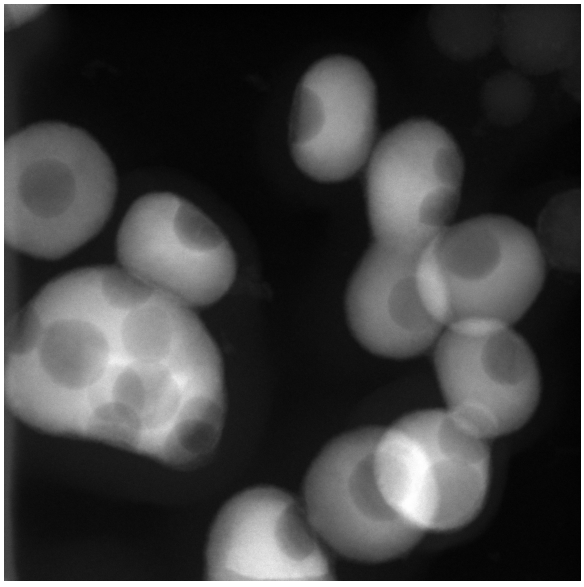

Figure 2. STEM picture of Si-Ge core-shell structures (dark: Si, bright: Ge).

Copper nanoparticle synthesis by an arc evaporation / condensation process

H. Förster[1] , C. Wolfrum[2] and W. Peukert[1]

[1]Institute of Particle Technology, Friedrich-Alexander-University Erlangen-Nürnberg, Cauerstr. 4, 91058 Erlangen, Germany
[2]ECKART GmbH, Werk Güntersthal, 91235 Velden, Germany

Keywords: metal nanoparticles, synthesis, arc evaporation/condensation.
Presenting author email: H.Foerster@lfg.uni-erlangen.de

Metal nanoparticles exhibit special properties which make them favourable for numerous applications in different fields, such as electronics, sensor technology, catalysis and optics. In this work the synthesis of copper nanoparticles in an arc aerosol furnace by the evaporation/condensation method is systematically investigated. Apart from the usual advantages of gas phase processes (e.g. high purity, scalability) the evaporation/condensation process allows direct synthesis using pure metals as starting materials and thus avoiding routes including reactions of expensive and potentially poisonous precursors.

In the system used for this study a d.c. arc provides the energy for evaporation of the metal target which is contained in a graphite crucible and has anodic polarity to avoid micro droplet formation (Mahoney, 1995). The cathode consists of a sharpened tungsten needle protected by a sheath gas flow (Ar). The arc length is adjustable by vertical movement of the anode setup. For transportation of the metal vapour out of the plasma zone and subsequent aerosol dilution a carrier (Ar) and quench gas flow (N_2) are applied respectively. To prevent any oxidation in the system, gases with purity grade 5.0 are used. Additionally the sheath gas stream is enriched with small amounts of hydrogen as getter material.

The arc stability and its effect on particle size are investigated (see Fig. 1).

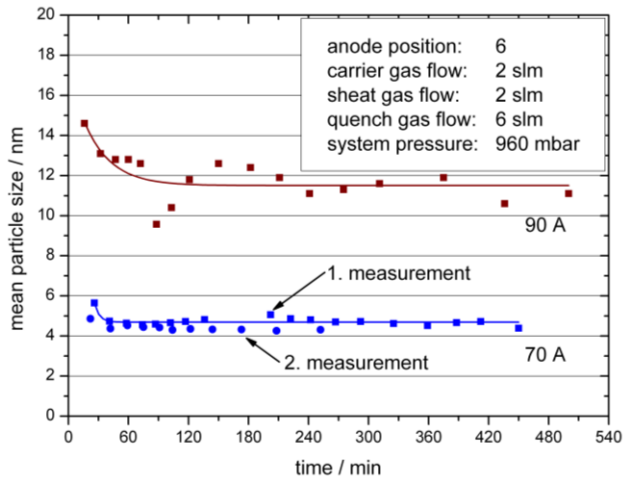

Figure 1. Long term stability and reproducibility of mean particles sizes (SMPS-measurement)

After a warm-up time of 1 h for an arc current of 70 A respectively 2 h for an arc current of 90 A the experiments reveal excellent long term arc stability for at least 6 h continuous operation delivering aerosols with high reproducibility (± 10 % of average mean particle size). The electric characteristics of the arc are studied for various operating conditions. The influence of the arc current and length (exemplarily shown in Fig. 2), the flow rates of the applied gases, the system pressure and the addition of hydrogen to the sheath gas on the average particle size and the agglomerate structure are analysed by scanning mobility particle sizing (SMPS), scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The average particle size could be well controlled in a size range from 4 to 50 nm by selecting appropriate operating parameters. The standard deviation exceeded not more than 5.5 % of the average particle size (minimum of 3 measurements per parameter set).

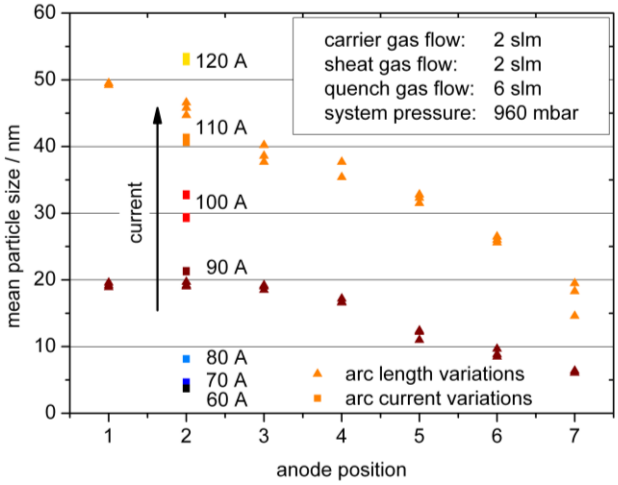

Figure 2. Influence of arc length and arc current on mean particle sizes (SMPS-measurement).

The material properties are analyzed by X-ray diffraction (XRD), energy dispersive X-ray spectroscopy (EDX) and thermo gravimetric analysis.

Photochemical synthesis of olivine ($Mg_{2x}Fe_{2-2x}SiO_4$; $0 \leq x \leq 1$) nanoparticles

R.W. Saunders and J.M.C. Plane

School of Chemistry, University of Leeds, Leeds, LS2 9JT, UK
Keywords: Photochemical reaction, Generation of nanoparticles, Electron microscopy
Presenting author email: r.w.saunders@leeds.ac.uk

The *olivine* family of minerals (end members: *forsterite* - - Mg_2SiO_4 and *fayalite* - Fe_2SiO_4) are a significant component of the Earth's crust/mantle in crystalline form, and are also considered to be the dominant composition, in both crystalline and amorphous structures, for nano-size meteoric smoke particles formed in planetary atmospheres and cosmic dust grains in the interstellar medium (Henning, 2010).

The laboratory synthesis of such mixed-metal silicates for crucial fundamental studies of their optical and physico-chemical properties has to date been restricted to a 'top down' bulk, sol-gel approach, whereby generated powders can be dried and ground down to micron-size particles. However, the properties of such particles at the nano-scale are likely to be significantly different, primarily as a consequence of the increasingly high surface area to volume ratios below sizes of ~ 100 nm (Hochella *et al.*, 2008).

In order to generate nano-sized olivine particles with variable Fe-Mg content (x) for further study, we have developed a novel photochemical technique (described in Saunders and Plane, 2011), whereby gas-phase Fe, Mg and Si oxide species are produced from the photo-oxidation of suitable precursor vapours ($Fe(CO)_5$ – iron pentacarbonyl, $Mg(OC_2H_5)_2$ – magnesium ethoxide and $Si(OC_2H_5)_4$ – tetraethyl orthosilicate) in a flow cell. Particles nucleate and grow from this oxide vapour 'mix', and are captured for electron microscope (TEM) imaging and compositional analysis (energy dispersive x-ray or EDX spectroscopy and electron energy loss spectroscopy or EELS).

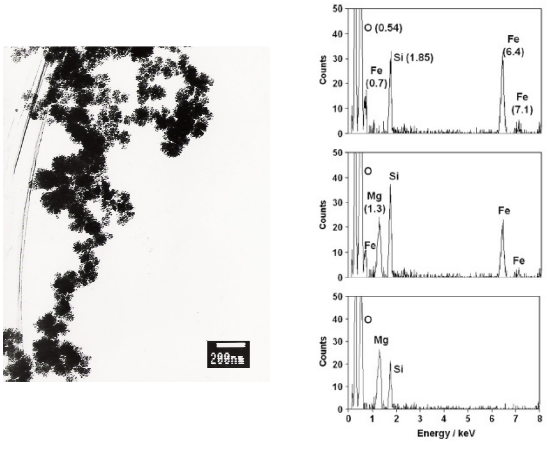

Figure 1. *Left* – TEM image of a particle aggregate formed in the tertiary vapour experiments described. *Right* – EDX spectra of olivine particles of varying Fe-Mg composition

Figure 1 (left panel) shows a typical 'fractal-like' particle aggregate (composed of primary particles of ~ 10 nm diameter), captured and analysed for composition. The right panel of this figure gives examples of EDX spectra (with characteristic elemental peaks indicated) acquired from particles formed in experiments with the absence of Mg-precursor (top) and of Fe-precursor (bottom) – leading to Fe_2SiO_4 and Mg_2SiO_4 particle compositions respectively. The middle panel is a spectrum of a mixed-metal olivine particle (x ~ 0.5) formed with all three precursor vapours generated in the reaction cell.

Control over the stoichiometry (value of x) of the end particle composition was found to be possible from the tertiary vapour photochemical system simply through careful variation of the initial flow ratio (R_p) of Mg and Fe precursor vapours i.e. R_p = $Mg(OC_2H_5)_2$ / $Mg(OC_2H_5)_2$+$Fe(CO)_5$, with quantitative EDX and EELS analysis indicating atomic Mg/Fe in particles α R_p – see Figure 2 below.

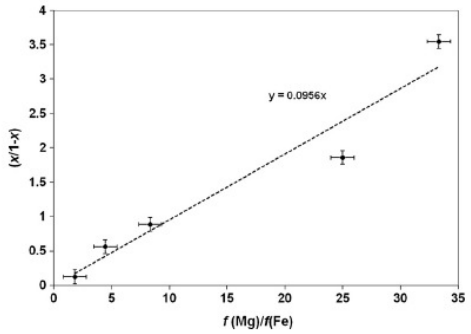

Figure 2. Correlation plot of the ratio of x/1-x (equivalent to measured Mg/Fe in particles) to the ratio of precursor flows used for particle generation.

In conclusion, we have shown that it is possible to efficiently and controllably generate mixed-composition olivine nanoparticles using a photochemical system (at atmospheric pressure and room temperature) and appropriate precursors for the formation and reaction of initial gas-phase metal oxide and Si oxide vapours, leading to particle nucleation.

Key Words: core-shell, nanoparticle synthesis, chemical kinetics, photochemistry

The synthesis of silica-encapsulated nanoparticles has received much interest in recent years as the production of such structures can enhance particle properties such as thermal stability and surface functionality. The production of composite nanoparticles by gas-phase methods allows for particles to be produced at high throughputs in inert or non-reacting environments with little or no surface impurities. Photochemical vapor deposition (photo-CVD) is a gas-phase approach that allows for the production of a variety of core-shell compositions, including organic (Zhang *et al.* 2008) and inorganic coatings (Boies *et al.* 2009) on nanoparticles. While the approach has been shown to work experimentally, a fundamental understanding of the chemical mechanisms involved in the coating process has not been presented.

This study presents a chemical mechanism of the photo-CVD process to describe the production of silica coatings from the decomposition of tetraethyl orthosilicate (TEOS). The chemical mechanism builds on the work of previous thermal TEOS decomposition mechanisms, but is the first to include photochemical reactions and nanoparticle surface growth. The mechanism is modeled within a plug-flow reactor with conditions that mimic those of previous experimental results. As shown in Figure 1, the particles and precursor enter near the vacuum ultraviolet (VUV, λ=172 nm) radiation source and are transported down the chamber by the bulk fluid motion as a series of gas-phase and surface reactions result in a silica coating.

The photochemical model is validated by examining the photodecomposition of O_2, a reaction that can be solved analytically. Results from the comparison confirm that photodecomposition can be adequately determined within the modeling environment, CHEMKIN-PRO. Modeled results of the entire photo-CVD mechanism indicate that the dominant reactions for the production of silica coatings are the photodecomposition of TEOS and the removal of surface ethyl groups from adsorbed TEOS species. Analysis of the effect of oxygen within the system indicated that it participates in both the gas-phase decomposition of TEOS and surface formation of silica, but is not the primary reaction pathway for most modeled conditions.

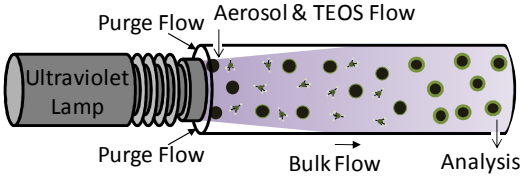

Figure 1: Experimental schematic of nanoparticle silica coating by photo-CVD with TEOS as a precursor.

Particle growth due to surface coating was modeled for a variety of precursor concentrations, radiation intensities and system residence times corresponding to previous experimental studies. Results from the modeled findings were compared to experimental studies published previously (Boies *et al.* 2009). As shown in Figure 2, the model is in agreement with experimental results, showing an increase in coating thickness with respect to increased TEOS flow and decreased nitrogen flow. The modeled growth trends of coating thickness as a function of TEOS flow rates most closely match experimental results in the case of greater TEOS absorption cross sections (an unknown parameter within the system) and diffuse radiation. These modeled results show a similar trend and are within an order of magnitude of the experimental results, which represents good agreement given uncertainties of many parameters including absorption cross sections and reaction rates.

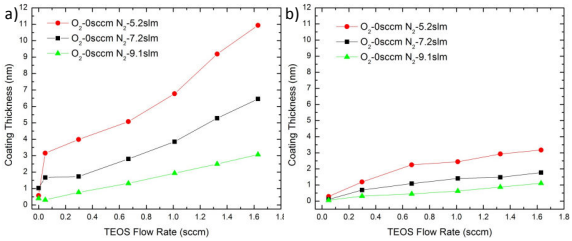

Figure 2: a) Experimental coating thickness, and b) modeled coating thickness as a function of TEOS and nitrogen flow rates.

Assessment of Size Distribution Models in Coupled 3D CFD Simulations for the Prediction of Nanoparticle Coagulation in Transonic Flows

J.F. Quaatz, M. Giglmaier and N.A. Adams

Lehrstuhl für Aerodynamik und Strömungsmechanik, Technische Universität München

Keywords: Nanoparticles, Aerosol modelling, CFD, Number size distribution
Presenting author email: frederik.quaatz@aer.mw.tum.de

The presented research is part of the joint project DFG PAK 75 that has the objective to design a gas dynamic process and a facility for the production of high-quality nanoparticles. The motivation is the coupling of 3D CFD simulations with particle-growth models to predict the size distribution and the number density. The focus of this report is the evaluation of combinations of 3D flow simulations with three different established coagulation models using experimental data obtained from the novel facility.

Main component of the facility (Figure 1) is a double-chocked flow channel. A precursor (TEOS – tetraethyl orthosilicate) is injected into the subsonic flow upstream of the first critical cross section A_1^*. Within the first nozzle the flow accelerates to supersonic speed of up to $M \approx 1.8$. A shock in the divergent part of the first Laval nozzle causes an instantaneous temperature increase above the ignition temperature of the precursor. Consequently, the flow is decelerated to subsonic conditions. Particle growth occurs within the subsequent reaction zone with constant cross section. A particular property of the novel facility is that in the reaction zone quasi constant thermodynamic conditions are maintained ($T = 1300K$, $p = 6bar$) that lead to a homogeneous coagulation. Particle growth is terminated by re-accelerating the flow to supersonic speed within the second Laval nozzle. This gas dynamic quenching process enables a cooling rate of $O(10^7)$ K/s. Furthermore, the total temperature of the gaseous flow is sufficiently reduced by water injection. Due to homogeneous and controllable thermodynamic operating conditions this gas dynamic process promises high-quality nanoparticles with well defined properties, such as narrow size distributions.

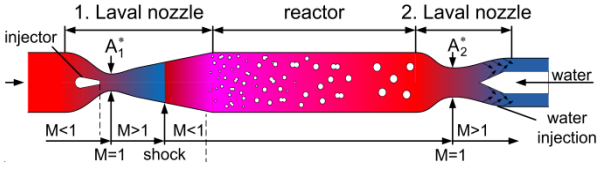

Figure 1. 1D sketch of the simplified gas dynamic process – M is the Mach Number of the flow, A_1^*, A_2^* are the chocked cross sections of both Laval nozzles, cool regions are indicated with blue color, hot regions are highlighted in red

We perform 3D CFD simulations of the full facility including both Laval nozzles and taking into account the heat release by the precursor combustion. For a proper consideration of secondary flows, e.g. corner vortices, an Explicit Algebraic Reynolds Stress Model (EARSM) is applied. In order to take turbulent mixing effects into account the particle-growth model is coupled with the CFD simulation. The characteristic quantities of the particle -size distribution are modeled as transported passive scalars. The coagulation terms of the General Dynamic Equation (GDE) are implemented as sources. Due to high super-saturation, nucleation processes are negligible. We compare three different approaches for approximating the particle size distribution (Figure 2): An efficient bimodal monodisperse model, a bimodal polydisperse model using the method of moments (Jeong, 2004) and a computationally rather expensive sectional model (Hounslow, 1988). We relate the model-specific underlying assumptions to the operating conditions within the given facility. Also, feasibility is assessed by comparing the numerical results with experimental data.

Since our numerical method couples CFD with the particle models, the size distribution of the nanoparticles is predicted at an arbitrary location within the 3D flow field. In order to highlight this advantage, we compare our results with a common post-processing-type method where the particle growth is only computed along isolated streamlines.

Keywords: metal nanoparticles, homogeneous nucleation, nucleation rate.
Presenting author email: onischuk@kinetics.nsc.ru

Nucleation of metals differ essentially from other systems nucleation and needs a detailed investigation. This work compares experimental routes of measurement of the nucleation rate from Zn and Bi vapor in a laminar flow chamber. The flow chamber consisted of a quartz tube (of i.d. = 0.7 - 1.0 cm) with an outer heater. A flow of Ar was supplied to the inlet with the rate 8 - 17 cm^3/c. A piece of metal (Zn, Bi) was put inside the heated zone, and that resulted in saturated vapor generation. At the outlet of the heated zone the temperature dropped down resulting in the nucleation onset. The concentration, size and shape of particles at the outlet of the tube was analyzed by TEM and automatic diffusion battery. The analysis of thermophoretic depletion of particle concentration in the region of temperature decrease, and the numerical simulation of nucleation coupled with the experimental axial and radial profiles of temperature have shown that the nucleation onset occurs within the layer of 1 mm near the wall of tube. Therefore, the axial profile and morphology of the wall deposit can give the information on the location of the region of maximum nucleation rate and the nucleation volume. However, there can be two different situations: the nucleation temperature T is less than the melting point (as it was in the case of Zn) and higher (Bi). In the first case it is easy to determine the nucleation rate, because the nucleation zone is easy to distinguish by the transition from smooth to powder-like deposit (Fig. 1a), the nucleation time may be estimated from the length of the initial increase in the wall mass deposit profile (Fig. 1b) and as the outlet particles are not aggregated (Fig. 1c) the nucleation rate can be estimated from the outlet particle concentration and the nucleation time. Thus, for example, for T = 660 K and supersaturation S = 15 the nucleation rate was found to be 10^{10} $cm^{-3}s^{-1}$.

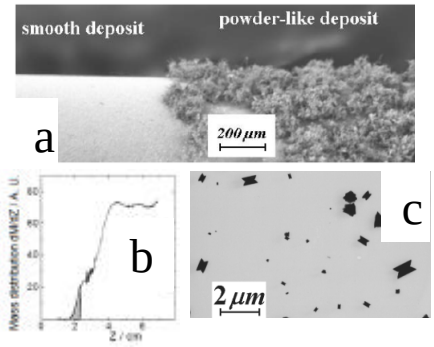

Fig. 1. Zn nucleation data :a) SEM image of wall deposit, b) wall deposit axial profile, c) TEM images of the outlet particles. Nucleation temperature T =660 K.

The situation is quite different in the case of Bi. At the outlet of the tube we observed the aggregates of small primary particles. Thus, to estimate the nucleation rate one should account the mean number of primary particles in aggregates. As the nucleation temperature is higher than the melting point, it is not possible to determine the nucleation zone just by the wall deposit SEM images. Additional methods are to be involved. One of them is light scattering. The light beam passes in the axial direction and the beginning of light scattering gives some information on the location of zone of maximum nucleation rate. Besides, the method of the "supersaturation cut-off" gives an additional information about the nucleation rate. The last experimental technique is as follows. A metal grid is inserted to the quartz tube perpendicularly to the flux. The outlet aerosol concentration is measured continuously. When the grid is downflow essentially after the nucleation onset point the outlet concentration is not disturbed by the presence of grid due to the low particle-to-grid diffusion deposition efficiency (because of the large size of particles). When moving the grid upflow the outlet concentration is decreasing (due to the vapor-to-grid deposition as well as the increase the particle-to-grid deposition efficiency) and the maximum rate of decrease of concentration corresponds to the region of maximum nucleation rate. The numerical simulation of vapor-to-particle transformation coupled with the experimentally measured axial and radial temperature profiles was also made. The simulation included wall vapor deposition, nucleation, particle growth due to vapor deposition and coagulation, particle wall deposition (diffusion + thermophoresis). An example of comparison of simulation results with the experimental measurements is shown in Fig. 3.

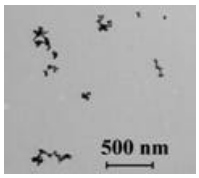

Fig. 2. TEM image of Bi aggregates. T = 710 K

Fig. 3. Bi concentration (as a constituent of both vapor and aerosol particles), light scattering intensity, nucleation rate vs. axial coordinate. Symbols and noisy line - experiment, smooth lines - simulation. T = 710 K.

[3]Aerosol & Particle Technology Laboratory, CERTH/CPERI, P.O. Box 60361, 57001 Thessaloniki, Greece
Keywords: fractal aggregates, friction, mobility radius, radius of gyration.
A.D. Melas: Anastasios.Melas@jrc.ec.europa.eu

Aerosol particles are of great importance because they influence the climate via direct and indirect processes and they may also induce adverse human health effects. Many aerosol particles are fractal-like objects composed of primary spherical monomers, e.g., combustion-generated nanoparticles. Their transport properties are characterized by the mobility radius R_k which is the radius of a spherical particle with the same friction coefficient under similar dynamic condition. The aggregate diffusion coefficient becomes $D_k = k_B T/6\pi\mu R_k$, where μ is the fluid viscosity, T the fluid temperature, and k_B Boltzmann's constant.

In this study we use a numerical method to calculate the mobility radius of fractal aggregates composed of k identical, spherical primarily particles (monomers of radius R_1) in the continuum regime, and to correlate it to their radius of gyration R_g. The aggregates are generated via a tunable cluster-cluster algorithm (Thouy and Jullien, 1996) as a function of a prescribed fractal dimension d_f to satisfy the scaling law $k = k_f(R_g/R_1)^{d_f}$, with k_f the fractal prefactor.

Experimental studies on the transport properties of nanoparticles have shown that the total mass transfer coefficient times the aggregate mobility is constant (Keller *et al.*, 2001). This approximate relationship holds for a large range of mobilities, and it is independent of the particle shape and chemical nature. Consequently, the molecule-aggregate collision rate K_k, which is proportional to the mass transfer coefficient, is proportional to the friction coefficient. The collision rate is calculated from the steady-state molecular diffusion equation via integrating the molecular diffusive flux over the aggregate surface. The appropriate boundary conditions are total absorption on the aggregate surface, fluid density $\rho = 0$ on the surface, and $\rho = \rho_\infty$ far from it. The k-aggregate friction coefficient, and its mobility radius, is obtained from the ratio of two molecular collision rates: the molecular collision rate with the k-aggregate and the molecular collision rate with a monomer K_1. Specifically,

$$\frac{\beta_k}{\beta_1} = \frac{K_k}{kK_1} = \frac{R_k}{kR_1} \quad ,$$

where the aggregate friction coeffient is $f_k = km_1\beta_k$, with β_k its average friction coefficient per unit monomer mass, and m_1 the primary-particle mass.

Isella and Drossinos (2011) validated this method for straight chains (d_f=1, $k_f = \sqrt{3}$) by solving the diffusion equation in cylindrical coordinates. We reproduced their calculations in 3d. Furthermore, we calculated the average friction coefficient of two three-dimensional, symmetric shapes composed of eight particles: a cube and a rectangle. The simulations were performed with the commercial finite-element code COMSOL. A comparison of our results with average friction coefficients calculated from a multipole expansion of the Stokes velocity (Filippov, 2000) is presented in Table 1. The good agreement suggests that the method is reliable to determine the friction coefficient of aggregates with $d_f \neq 1$.

Structure	Filippov (2000)	Collision rate
Cube ($2\times2\times2$)	0.293	0.290
Rectangle ($2\times4\times1$)	0.361	0.366

Table 1: Friction coefficient of two symmetric objects.

According to the tunable cluster-cluster algorithm the computer-generated fractal aggregates (composed of uniform spherical primary particles) can have prescribed fractal dimensions between 1 and 2.5. A typical 256-monomer cluster is presented below.

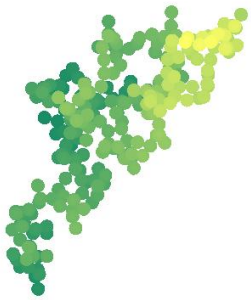

Figure 1: A random 256-monomer aggregate of $d_f = 2$.

Keywords: DMA, Mass spectrometry, mobility, proteins
Presenting author email: anne.maisser@univie.ac.at

Differential mobility analysis (DMA) has been widely applied for mobility measurements of electrosprayed, charge reduced globular proteins. In conjunction with mass spectrometric measurement (MS), DMA permits examination of the density and structure of proteins in the gas phase. In previous studies by Bacher *et al.* (2001), and Kaddis *et al.* (2007) a gas-phase electrophoretic mobility molecular analyzer (GEMMA, TSI Inc.) has been used. This device consists of a modest resolution DMA (the TSI nano-DMA) in combination with an electrospray aerosol generator (EAG) and a condensation particle counter (CPC). A linear relation between particle diameter and the 1/3rd power of the protein ion mass has been found in these studies. However, the density calculated from those measurements is ~0.6 g cm^{-3}, which, when compared to density of peptides (~1.35 g cm^{-3}), is anomalously low. While mobility measurement of charge reduced protein ions is no doubt a promising analytical technique for protein structural analysis, the questionable protein density inferred from these measurements casts doubt on the conclusions drawn in prior work. In an effort to better understand the structure of gas-phase protein ions, we have performed systematic measurements of the mobility diameters of various protein ions in air with a higher resolving power DMA (the Nanoengineering ½ mini DMA, which has a resolving power of ~25, Fernandez de la Mora, and Attoui, 2008) than has been used in prior work.

Experimental Results

Five different proteins in the sub 10 nm size range were examined: Lysozyme, Cytochrome C, Myoglobin, Ovalbumin, and Bovine Serum Albumin.

Gas-phase protein ions were produced using the TSI electrospray aerosol generator, in which a Po-210 radioactive alpha source is used for charge reduction of the highly charged droplets generated during the electrospray process. The electrospray was operated in Cone-jet mode, which was verified by both measurement of the electrospray current as well as visual observation of the electrospray cone. To produce protein ions, solutions were made in two different buffer solutions: a 20 mM ammonium acetate aqueous buffer thought to prevent the denaturation of proteins during the electrospray process, and a strongly denaturing formic acid in 50:50 methanol to water buffer solution. For each electrosprayed protein, the mobility spectra was determined by stepping the DMA voltage with a constant step size. The measured mobilities were inverted to mobility diameters using the Stokes-Millikan equation. In addition to the mobility measurements the same proteins were investigated for their molecular mass using a TOF-MS (QSTAR Pulsar I, Applied Biosystems). In that case a home made electrospray source, without charge reduction is used.

The relation between measured mobility diameters and protein ion masses is shown in Fig. 1. The data points were fitted with a power function $y=cx^3$ were c is a constant.

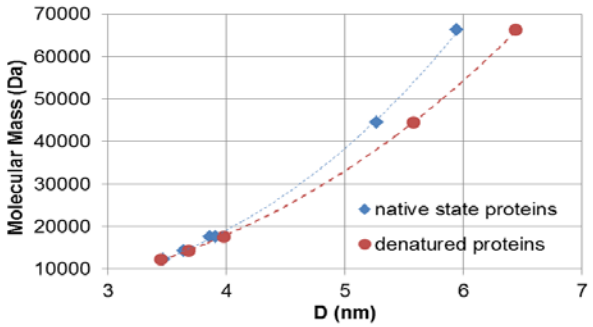

Figure 1. Mobility diameters of singly charged monomers of native state proteins and denatured proteins

The mean density found from measured mobility diameters of proteins electrosprayed from non-denaturing buffer solutions is 0.970 ± 0.043 g cm^{-3}. For denaturing buffer solutions the density is slightly less with a mean value of 0.863 ± 0.06 g cm^{-3}. These values are significantly higher than what has been found with standard DMA instruments before, but are in good agreement with recent DMA-MS measurements of non-charge reduced protein ions (Hogan & Fernandez de la Mora, 2011) as well as measurements made in N_2 with a drift tube mobility spectrometer (Bush et al., 2010).

Keywords: fibrous filter, filtration, numerical simulation, particle deposition

INTRODUCTION

When deposit accumulates inside a fibrous filter the fluid flow through the filter, and hence the filters collection efficiency, is altered. Although this is well known, it is difficult to model the particle build up within a filter. However it is crucial that a full understanding of the process of particle deposition and its effects upon further deposition is obtained in order to understand the performances of fibrous filters. We have been developing a numerical model of fibrous filtration aimed at investigating deposition due to various mechanisms and the effect filter properties and particle characteristics have upon it (Dunnett and Clement 2006, 2009). We have shown that, for small particles where the dominant mechanism by which particles deposit is diffusion, the porosity of the deposit formed does not significantly influence further deposition. For larger particles the porosity of the deposit has been seen to have a greater influence upon the flow field, and hence upon particle behaviour. In this paper we consider particles for which interception is the main mechanism of deposition.

NUMERICAL MODEL

In earlier work, Dunnett and Clement (2009), a numerical model has been developed which determines the flow field, and particle motion, around a single fibre which has a porous deposit made up of collected particles on its surface. Flow through the porous material is described by the Darcy equation in the model. Neighbouring fibres are taken into account by the application of boundary conditions. Further deposition of particles onto the porous surface has then been determined. It was found that the parameter $s = \kappa/\delta$ was the main factor determining the deposition mechanism. In this expression κ is the ratio of the particle to fibre diameters also known as the interception parameter, and δ is the non-dimensional thickness of the diffusion layer. For $s<1$ diffusion is the dominant mechanism of deposition, for $s=O(10^0)$ interception dominates and for large values of s impaction becomes important. For small particles for $s<<1$ where diffusion is dominant, deposition remains mainly spherically symmetric around the fibre as the deposit builds up and the porosity does not significantly affect further deposition. However as particle size increases and $s>1$ then the porosity has a more significant affect. In this work deposition by interception has been considered and we will report the results obtained from our model as the deposit builds up. Initial results have shown that the shape of the deposit formed is dependent upon the flow through the initial porous deposit. As an example, the particle build up is shown in Figure 1a for the case when $\kappa=0.05$ and $\varphi=0.9$ when the numerical model has been used to build the deposit up in layers starting with a clean fibre. Here φ is the fraction of the porous media that is occupied by void space. In Figure 1b the particle build up is shown also for $\kappa=0.05$ and $\varphi=0.9$ but in this case it has been assumed that the fibre initially has a layer of deposit on it, shown by the line in the Figure flattened at the front

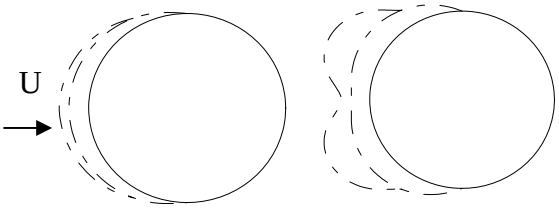

Figure 1a. Figure 1b

As can be seen the shape of the initial deposit has a significant effect upon the subsequent deposit. The deposit shown in Figure 1b resembles that observed by Kanaoka et al (1986) and indicates that the assumptions made in the numerical model may lead to inaccuracies for the initial particle build up.

The validity of the assumptions made is being investigated. We find that Darcy's equation should ideally be replaced by the Brinkmann equation for the porous flow when the deposited layer is thin. We also investigate the effect of various parameters as the deposit builds up.

Break-up of agglomerated TiO_2 particles due to impaction

Ihalainen M.[1,2], Lind T.[1], Güntay S.[1], and Jokiniemi J.[2,3]

[1]PSI Paul Scherrer Institut, The Laboratory for Thermal-Hydraulics, CH-5232 Villigen PSI, Switzerland

[3]VTT Technical Research Centre of Finland, Fine Particles, P.O. Box 1602, 02044 VTT, Espoo, Finland

Keywords: de-agglomeration, impactor.

The interparticle forces in an agglomerate significantly affect how that agglomerate behaves when it is stressed with external forces, i.e. whether the agglomerate breaks up, bounces or sticks to the surface during impaction onto a surface. During a postulated pressurized water reactor (PWR) steam generator tube rupture accidents involving core melt, agglomerate behaviour during impaction at high velocity on tube surfaces adjacent to the breach needs to be characterized (Güntay *et al*., 2004). Possible deagglomeration during impaction might modify the physical properties of the particle, e.g., the particle size which is one of the key parameters affecting further deposition/transport behaviour in the secondary side of the steam generator.

In this study the agglomerates are impacted onto a surface at controlled conditions and the bond energies are estimated from several measured quantities. Similar approach to study agglomerate break up has been used in earlier empirical studies (Froeschke *et al*., 2003; Seipenbusch *et al*., 2007), however in this study, in addition to the break-up, the study of the bounced particles due to the impaction is also emphasised. The conditions leading to particle bouncing and the characteristics of the bounced particles will be studied.

A chemical vapour synthesis was used to generate TiO_2 agglomerates and a differential mobility analyzer (DMA) was used for size classification of the agglomerates. In these measurements electrical mobility of 250nm for the agglomerates was used.

The agglomerates were impacted onto an impaction plate located in a single stage Micro-Orifice Uniform Deposit Impactor (MOUDI). There was also a Transmission Electron Microscope (TEM) grid on the impaction plate for the TEM analysis of the impacted particles. The agglomerate impaction velocity was adjusted by changing the pressure difference over the impactor. The impaction velocities were estimated by calculating the particle trajectories with Euler method. The gas properties, e.g. gas velocities, needed to calculate the particle trajectories were evaluated with the Computational Fluid Dynamics (CFD) modeling. Similar method was previously used by e.g. Arffman *et al*, 2011.

The bounced particles were measured with a Scanning Mobility Particle Sizer (SMPS), an Electrical Low Pressure Impactor (ELPI) and a TEM-grid sample. For these measurements the air stream after the impactor, which is at low pressure, was collected to a sampling chamber, which was designed and built for this purpose (Ihalainen *et al*. 2010). After the collection of the sample the chamber was pressurized to the normal pressure and the measurements from the chamber were carried out. The measurements were also conducted without the impaction plate. This way the intact agglomerates could be sampled and studied from the chamber, as the agglomerates flow through the same measurement set-up but without impaction.

TiO_2 agglomerates were impacted onto an impaction plate at different velocities. In Figure 1. the size distributions of the bounced particles, measured with the SMPS, are shown. As the impaction velocity increases the size of the particles decreases, i.e. agglomerate fragments into smaller pieces. The number concentration of the bounced particles increased as the velocity increased. Further analysis of the break-up process will be presented, as well as particle shape characterization. In addition, impacted particles will be characterized.

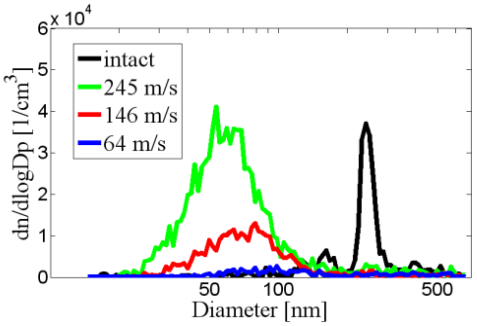

Figure 1. Size distributions of the TiO_2 agglomerates before impaction (intact) and the bounced particles

Presenting author email: francois-xavier.ouf@irsn.fr

The manufacturing of nanoparticles is increasing and opens new applications and economical developments. According to a recent report of the National Science Foundation, the nanomaterials marketplace will represent in 2010-2015 more than 300 billions $. Nevertheless, these economical concerns should not occult the social impact of nanoparticles and investigations dealing with toxicity of such products must be carried out. As a consequence of this social concern, the containment of nanoparticles during production processes is a key issue to reduce as much as possible workers exposure. In this field, dynamic containment devices like glove boxes associated to High Efficiency Particulate Air filters are a widely used solution and the question of penetration of nanoparticles through media and clogging (Kim et al., 2009a and b) of such filters must be investigated.

The aim of this study is to measure experimentally the porosity of cake deposits formed during filtration of nanoparticles aggregates and to propose a theoretical description of the clogging of filters by such particles. The experimental device presented in figure 1 is composed of two different sources of nanoparticles aggregates; a spark discharge generator (PALAS GFG 1000) with carbon electrodes and a combustion aerosol generator using propane as fuel (miniCAST 5201 Jing.).

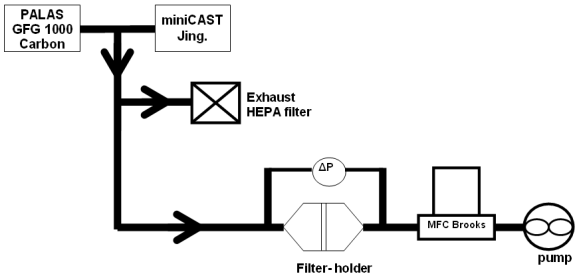

Figure 1. Experimental device of clogging of media by nanoparticles aggregates

A filter holder is implemented at the outlet of these aerosol generators, the filtration flow-rate is controlled by a mass flow rate controller (MFC Brooks 5850) and the pressure drop is measured with a differential pressure transducer (Wöhler DC2000 Pro). In order to reduce the in-depth filtration regime, PTFE membranes (Millipore FSLW04700 with 3.0 µm pore size) have been used and the deposited mass of nanoparticles has been measured with a METTLER AE 240 weighing cell with a resolution of 0.01 mg. The filtration surface area has been measured with an optical microscope and the height of the cake with a focus-variation surface metrology system (InfiniteFocus ALICONA). The porosity of the cake ε is computed according to the following relationship:

$$\varepsilon = 1 - \frac{M_c / \rho_{pp}}{H.A_f},$$

where M_c is the mass of the cake, ρ_{pp} is the density of nanoparticles (kg/m^3), H the height of the cake (m) and A_f is the filtration surface area (m²). Table 1 presents mean porosity obtained for the following experimental conditions.

Table 1. Experimental conditions and mean porosity

Aerosol generator	GFG 1000		CAST	
Monomer diameter (nm)	7		19	
Fractal dimension	2		1.6	
Density (kg/m^3)	2000		1800	
Filtration velocity (cm/s)	1.1	8.8	1.1	8.8
Mean porosity	**0.987**	**0.985**	T.b.m.	

T.b.m.: to be measured

According to our results for the GFG 1000, one must noticed that the porosity is not significantly modified by the filtration velocity. A mean value close to 0.986 can be proposed to be typical of our nanoparticles deposits on membrane in the range 1.1 – 8.8 cm/s. Further investigations are actually conducted on the CAST generator in order to underline the influence of the size of primary particles/aggregates and the fractal dimension. Finally, a theoretical description of the clogging of filter by nanoparticles aggregates, including the fractal morphology of such particles, will be presented and compared to experimental results.

Transfer of gas-borne carbon nanoparticles onto liquid surfaces

D. Koch and A.P. Weber
Institute of Particle Technology, Clausthal University of Technology, 38678 Clausthal-Zellerfeld, Germany
Keywords: nanoscale carbon particles, surfactants, deposition, bubble column.
Presenting author email: koch@mvt.tu-clausthal.de

The transfer of gas-borne nanoparticles into a liquid consists of a diffusional transport step onto the liquid surface, the wetting of the adsorbed nanoparticles and the incorporation into the liquid. Such processes are relevant for gas cleaning in wet electrostatic precipitators and wet scrubbers, but also for the recovery of nanoparticles. Basis for the present study was the synthesis of organic nanoparticles from pharmaceutical substances by Rapid Expansion of Supercritical Solutions (RESS) which are discharged into aqueous solution to prevent further growth by coagulation (Türk and Lietzow, 2004 and 2008). To stabilize the small particle size and, therefore, to preserve the high bioavailability, surfactant molecules have been added to the solution. Thus, the nanoparticles arriving at the interface encounter a surfactant-loaded liquid surface.

In order to study the deposition behaviour of nanoparticles in different suspensions, nitrogen-borne carbon nanoparticles are generated in a spark generator. The aerosol is injected via a nozzle (diameter: 150 μm) into a bubble column, in which the different suspensions are filled. The internal aerosol flow is expected to depend on the properties of the gas-liquid interface. To vary the interface properties, different surfactants (e.g. polyvinylpyrrolidone (PVP) of the types K25 and K90) with varying concentrations are used.

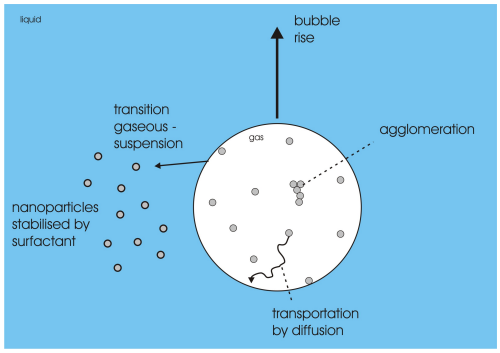

Figure 1: Transfer steps of gas-borne nanoparticles.

During the experiment, the mass transfer of the carbon particles (see fig. 1) is measured twice by an extinction device, from which the precipitated mass in the liquid can be calculated, and furthermore by a “Scanning Mobility Particle Sizer (SMPS)”. According to these measurement results, the deposition efficiency of the liquid phase can be calculated by the quotient of the number concentration before and after the bubble column. Table 1 shows the experimental results for the deposition efficiency of carbon nanoparticles (mean mobility equivalent diameter: $60-70$ nm , number concentration: $1.6\cdot10^{7}$ cm^{-3}).

Solution	Concentration (% (weight))	Deposition efficiency (-)
Water	-	0.71
PVP K25	0.4	0.18
PVP K25	1.0	0.16
PVP K90	0.4	0.24
PVP K90	1.0	0.25

Table 1: Deposition efficiency of pure water and different PVP solutions.

In order to proof the experimental results, existing models for the transfer of aerosol particles to the interface in rising bubbles (Fuchs, 1964; Pich and Schütz, 1991) can be used. Fuchs introduced the model for larger bubble sizes (0.3 to 0.6 cm), bigger particles ($1\cdot10^{-7}$ m) and pure water as liquid. For the particle sized used here, the diffusional deposition is the major process, which takes mainly place in the equatorial region of a gas bubble and depends on the internal circulation inside it (fig. 2).

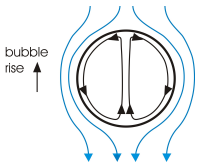

Figure 2: Internal circulation (Hill’s vortex) inside a gas rising bubble.

In this contribution further separation efficiencies of different systems (combination of surfactant and concentration) depending on the relative bubble velocity will be presented, which are the profit of additional experiments. Additionally the Fuchs model will be discussed and possible extensions for the description for the deposition of nanoparticles in surfactant-containing liquids will be proposed.

Keywords: Nanoparticles; Aerosol filtration; Charged particles.
Presenting author email: virgomez@unizar.es

This abstract presents the results of an experimental investigation on the deposition of charged and neutral nanoparticles on wire screens by the combined mechanisms of diffusion and image force. Experiments were performed with particles having diameters below 10 nm and using four different flow rates and three kinds of wire screens.

As the experimental results have shown, the single fiber efficiencies for the mechanisms of image force, $\eta_{IM,}$ and diffusion, η_D, are of the same order of magnitude and, furthermore, they are both much smaller than one. Under these conditions, the total capture efficiency can be approximated as the sum of the efficiencies by diffusion and image force deposition, $\eta = \eta_D + \eta_{IM}$. The efficiency for the image force mechanism will be obtained from fitting of experimental results to an expression of the form $\eta_{IM} = AK_{IM}^B$, where

$$K_{IM} = \left(\frac{\varepsilon_f - 1}{\varepsilon_f + 2}\right)\frac{Cp^2e^2}{12\pi^2\mu\varepsilon_0 u d_p d_f^2} \qquad (1)$$

is the image forcé number (ε_f : dielectric constant of the fiber; ε_o: vacuum permittivity; C: slip correction factor; p: number of charges per particle, e: elementary charge; μ: air viscosity; u: air flow velocity; d_p:: particle diameter; d_f: fiber diameter).

For the experiments, an evaporation-condensation NaCl aerosol was charged in a ^{241}Am neutralizer. Positively charged particles of known size were withdrawn from a differential mobility analiyzer (DMA, TSI short column, L=11.11 cm) operated at an aerosol-to-sheath flow rate ratio of 2/20. Since our study has been restricted to particle size below 10 nm, all the particles classified by DMA were singly charged. These positively singly-charged monodisperse particles can follow two alternative routes: one, containing a ^{241}Am neutralizer and an electrostatic precipitator, and the second one, a bypass route to transport the +1 particles into the filter unit.

The filtration unit consists essentially in a grounded cylinder made of brass having a length of 186 mm and inner diameter of 8 mm. A series of five rings, 4 mm in width and made of brass, were placed inside the main cylinder. The wire screens were placed in between any two consecutive rings, so that the screen fibers are in contact with the grounded cylinder.

Three types of screen were used in the experiments; their characteristics are listed in Table 1. The “sandwich” wire screen consisted of a gold wire screen between a pair of aluminum wire screens; it has been experimentally assessed and its characteristics are also showed in Table 1**.** Penetrations were determined for varying values of: (i) aerosol flow rate through the filter; (ii) particle size; and (iii) number of charges on the particles (0, +1).

Material	Aluminium	Stainless steel	Sandwich
Fibre diameter, d_f (μm)	100	66	55
Opening (μm)	110	103	
Thickness (μm)	260	120	524
Density (g cm^{-3})	2.70	7.96	
Surface density (g cm^{-2})	0.02	0.03	
Open area fraction (-)	0.27	0.37	
Solid volume fraction (-)	0.30	0.32	0.32
Screen parameter , S	1.44	1.08	5.77

Table 1. Characteristics of the wire screens employed

From the experimental results, the following correlation has been obtained:

$$\eta_{IM} = 36.06K_{IM}^{0.55} \qquad (2)$$

The total penetration can then be calculated as

$$P = \exp\left[-nS\left(2.7Pe^{-2/3} + 36.06K_{IM}^{0.55}\right)\right] \qquad (3)$$

where n is the number of screens, and is compared in Figure 1 with typical experimental results obtained in the course of this work.

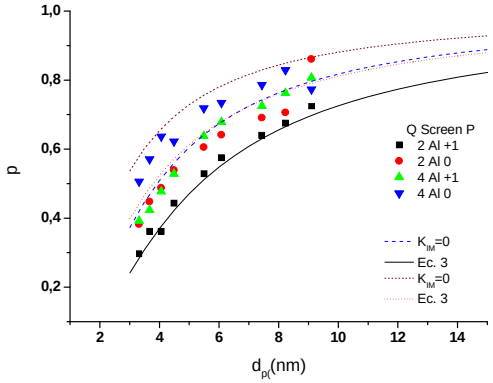

Figure 1. Comparison between experimental penetrations and those calculated with Ec. (3) for 2 and 4 aluminium screens and aerosol flow rates of 2 lmin^{-1} and 4 lmin^{-1}.

Session 3A: Bioaerosols / Specific Aerosol Types

Ergosterol, arabitol and mannitol as tracers for biogenic aerosols in the eastern Mediterranean

N. Burshtein, N. Lang-Yona, and Y. Rudich

Department of Environmental Sciences, Weizmann Institute of Science, Rehovot 76100, Israel

Keywords: bioaerosols, fungi, ergosterol, arabitol, mannitol.
Presenting author email: noa.burshtein@weizmann.ac.il

Aerosols containing biological components can have a significant effect on human health by causing primarily irritation, infections and allergies. Specifically, airborne fungi can cause a wide array of adverse responses in humans depending on the type and quantity present.

In this study we used chemical biomarkers for analyzing fungi-containing aerosols in the eastern Mediterranean region during the year 2009 in order to quantify annual fungal abundances. The prime marker for fungi used in this study was ergosterol, and its concentrations were compared with those of mannitol and arabitol which were recently suggested to also correlate with fungal spores concentrations (Bauer et al., 2008a).

	Arabitol vs. mannitol	Mannitol vs. ergosterol	Arabitol vs. ergosterol
Winter	−0.18	−0.06	−0.03
Spring	**0.78**	**0.60**	**0.81**
Summer	**0.83**	−0.11	−0.24
Autumn	**0.66**	***0.41***	**0.66**

±0.70–1.00 – high correlation
±0.50–0.70 – moderate correlation
±0.30–0.50 – low correlation.

Table 1: Pearson coefficient (r) was used in order to determine the correlation between the markers during each season.

Back trajectory analysis, inorganic ions abundance, humidity and temperature were used in an attempt to identify sources as well as the dependence on seasonal and environmental conditions.

We found that the ambient concentrations of ergosterol, arabitol and mannitol range between 0 and 2.73 ng m−3, 1.85 and 58.27 ng m−3, 5.57 and 138.03 ng m−3, respectively. The highest levels for all biomarkers were during the autumn, probably from local terrestrial sources, as deduced from the inorganic ions and back trajectory analysis. Significant correlations were observed between arabitol and mannitol during the entire year except for the winter months. Both sugars correlated with ergosterol only during the spring and autumn.

We conclude that mannitol and arabitol might not be specific biomarkers for fungi and that the observed correlations during spring and autumn may be attributed to high levels of vegetation during spring blossoms and autumn decomposing. (Burshtein *et al. ACP, **11**, 829–839 (2011)).*

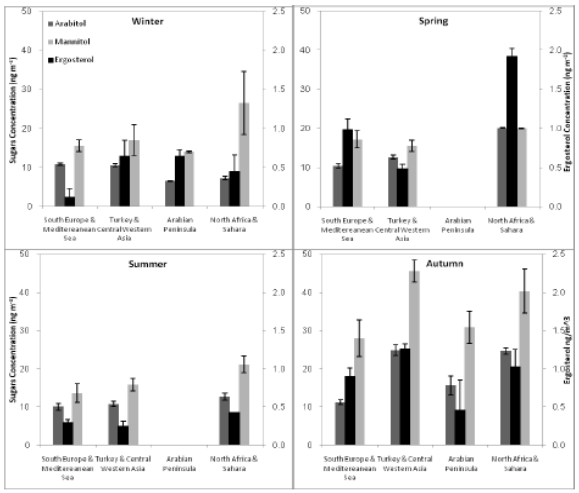

Figure 1: Average concentrations of the biomarkers divided to the typical air mass sectors, according to seasons.

Presenting author email: mgatari@uonbi.ac.ke

Understanding of the free tropospheric aerosol is important in the investigation of transboundary and interhemispherical contribution to local air pollution. The Global Atmosphere Watch (GAW) station is located on the northern western slopes of Mt Kenya (Fig. 1). It is on the equator at 37^0 E at altitude 3700 m and has free view in all directions thus offering a good site for free troposheric aerosol characterization (Henne et al 2008). Gatari et al (2009) reported high elemental concentrations of Ca, Fe and K in all analyzed $PM_{2.5}$ and PM_{10} samples implying high mineral dust in the aerosol. However the local soil dust influence due to the mountain winds was not assessed. This study was therefore designed to assess the contribution of long-range transported mineral dust and local contribution through mountain winds.

In August 2009 two cyclone samplers (BGI 400 personal samplers) and an Andersen dichotomous impactor were used to sample $PM_{2.5}$ and size segregated PM_{10} respectively. In August 2010 the measurements were repeated and an aerosol monitor (TSI model 8530 DUST TRAK II) fitted with a $PM_{2.5}$ sampling head was included. The measurement reported here were from 10 day field campaign at the GAW station which included random collection of top soil samples from the area.

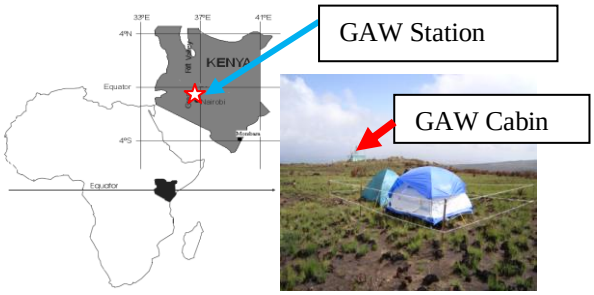

Figure 1. The location of Mt Kenya in Kenya in Africa

Teflon filters (Pall R2PJ037) were used in all the samplers. The monitor gave real time readings and particles on its internal filter. All the filter samples from all the instruments were analyzed for elemental content using EDXRF. The soil samples were analyzed for particle size distribution using a Laser particle diffraction analyzer (LPDA) (Horiba model LA-950V2), and for soluble and insoluble elemental content by TXRF (Bruker model AXS S2 PICOFOX). A digital microbalance (Mettler model MT5) was used for gravimetric determination of the filter collected PM. The LPDA uses Mie theory and its measurements are in equivalent spherical particle diameter (Eshel et al 2004).

The mean $PM_{2.5}$ concentration was 10 µg m^{-3} out of which 22 % was nighttime contribution on average. The elemental concentrations of Ca, Fe, K and Ti were 50 ± 29, 50 ± 12, 31 ± 2, 4 ± 1 g kg^{-1} in the particulate aerosol, respectively and 5 ± 0.005, 42 ± 0.01, 5 ± 0.006, 8 ± 0.005 g kg^{-1} in the top soil. These results and in addition the small available percentage of $PM_{2.5}$ particles in the top soil implied negligible contribution of Ca and K bearing particles to the aerosol while Fe and Ti was substantial. The study also showed high daytime contribution of mineral dust and that which is from long range transport as a major component that needs further investigation besides other aerosol components.

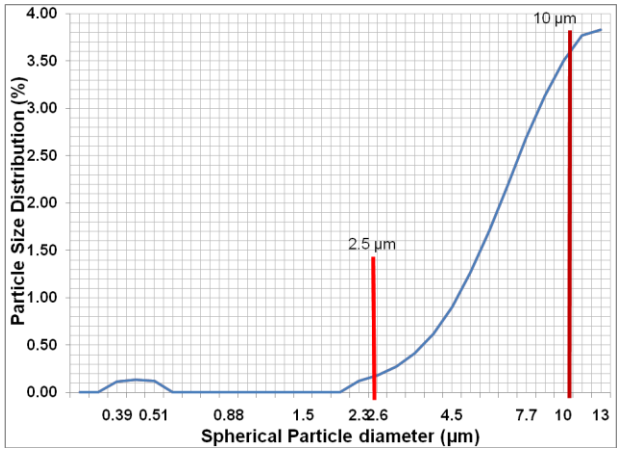

Figure 2. Particle size distribution in the top soil within the area of the GAW site on Mt Kenya.

Abstract

Numerous threats from biological aerosol exposures, such as H1N1 influenza, SARS, bird flu, and bio-terrorism necessitate the development of a real-time bioaerosol sensing system, which however is a long standing challenge in the field. Here, we reported real-time detection of airborne influenza H3N2 viruses by integrating electrically addressable silicon nanowire (SiNW) sensor devices with microfluidics and a bioaerosol-to-hydrosol air sampling system. Influenza A viruses were aerosolized into exposure chamber, and collected by an automated electrostatic sampler (AES) at a sampling flow rate of 5 L/min and transported onto the SiNW sensor device via microfludic channel via a peristaltic pump at a flow rate of 0.4 L/min in a real-time manner. The electrical conductance of the SiNW device was monitored using a pre-amplifier and a lock-in amplifier.

Results show that when airborne influenza H3N2 virus samples were collected and delivered to antibody-modified SiNW devices, discrete nanowire conductance changes were observed within seconds. However, the conductance levels remained relatively unchanged when indoor air or clean air samples were delivered. Quantitative polymerase chain reaction (qPCR) tests indicated that higher virus concentrations in the air samples corresponded to higher conductance levels in the SiNW devices. The sensing system here has been demonstrated to have the capability to monitor the airborne presence of influenza A viruses in a real-time manner, typically from 1 to 2 minutes. This response time scale exceeds many of those available bioaerosol sensing systems. The work here opens a new arena for real-time monitoring of biological aerosols by integrating the technologies in different disciplines, holding great promise in the combat of fighting both infectious diseases and bio-terrorism.

Keywords : Influenza A H3N2 virus, bioaerosol, Silicon Nanowire, aerosol-to-hydrosol, qPCR, real-time detection

Characterization of aerosol from ship emissions in the Central Mediterranean Sea (Lampedusa island)

One of the most important task for atmospheric research, air pollution and climate policy is the evaluation of ship emissions and their impacts on environment.
Studies on ship aerosol contribution are so far based on inventories and modellistic approach (e.g. Marmer et al., 2009 and references therein) and show that the simulated contributions of ships to air pollutant levels in the Mediterranean atmosphere are significant, although strongly dependent on the inventory applied. The validation of the consistency of ship emissions inventories with observations is a difficult task due to lack of continuous observations over the open sea.
We present here the estimate of ship emissions to PM10 in Central Mediterranean Sea by chemical characterization of PM10 sampled at Lampledusa Island (35.5°N, 12.6° E).
Ship emissions events are identified using the soluble fraction of V and Ni in HNO_3 at pH1.5 (V_{sol} and Ni_{sol}). Events of ship aerosol presents V_{sol} higher than 6 ng m^{-3}; this threshold was established on the basis of V/Si enrichment factor with respect to the upper continental crust. The V_{sol} and Ni_{sol} are as average 80% of the total V and Ni content determined by PIXE during the identified events of ship aerosol. On the contrary the soluble fraction results less than 50% in events characterized by high crustal content (Saharan dust events).

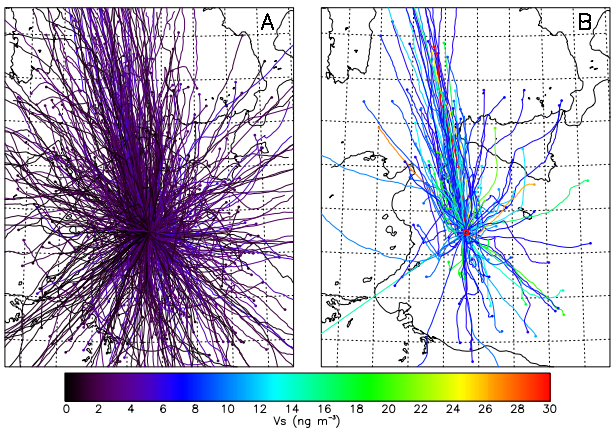

Figure 1. 18-hours back trajectories corresponding to the measurements of V_{sol} less than (plot on the left) or greater/equal to (plot on the right) 6 ng m^{-3}.

Back trajectory analysis (Fig.1) confirms that the selected events are affected by sea-going ships and not by local pollution (i.e. Lampedusa harbour), establishing their origin from the ship tracks crossing the Strait of Sicily. The longer and more relevant events are related to episodes lasting more than one day, confirming that the ship contribution to aerosol load in central Mediterranean can be regarded as a "continuous" emission corresponding to the main ship track that increases the aerosol load and whose contribution at Lampedusa is modulated by the atmospheric dispersion and transport.
Seasonal behaviour with summer maxima is observed for all the ship aerosol markers and in particular for the V_{sol}. Such a pattern can be explained by several factors: (i) increased photochemical activity of atmosphere in summer, leading to an increased production of secondary aerosol, mainly $nssSO_4^{2-}$, but also metals from heavy oil combustion related to particles containing sulphur, (ii) lower rain fall that increases the atmospheric life-time of aerosol species, (iii) higher marine boundary layer stability in summer.
A very intense event in spring 2008 was chemically and size characterised showing that elements arising from heavy oil combustion (V, Ni, Al, Fe) are distributed in the sub-micrometric fraction of aerosol and the metals are present as carbonates, idroxides or metallorganic compounds, so that they are dissolved in mild condition (HNO_3, pH1.5).
Taking into account the source emission profile obtained from exhaust samplings at sea-going ships (Agrawal et al., 2008) it was possible to estimate the ship aerosol contribution to the total PM10 sampled at Lampedusa island. In the selected events we found that aerosol from this source contributes as average for about 0.9 μg m^{-3} and represents as average the 3% of the PM10 mass.

Keywords: carbonaceous aerosol, elemental composition, lowermost stratosphere, upper troposphere

Introduction

Previous measurements in the upper troposphere (UT) and the lowermost stratosphere (LS) have indicated the presence of a carbonaceous component in the aerosol (Murphy et al.,1998, Nguyen et al. 2008, Martinsson et al. 2009). Here the occurrence of carbonaceous and sulfurous particles around the tropopause is investigated. The data were taken from the CARIBIC (Civil Aircraft for Regular Investigation of the atmosphere Based on an Instrument Container) platform, where instruments onboard a Lufthansa passenger aircraft on inter-continental flights are implemented for examination of the atmospheric composition in the UT/LS at 8-12 km altitude (Brenninkmeijer et al. 2007). CARIBIC undertakes aerosol sampling for chemical characterization, as well as measurements of particle number concentrations and mixing ratios of a large number of trace gases including O_3, CO, NO/NO_y, Hg, water (gaseous and condensed), acetonitrile, greenhouse gases and halogenated hydrocarbons. The CARIBIC dataset also contains data on meteorological conditions.

Methods

900 aerosol samples were collected during 200 flights with a typical sampling time of 100 minutes by an impaction technique (Nguyen et al., 2006). Specimen are then analyzed by quantitative multi-elemental analysis by PIXE (Particle-Induced X-ray Emission) and PESA (Particle Elastic Scattering Analysis) to obtain elemental concentrations for sulfur, iron, titanium, potassium, hydrogen, carbon, nitrogen and oxygen among others (Nguyen and Martinsson, 2007).

Results and Conclusions

The concentrations of particulate carbon and sulfur shows an increase from the tropopause into the LS, with a strong dependence on potential vorticity (PV). A seasonal cycle in the concentration to PV ratios is observed in the LS for ozone, carbon and sulfur (Fig.1).

The peak of the oscillations is found in the end of April to the beginning of May for carbon and ozone. The sulfur peak is shifted more than a month in respect to ozone and carbon, indicating different formation patterns for carbonaceous and sulfurous aerosol in the stratospheric circulation.

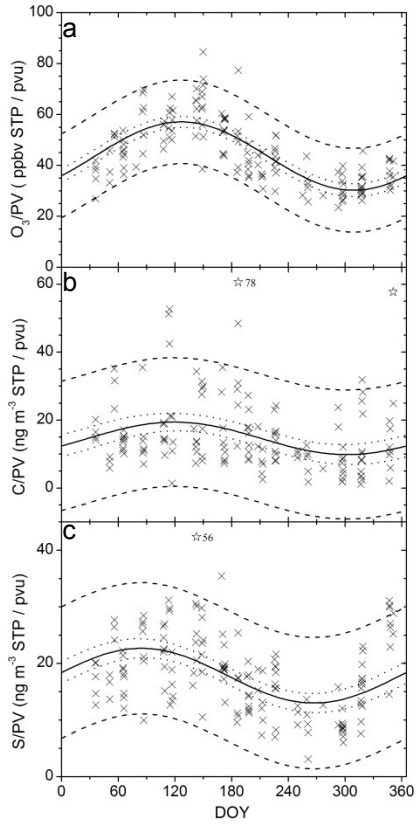

Figure 1. Concentration to potential vorticity ratios vs. day-of-year for a) ozone, b) particulate carbon and c) particulate sulfur, from stratospheric measurements. Solid lines shows regressions. Dotted lines shows 95% confidence interval for model. Dashed lines 95% prediction interval for data. Stars represents outliers not included in the model.

Presenting author email: darius.ceburnis@nuigalway.ie

Volcanoes represent a major source of natural aerosol, including ejected rock, ash, $nssSO_4$ and are contributing to the whole array of secondary processes either directly or by catalysing chemical reactions. Even passive (non-eruptive) volcanic emissions contribute significantly to natural sulphur cycle along with regional impacts as demonstrated by Ovadnevaite *et al* (2009).

Eyjafjallajokull volcano explosively erupted on April 14, 2010 and while it was a moderate eruption has caused havoc in European air space. Due to the dominated south-south-easterly flow from Iceland it had an impact on air quality as well with over 30 plumes of nss sulphate detected at Mace Head station on the west coast of Ireland (O'Dowd et al, 2011).

Volcanic ash was observed in aerosol samples at Mace Head station, about 1000km downwind from volcano, when several major ash plumes were encountered as demonstrated by increased sulphate concentrations (Figure 1). A combination of on-line (AMS) and off-line chemical analysis (IC and XRF) revealed significant chemical processing of ash during long-range transport including gypsum formation and mineralization of metal oxides. Major compound classes present in particulate mass during two major plumes are summarised in Table 1 exhibiting similar share of ash, $nssSO_4$ and sea salt in PM_{10} mass. More importantly, volcanic ash elemental composition was well preserved after 1000km long-range transport and dominated by silicon and aluminium oxides as they were in volcanic lava and ash fall-out.

In-situ volcanic ash was obtained from ash fall-out samples at various distances from volcano and different times during eruption period and was examined by physical and chemical methods. Ash samples were dissolved in water and atomised for size distribution measurements by SMPS and APS which spectra revealed not only the presence of super-micron particles, but significant amount of sub-micron ones. SEM images confirmed the abundant presence of sub-micron particles with the aforementioned elemental composition. The result confirmed that sub-micron particles associated with volcanic ash plumes in the atmosphere are made of not just by secondary formation of $nssSO_4$, but indigenous ash as well. These results should help to better constrain regional atmospheric models used to predict volcanic ash advections.

Table 1. Percentage contribution of major compound classes to particulate mass concentrations (24h) at Mace Head derived from XRF analysis.

Date	PM_x*, $\mu g/m^3$	Nss SO_4, %	Ash, %	Sea salt, %
	PM_{10}			
04/05/10	9.23	35	24	40
17/05/10	11.45	33	39	28
	$PM_{2.5}$			
04/05/10	3.53	76	22	1
17/05/10	5.03	64	30	7
	$PM_{2.5-10}$			
04/05/10	5.70	10	26	64
17/05/10	6.42	10	46	44

*PM_x concentrations exclude nitrate, ammonium, organic matter (all in negligible amount) and compound bound water (as in gypsum, sulphuric acid, etc.).

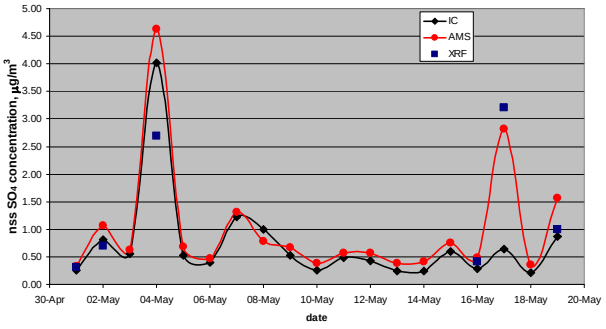

Figure 1. Time trend of 24h $PM_{2.5}$ $nssSO_4$ concentrations during May 2010 by IC, AMS and XRF. Significant volcanic plumes were detected on May 2, 4, 17 and 19.

This study presents new insights into volcanic ash formation and transformation in the atmosphere which should have significant climatic implications.

Keywords: new particle formation, particle growth, condensation sink, gas-phase sulphuric acid
Presenting author email: salma@chem.elte.hu

Number concentrations of atmospheric aerosol particles were measured by a flow-switching type differential mobility particle sizer (DMPS) in an electrical mobility diameter range of 6–1000 nm in 30 channels at the campus of the Eötvös University near central Budapest with a time resolution of 10 min continuously from 3 November 2008 to 2 November 2009. Air temperature, ambient relative humidity, solar radiation and wind speed were also recorded with a time resolution of 10 min at the campus. Concentration of criteria air pollutants including SO_2, O_3, NO_x, CO and PM_{10} aerosol mass were obtained from municipal authorities at a site near our measurements.

New particle formation and growth obviously occurred on 83 days, which represent 27% of all relevant days. The frequency is comparable to that for rural and background locations. Hence, new particle formation is not a rare phenomenon in Budapest. Its frequency showed an apparent seasonal variation with a minimum of 7.3% in winter and a maximum of 44% in spring.

New particle formation events are usually linked to increased gas-phase H_2SO_4 concentrations, which could not be unfortunately obtained for our measurement site, and, therefore, a simple but reasonable proxy containing both source and sink terms for H_2SO_4 was calculated from SO_2 concentration ($[SO_2]$), solar radiation (Rad) and condensation sink (CS) as:

$$[H_2SO_4] \propto \frac{[SO_2] \times Rad}{CS}.$$

The results are summarized in Table 1. It is seen that concentration of SO_2 did not change substantially for the event and non-event days. The larger value for the non-event days in winter is related to temperature inversions. Solar radiation was larger by a factor of ca. 2 for the event days than for non-event days over the whole year. The difference is, however, biased by the seasonal cycle of solar radiation via the seasonal variation of new particle formation frequency. Condensation sink was smaller for the event days than for the non-event days by approximately 30% over the year. In winter, daily average CS for the event days was smaller by 64% than for the non-event days. This can be explained by generally higher level of air pollutants – including pre-existing aerosol particles – in winter due to temperature inversions that often occur in Budapest in winter.

Table 1. Median SO_2 concentration, solar radiation (Rad), condensation sink (CS) and gas-phase H_2SO_4 proxy (Proxy) averaged separately for the days with (NPF yes) and without new particle formation event (NPF no) over the seasons and year.

Period	NPF	SO_2	Rad	CS $\times 10^3$	Proxy $\times 10^{-3}$
		[μg m^{-3}]	[W m^{-2}]	[s^{-1}]	[μg m^{-5} Ws]
Winter	yes	6.7	60	6.8	50
	no	8.6	37	18.7	18
Spring	yes	6.1	228	12.6	93
	no	6.1	182	14.4	63
Summer	yes	5.8	239	9.4	150
	no	5.8	244	13.7	114
Autumn	yes	7.5	183	15.4	90
	no	7.1	78	17.5	43
Year	yes	6.6	215	12.3	96
	no	6.8	104	15.6	47

The combination of these three effects caused that the median H_2SO_4 proxy was larger by a factor of about 2 for the event days than for the non-event days over the year, and similar tendency is observed for the seasons. This clearly indicates the relationship between new particle formation and gas-phase H_2SO_4. In summer, the proxy for the event days was larger by a factor of 1.32 than for the non-event days with almost identical solar radiation for the event and non-event days. In the studied area, new particle formation is favoured by low pre-existing aerosol concentration level, low condensation sink, and high solar radiation. At the same time, the formation process seems to be not sensitive to SO_2. This suggests that this precursor gas is always available in excess.

Influence of key aerosol, trace gas and meteorological parameters on new particle formation in Southern Spain

J.-M. Diesch[1], F. Drewnick[1], V. Sinha[2,3], J. Williams[2] and S. Borrmann[1,4]

[1]Particle Chemistry Department, Max Planck Institute for Chemistry, Mainz, 55128, Germany

[3] now at: Indian Institute of Science Education and Research, Mohali, 160019, India
[4]Institute for Atmospheric Physics, University of Mainz, Mainz, 55128, Germany
Keywords: particle nucleation, source regions, aerosol mass spectrometry, coastal location.
Presenting author email: j.diesch@mpic.de

Atmospheric particle formation and subsequent growth have been observed in different locations including coastal, rural and urban areas (Zhang *et al.*, 2004). Regardless of the environment, nucleation events are one of the major sources of ultrafine particles which are potentially hazardous to human health (Jeong *et al.*, 2010). Both sulfuric acid and organic precursors are believed to play a key role in particle formation and growth (Kulmala *et al.*, 2005).

Measurements of the ambient aerosol, various trace gases and meteorological parameters were performed at the Southern coast of Spain within the framework of the DOMINO (*Diel Oxidant Mechanisms In relation to Nitrogen Oxides*) project. The field campaign took place from November 20 to December 9, 2008 at the atmospheric research station "El Arenosillo". The station is located at the interface between a natural park, industrial cities (Huelva, Seville) and the Atlantic Ocean. Number and mass concentrations as well as PAH and black carbon concentrations were measured in PM_1 and size distribution instruments (OPC, FMPS, APS, ELPI) covered the size range from 5.6 nm to 32 µm. The chemical composition of the non-refractory aerosol in the submicron range was measured by means of an Aerosol Mass Spectrometer (Aerodyne HR-ToF-AMS). Gas phase species analyzers monitored various trace gas concentrations in the air and a weather station provided meteorological parameters.

The variability of the air composition associated with advection from different source regions affects the emergence and temporal evolution of nucleation events. Nucleation events occurring in continental air masses and the so-called "pollution events" measured when trajectories pass urban source regions exhibit different characteristics. For the fine particle aerosol fraction, a sharp transition to a predominant mode at 10 nm with subsequent growth of the diameter was typically observed for nucleation events (Figure 1a). Pollution events are characterized by clearly bimodal size distributions during the growth period indicating the additional occurrence of freshly formed particles of industrial origin (Figure 1b). This additional particle surface results in smaller growth rates (~2 nm/h) during pollution events compared to nucleation events in "cleaner" air masses (~3 nm/h). During nucleation events the number concentration of particles increased abruptly from $6*10^3$ to $7.5*10^4$ # cm^{-3} (formation rate: 14 cm^{-3} s^{-1}) however, maximum particle number concentrations were reached during pollution events (~$1.2*10^5$ # cm^{-3}). At the beginning of the nucleation events low PM_1 mass (0.9 µg m^{-3}) and gas phase concentrations (SO_2: 0.2 ppb) were measured. In contrast, pollution events were characterized by enhanced gas and aerosol mass concentrations, with sulfur dioxide and sulfate concentrations originating from industrial sources in particular, being substantially higher. Hence, different influences of anthropogenic and biogenic emissions onto particle formation and growth in urban and continental source regions can be identified. Generally, ultrafine mode particles were found to be more acidic during the particle growth period compared to the nucleation period in both cases.

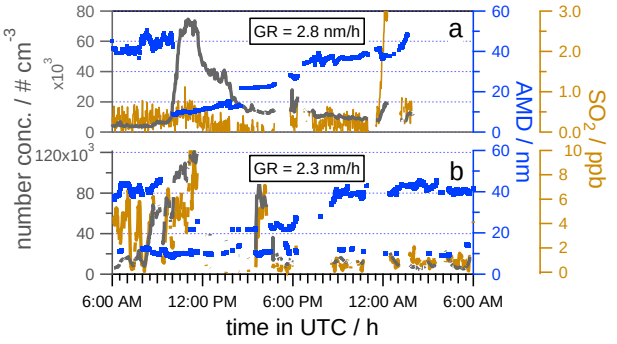

Figure 1. Variation of the number concentration (PM_1), arithmetic mean diameter (AMD, 5.6-560 nm) and sulphur dioxide concentration during a particle nucleation (a) and a pollution event (b) .

In addition to a detailed investigation of the characteristics of particle nucleation and pollution events, we will discuss differences of the measured parameters during nucleation, coagulation and growth periods. We will also focus on precursor gases, OH reactivity and meteorological conditions which favor the occurrence of new particle formation.

Keywords: Nucleation, Trajectory analysis, Ultrafine aerosols.

A year (6-April-2008 to 14-April-2009) of particulate monitoring was conducted at the remote coastal station of Finokalia (35°24′ N 25°60′ E) on the island of Crete, Greece in the Eastern Mediterranean. Ambient size distributions ranging between 0.8 – 40 nm were measured by an Air Ion Spectrometer (AIS) and between 10 – 600 nm by a Differential Mobility Particle Sizer (DMPS). 58 regional particle formation events were identified half of which occurred during the coldest months of the year (December-March).

A back trajectory analysis was conducted, using 20-day retroplume calculations with the particle dispersion model FLEXPART in backward mode and five (5) source regions were identified (West Crete, Greece, Turkey, East Crete, Marine). Particle formation was favored by air masses arriving from the west that crossed Crete or southern Greece prior to reaching the site (Table 1). This is consistent with the hypothesis of a missing reactant which has sources over land. When the air mass does not pass over Crete, it is conceivable that this reactant is exhausted and nucleation does not take place.

Table 1. Back-trajectory analysis of events.

	Airmass Origin				
	West Crete	Greece	Turkey	East Crete	Marine
Retroplumes investigated	216	161	298	185	186
Events	21	19	6	5	7
Normalized Frequency ($year^{-1}$)	102	123	21	28	39

Aerosol composition data, which were acquired during month-long campaigns in the summer and winter (named FAME-08 and FAME-09 respectively), suggest that nucleation events occurred only when particles were neutral (Fig. 1). This is consistent with the hypothesis that a lack of NH_3 which is not present in the gas phase during periods when the particles are acidic may limit nucleation in sulfur-rich environments (Jung *et al.*, 2008).

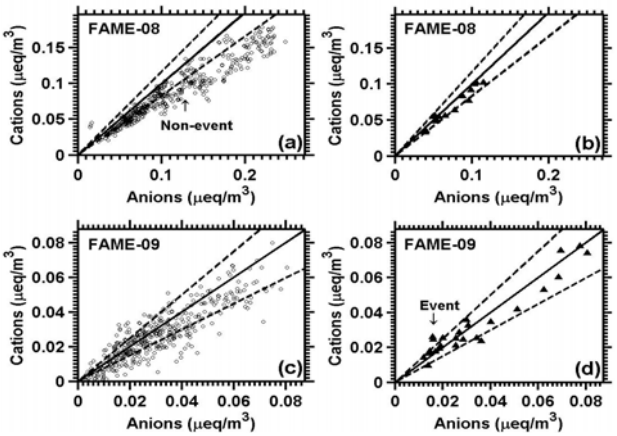

Figure 1. Cations versus anions during summer 2008 (FAME-08) and winter 2009 (FAME-09). (a) summer period without nucleation, (b) summer period during nucleation events, (c) winter period without nucleation and (d) winter period during nucleation events. Dashed lines correspond to one and two standard deviations from unity in the cases of FAME-09 and FAME-08, respectively. Solid line corresponds to neutral aerosol.

Nucleation was not limited by the availability of SO_2 alone, as nucleation events often did not take place during periods with high SO_2 or H_2SO_4 concentrations. The above results support the hypothesis that an additional reactant (other than H_2SO_4) plays an important role in the formation and/or growth of new particles (Berndt *et al.*, 2010). Our results are consistent with NH_3 or compounds which covary with it, being this missing reactant.

Introduction

Volcanic eruptions caused major weather and climatic changes on timescales ranging from hours to centuries in the past. Particles emitted during these eruptions absorb the incoming solar radiation, thus cooling the Earth (Zielinski et al. 1994). The volcanic particles that are injected in the atmosphere as primary particles (supermicronic ashes) are responsible for a cooling effect in the vicinity of the volcano, but these particles are rapidly deposited due to their large sizes. On another hand, sulphur dioxide is also substantially enhanced (Self et al. 2006) in volcanic ash plumes and subsequently many authors (Highwood et al. 2003) suspect that sulphuric acid may be formed by photochemical processes within the stratosphere, thus giving rise to new secondary particle formation (Kulmala et al. 2000) which are implicated in a more long-term effect. However, large condensational sinks due to pre-existing particles within the plume, and unknown nucleation mechanisms under these circumstances make the hypothesis uncertain. In this work, we report the first observation of a nucleation and new secondary particle formation events in a volcanic plume.

Methods

These measurements were performed at the puy de Dôme atmopsheric research station in central France during the Eyjafjallajokull volcano eruption in Spring 2010. The puy de Dôme research station is located at 1465 m above sea level in central France (45°46' N, 2°57 'E). The station is surrounded mainly by a protected area where fields and forests are predominant;the city of Clermont-Ferrand islocated 16 km East of the station. Meteorological parameters and radiation, atmospheric trace gases (O_3, NO_x, SO_2, CO_2) and particulate black carbon (BC) are monitored continuously throughout the year. Particle measurements were performed using a Neutral cluster and Air Ion Spectrometers (NAIS, 0.5- 42 nm), a Scanning Mobility Particle Sizer (SMPS, 10-450 nm) and an optical particle counter (Grimm spectrometer, 0.3-20 microns). Atmospheric dynamics and stratification are monitored using a Rayleigh-Mie LIDAR (355 nm), with parallel and perpendicular polarization channels.

Results

A strong depolarization signal indicative of volcanic ahses[19] was detected using LIDAR measurements from the 18th to the 20th of May 2010 in the boundary layer (Fig. 1) where it could be characterized by ground-based in situ instrumentation. During this period, condensation nuclei (CN) concentrations follow a clear diurnal variation, both on the 19th and on the 20th of May, with number concentrations that are multiplied by 5 in the size range 0.5 – 42 nm. The size distribution measured with the NAIS unambiguously shows that these particles are formed from the nanometric scale, i.e. by nucleation and subsequently growth process. Simultaneously, SO_2 concentrations peaked until reaching a maximum value of 2.25 ppt exceeding the 99th-percentil over the 2005-present period. We show that nucleation is linked to exceptionally high concentrations of sulphuric acid and unusually high particle formation rates. In addition, we demonstrate that the binary H_2SO_4-H_2O nucleation scheme, as it is usually considered in modeling studies (Zhao et al. 1995), underestimates by 7 orders of magnitude the observed particle formation rate and, therefore, cannot be applied at least under tropospheric conditions.

The controlling mechanism of tropospheric nanopartile formation is still being debated. Field and laboratory measurements have clearly indicated a strong correlation between observed sulphuric acid – a product of oxidation of SO_2 by the OH radical – and nanoparticle concentrations and formation rates. On the other hand, observed seasonality and comparisons with plant-emitted volatile organic compound (VOC) emission strengths show that aerosol formation is also correlated with biogenic organic compound oxidation products. Laboratory studies with real plant emissions have shown a clear dependence of aerosol formation on the VOC emission strength and also the chemical mixture, thereby ruling out the possibility that aerosol formation would be completely independent of organic compounds.

As it is likely that atmospheric particle formation is caused by several different processes, each of which dominate in different precursor concentration domains, reconciling the sulphuric acid and VOC-dependent explanations for aerosol formation is key to understanding the production of aerosol number in the lower atmosphere. We investigated the formation of nanosized condensation nuclei (nano-CN) from sulphuric acid and plant emissions in the Jülich Plant atmosphere Chamber setup (JPAC, see eg. Mentel et al., 2009). The extensive measurement setup consisted of several condensation nuclei counters (CPCs) including a pulse-height CPC and a Particle Size Magnifier for detection of sub-3 nm CN. Particle size distributions were monitored using an SMPS. Sulphuric acid levels were measured using chemical ionization mass spectrometry, while VOC concentrations were monitored with proton transfer reaction mass spectrometers and a gas chromatograph – mass spectrometer. We also deployed an Atmospheric Pressure Interface TOF spectrometer (API-TOF) to monitor the concentrations and distribution of charged clusters and molecules in the chamber.

We performed a series of experiments using boreal forest tree emissions at levels commonly found in the boreal boundary layer. The sulphuric acid concentration in the chamber was varied by changing the intensity of hydroxyl radical production and addition of SO_2 to the chamber; sulphuric acid levels were on par with atmospheric observations. The reaction chamber was flushed with ozone to achieve a steady-state concentration of 60 ppb when no OH was produced. During the experiment series we varied the emissions of BVOC, the OH production intensity, the O_3 concentration and performed experiments with addition of specific organics, e.g. isoprene.

We found that while the variation of the VOC concentration had a strong impact on the gas phase chemistry and also the hydroxyl radical and sulphuric acid levels, the changes in particle formation rates were not explainable by sulphuric acid concentration variations alone, but the particle formation process is directly influenced by the organic compounds. Also, the effects of different organics via their OH reactivity could be observed, for example the suppression of particle formation by isoprene as observed earlier (Kiendler-Scharr et al., 2009).

We present a detailed description of the evolution of the early nano-CN distribution and the influence of both sulphuric acid and biogenic organic oxidation products on it. The connections to the dynamics of the charged cluster and large molecule distribution as a function of ongoing oxidation by both ozone and the hydroxyl radical will also be discussed. We will discuss the implications of our findings regarding atmospheric nucleation by presenting a comparison of our results to findings from atmospheric field observations of natural nano-CN formation.

Abstract

Based on the studies of Haagen-Smit and Went, new aerosol particle formation by biogenic terpene oxidation products has been proposed. This certainly has remarkable atmospheric effects, since vegetated areas are extensive in space but diverse in composition and emission of reactive volatile organic compounds (VOCs). So far independent pathways from sulphuric acid derived nucleation have not been formulated and accepted. Here we aim to explain the observed nucleation process by a purely organic algorithm obtained from laboratory investigations, which we could perform successfully. The important role of organic radical (RO_2) formation by monoterpenes was elucidated, which activated the sesquiterpene derived nucleation core. Therefore both terpene groups and their reactivity with respect to ozone and OH are important for new aerosol particle formation in a non-linear system.

Methods

We focus on two controlled greenhouse experiments a) at Frankfurt University in June 2010 and b) at Max-Planck Institute for Chemical Ecology in Jena, in December 2010. While the first measurements were done in a greenhouse with changing light and temperature conditions, the second set of measurements were run at a constant temperature T of 24°C and constant illumination. The used three different tobacco plant types provided three different emission patterns with respect to sesquiterpenes, i.e. (i) one wild type and two genetically modified ones emitting (ii) a mixture of two sesquiterpenes (α-farnesene and α-bergamotene) or (iii) α-farnesene only.

In Frankfurt plant incubation was done using a Teflon bag while in Jena each plant was incubated in a single plant cuvette and was treated with different ozone stress intensities between 400 and 833 ppb_v.

Total particle concentration was measured by a condensation particle counter (UCPC 3776, TSI) with a lower cut-off size of 2.7 nm. All measurements have been conducted on the 13th-18th of December 2010 at the Max-Planck Institute in Jena.

Nucleation mechanism assumed

Based on the laboratory investigation on new particle formation by alkenes and ozone (see other presentation), the following mechanism was assumed:

1. Formation of stabilised Criegee intermediates (sCI) by sesquiterpenes and ozone
2. Formation of reactive secondary ozonides (SOZ) from sCI and available carbonyl compounds.
3. Activation (reaction) by monoterpene and OH derived large organic peroxy radicals (RO_2).

Taking into account the inhomogeneity of the cuvettes and the uncertainty of the radicals, a reasonable match between observation and calculation was obtained. As a conclusion it can be stated: The reaction rate constants of sesquiterpenes and of monoterpenes with O_3 and OH affect the entire nucleation process and the system is non-linear.

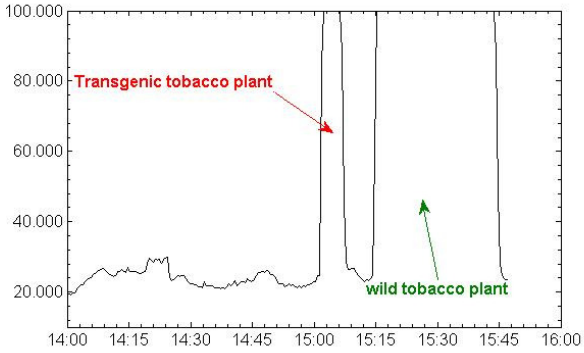

Figure 1. Effect of sudden rise in provided ozone. Particle number and sesquiterpenes concentrations rapidly increased in Frankfurt.

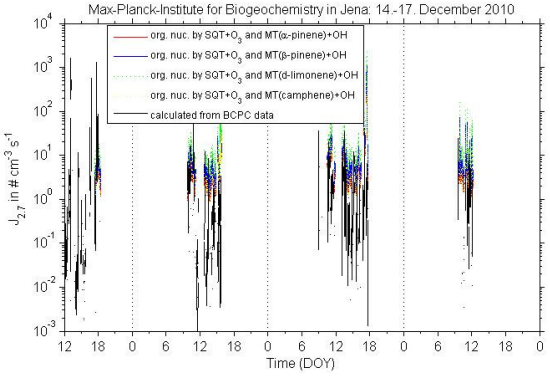

Figure 2. Simulated and measured nucleation rates for experiments performed at Jena.

Vegetation is the major source of biogenic volatile organic compounds (BVOC) in the troposphere. These BVOC impact atmospheric oxidation capacity and serve as precursors for secondary organic aerosols (SOA). In regions with low pre-existing particulate matter, BVOC oxidation by OH, ozone, and NO_3 can produce low volatile products which are involved in SOA formation.

Isoprene and monoterpene emissions from vegetation are well known. However, during and after stress situations plants emit many other BVOC. Sesquiterpenes (SQT) such as α- and β-farnesene, C_6-aldehydes and -alcohols produced within the octa-decanoid pathway (green leaf volatiles, GLV), or many different aromatic compounds originating from the phenylpropanoid pathway are typical BVOC emitted during biotic and abiotic stress.

In this study we measured the formation of secondary organic aerosols (SOA) from stress-induced BVOC emissions emitted from grey poplar seedlings (*Populus x canescens*). The experiments were conducted in the Jülich Plant Atmosphere Chamber (JPAC, Mentel *et al*., 2009). This system consists of two temperature controlled chambers, one housing the plants (plant chamber) and the second one was used for photochemical SOA production (reaction chamber). BVOC emitted from the poplar plants in the plant chamber were transferred into the reaction chamber where they were oxidized by ozone and by OH radicals. OH was produced by photolysis of ozone in presence of H_2O. OH concentrations were typically in the range of 3-8×10^7 cm^{-3}. Ambient conditions such as temperature, relative humidity, photosynthetic active radiation (PAR), CO_2, O_3, and NO_x levels were controlled.

We used 4-month-old wild type (WT) poplar plants that emit high amounts of isoprene and transgenic poplar lines down-regulated in isoprene emission (R-lines, Behnke *et al.*, 2007). Comparing particle formation from BVOC emitted from these plants enabled the characterization of the impact of isoprene on the SOA formation from plant emissions. Unstressed poplar plants emitted nearly exclusively isoprene whereby the emissions from the down regulated R-lines were more than an order of magnitude lower than those from the wild type. Using unstressed plants as BVOC sources for particle formation we found inefficient SOA formation with nucleation rates far below 1 cm^{-3} s^{-1}.

All lines showed strong additional emissions of sesquiterpenes and aromatic compounds after stressing the plants by short ozone pulses. Their emission rates and therefore the BVOC emission pattern changed on a time scale of several days after stress application, allowing to study SOA formation under nearly steady state conditions. Feeding BVOC mixes into the reaction chamber resulted in very strong SOA formation events with nucleation rates exceeding 3000 cm^{-3} s^{-1}. Normalized to the BVOC turnover the nucleation rates were generally lower for the isoprene emitting WT poplars compared to non-emitting mutants. This observation confirmed former findings of suppression of nucleation by isoprene (Kindler-Scharr *et al*., 2009).

Rapid variations of PAR in the plant chamber resulted in fast changes of isoprene emissions whereas the emissions of the other BVOC responded on a much longer time scale. Hence, switching off the lamps in the plant chamber allowed removing isoprene very fast while keeping the level of other BVOC concentrations high. Conducting this procedure during a particle formation event caused a fast decrease of isoprene concentration and a strong increase of OH concentrations in the reaction chamber followed by increases in particle number and mass. This also shows that suppression of OH concentrations by isoprene is the major reason for suppression of nucleation from non-isoprene BVOC.

Using a low isoprene emitting poplar plant as BVOC source and adding deuterated isoprene from a diffusion source we estimated isoprenes' contribution to the SOA mass formed from the BVOC emitted from poplar. While isoprene contributed to about 7% [C/C] to the BVOC in the gas phase the contribution to the particulate phase was only 1 %. Thus isoprene oxidation products partitioning into the SOA can not compete with that of oxidation products from the other BVOCs. However the SOA mass produced by isoprene oxidation products does not compensate the decrease of other BVOC particle precursors caused by the decrease of OH concentrations in the presence of isoprene.

Session 3C: Chemical Mechanisms and Transformation Processes in Aerosol

Evolving morphology, hygroscopicity and volatility of mixed oleic acid/sodium chloride/aqueous aerosol during oxidative aging

B.J. Dennis-Smither, R.E.H. Miles, N.-O.A. Kwamena and J.P. Reid

Keywords: oxidative aging, organic aerosol, hygroscopicity, volatility.
Presenting author email: j.p.reid@bristol.ac.uk

We present measurements of the oxidative aging of mixed component aerosol trapped using optical tweezers. Single particles containing an effloresced sodium chloride phase and a liquid organic phase are exposed to gas phase ozone and the particle composition and size are monitored during the heterogeneous reaction. Partitioning of organic products between the gas and condensed phases is observed along with an increase in the hygroscopicity of the condensed organic phase. The impact of relative humidity (RH) on the oxidation kinetics/mechanism is explored.

Atmospheric aerosol is formed from variety of inorganic and organic components and this can lead to complex particle morphology. Organic components can modify aerosol properties including hygroscopicity, optical properties and toxicity. The chemical processing of organic compounds through the heterogeneous reaction with gas phase oxidants such as OH, O_3 and NO_3 forms aged organic aerosol and is of key importance when considering the composition and physical properties atmospheric aerosol.

The oleic acid – ozone reaction system has emerged as a benchmark system for the study of heterogeneous oxidation of organic compounds (Zahardis & Petrucci, 2007). Oleic acid (OL) is a C_{18} mono-unsaturated fatty acid and acts as a proxy for unsaturated organic matter in atmospheric aerosol and a model compound for the study of aerosol reactivity. OL reacts with ozone via cleavage of the C=C double bond to form initial C_9 products. Complex secondary chemistry involving the initial products leads to a variety of oxygenated final products, including C_9 compounds and oligomeric structures (Zahardis *et al.*, 2006).

We have used optical tweezers to isolate a single aqueous sodium chloride particle which is then coagulated with OL aerosol. The trapping of a single particle at the focal point of a tightly focused laser beam allows the mixed component particle to be suspended in an environment with controlled RH and ozone mixing ratio over several days. The composition and structure of the trapped droplet is probed using Raman spectroscopy.

The mixed component aerosol has 2 distinct liquid phases at RHs above the efflorescence point of the sodium chloride. The OL and aqueous phases have very low mutual solubilities and the particle phase separates to forms a partially engulfing OL lens on the aqueous droplet as predicted by a recent equilibrium morphology study (Kwamena *et al.*, 2010). The organic phase is observed to have negligible impact on the phase transitions of the sodium chloride. In particles containing effloresced sodium chloride, a spherical structure is adopted which we propose consists of a crystalline sodium chloride core coated in an organic shell.

Raman spectroscopy is used to probe the core-shell particles during the oxidative aging by ozone. The spontaneous Raman scattering allows the composition of the droplet to be investigated and the relative OL content to be monitored. The occurrence of sharp stimulated Raman peaks provides insight into the structure of the core-shell particles and allows determination of the particle radius, allowing the kinetics of oxidation to be monitored with considerable accuracy. The products of the reaction have a range of volatilities and the formation of highly volatile species leads to rapid decrease in organic volume on the timescale of the OL oxidation. Semi-volatile products are observed to evaporate on much longer timescales. The formation of a significant volume of involatile organic that remains in the condensed phase even over long timescales (days) is observed and we propose this as evidence for the formation of very low volatility oligomeric species. The measurement of particle radius as the RH is varied allows the hygroscopicity of the organic phase to be measured before and after oxidation and a significant increase in the hygroscopicity of the condensed organic phase is determined. The oxidative aging of the single aerosol particles has been investigated at RHs from less than 2 % to 70 % and ozone mixing ratio from less than 1 ppm up to 20 ppm.

Session: Multiphase chemical processes and interactions involving aerosol

Cooking aerosols have recently been recognised to contribute substantially to the urban aerosol burden.[1] One of its most prominent reactive components is oleic acid. The importance of the amorphous solid state in aerosols has been illustrated by Virtanen *et al.*[2] Synthesising previous work in a detailed model analysis we explored if variations in the aerosol diffusivity may explain long lasting controversies. We extend recently developed models[3,4] for description of a 12-component mixture representative of atmospheric cooking aerosols. We show how this model may be used to resolve surface and bulk processes in varying phases considering diffusivities altered by oligomerisation of reaction products. This new model allows consideration of aerosol ageing over much extended lifetimes since properties of product species may be described in detail.

Ozonolysis of oleic acid is a model system for ageing of organic aerosols in the atmosphere. Recent experimental evidence underlines the importance of changes in diffusivity inside atmospheric aerosols. We review recent studies that investigate the importance of phase transitions on the ageing of oleic acid in the atmosphere and model a 12-component aerosol mixture by applying and extending the KM-SUB model (see Fig. 1).[3]

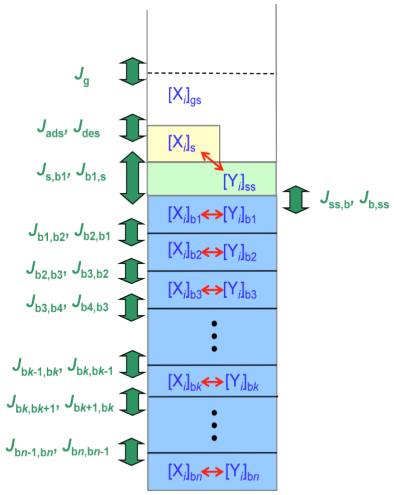

Figure 1. Model description of a 12-component mixed aerosol system and its chemical and physical transformations: model layers, chemical species (X and Y) and fluxes (*J*) between these layers based on KM-SUB.[3] Gas-phase species X is O_3 and 12 liquid-phase Y components are described here in 250 bulk layers. Product formation and oxidation-induced viscosity changes are also described (not shown for visual clarity).

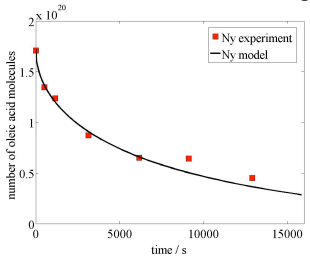
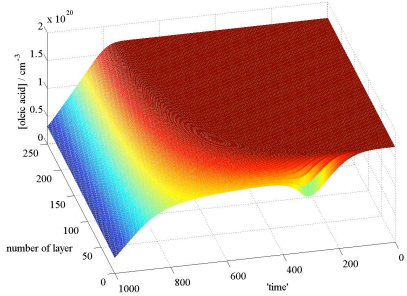
Fig. 1 illustrates the structure of the model used for the present study. The model was validated by comparison with experimental data from Huff Hartz *et al.*[5] We explored if changes in the diffusivity may explain the observed evolution of loss rates in ageing aerosols.

Fig. 2 (a) illustrates matching time decays of oleic acid molecules in model and experiment. Fig. 2 (b) shows the evolution of the concentration of oleic acid resolved in depth (layer 250: aerosol core) and time. We observe crust formation on the aerosol surface with diffusion being reduced due to formation of viscous products.



(a)



(b)

Figure 2. Selected modelling results and comparison with experimental data from Huff Hartz *et al.*[5]

The work presented is the first application of recently developed kinetic models[3,4] to multi-component atmospheric aerosols. We successfully describe the time evolution of multiple reactive species on the surface and in the bulk. Our model description is consistent with retardation of the reactive loss of the organic species caused by increased viscosity in aged aerosols. Viscosity and phase changes of atmospheric aerosols could reconcile discrepancies between lifetimes derived from laboratory and field observations.

Real-time, controlled OH-initiated oxidation of biogenic secondary organic aerosol

J.G. Slowik[1,2], J.P.S. Wong[1] and J.P.D. Abbatt[1]

[1]Department of Chemistry, University of Toronto, Toronto, ON, M5S 3H6, Canada
[2]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland
Keywords: biogenic particles, OH-induced oxidation, aerosol mass spectrometry, boreal forest
Presenting author email: jay.slowik@psi.ch

Atmospheric aerosol particles have important effects on human health, visibility, and climate. Quantification of these effects requires a detailed understanding of particle sources and atmospheric transformations. The wide array of sources and processes contributing to ambient aerosol composition makes it difficult to quantitatively resolve the effects of specific factors via ambient measurements. Laboratory studies enable controlled studies of simple systems, but may not adequately capture the complexity of the atmosphere, contributing to discrepancies with atmospheric measurements. Controlled investigation of atmospheric processes via oxidation of real-world particle/gas mixtures provides a promising approach to addressing this challenge. Here we present results from the initial field deployment of the Toronto Photo-Oxidation Tube (TPOT), a system for real-time analysis of OH-initiated oxidation of ambient gas/particle mixtures.

Ambient aerosol are continuously sampled by the TPOT and mixed with N_2, O_2, O_3, and H_2O. This flow is then split into reaction and bypass tubes. Both tubes are constructed from Silco Steel and contain a glass tube on the center axis, which in the reaction tube houses a 254 nm Hg lamp. Photolysis of O_3 in the presence of H_2O vapors produce OH radicals, which control experiments indicate are the dominant oxidants in the system. OH concentrations are controlled by varying the input O_3 concentration. Flows are pulled continuously in both tubes, while measurement of aerosol composition alternates between the tubes with a period of ~12 min. The composition is measured by an Aerodyne time-of-flight aerosol mass spectrometer (AMS) (Drewnick *et al.*, 2005).

The TPOT was deployed in Whistler, BC, Canada, during the WCAS 2010 (Whistler Cloud and Aerosol Study) field campaign, from 8 to 27 July, 2010). Sampling was conducted in the boreal forest on Whistler Mountain at 1300 m asl. The site is strongly influenced by biogenic secondary organic aerosol (SOA) from terpene emissions. Periods of influence by anthropogenic emissions and biomass burning plumes were also observed.

Under the conditions present during WCAS 2010, oxidative processing in the TPOT was dominated by heterogeneous oxidation and/or gas-phase reaction of semivolatile organics, rather than SOA formation. However, this is likely due in part to the low SOA yields of current flow tube systems (Lambe *et al.*, 2010). Figure 1 shows the effects of heterogeneous OH processing on the total organic mass, as well as the signal at *m/z* 43, 44, and 91. After ~10 days of oxidation, the figure shows a 20% decrease in total organic mass. Larger decreases are evident in the signals at *m/z* 43 (~40%) and 91 (~70%), which are characteristic of fresher, less-oxidized SOA. In contrast, a mass increase of up to ~30% is observed at *m/z* 44 (CO_2^+, characteristic of carboxylic acids). These trends are also evident at shorter time periods, with increased *m/z* 44 (~10%) and decreased *m/z* 91 (~20%) after less than a day of oxidation. OH oxidation of the ambient aerosol causes spectra to approach the low-volatility oxygenated organic aerosol (LV-OOA) spectra that have been widely extracted from factor analysis of AMS datasets and are thought to represent aged organics (e.g. Ng *et al.*, 2010).

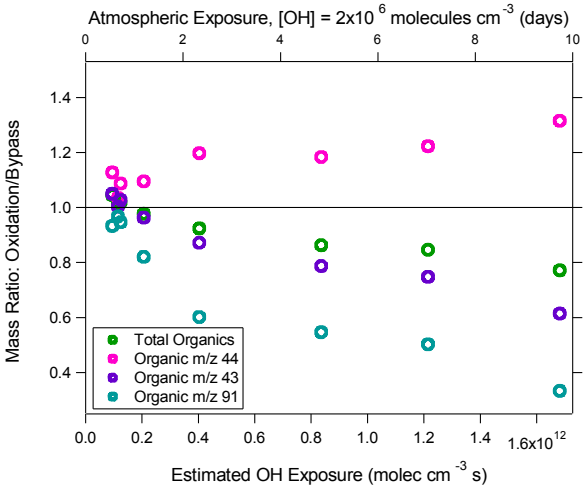

Figure 1. Evolution of the organic aerosol mass spectrum with OH oxidation.

Heterogeneous reactions of ozone with aerosol particles have been studied extensively, but the molecular mechanism and kinetics remained unresolved. Among the organic aerosol components readily reacting with ozone, polycyclic aromatic hydrocarbons (PAHs) are one of the most prominent groups related to health effects. Chemical transformation can change the toxicity of PAHs and modify the hygroscopic properties and climate effects of combustion aerosol particles. Several studies have shown that ozone can also promote the nitration of protein molecules contained in primary biological aerosol particles like pollen and fungal spores (Franze et al. 2005). This posttranslational modification can enhance the allergenic potential of proteins. It provides a molecular rationale for the enhancement of allergic diseases by traffic-related air pollution in urban and rural environments, which has been observed in epidemiological studies but remains to be elucidated on a molecular level (Gruijthuijsen et al. 2006).

Based on new experimental data and model calculations, here we show that long-lived reactive oxygen intermediates (ROIs) are formed upon oxidation of PAH and nitration of protein (Shiraiwa et al. 2011). The chemical lifetime of these intermediates exceeds 10^2 s, which is much longer than the surface residence time of molecular O_3 (~10^{-9} s). The ROIs explain and resolve apparent discrepancies between earlier quantum mechanical calculations and kinetic experiments. They play a key role in the chemical transformation and adverse health effects of toxic and allergenic air particulate matter, such as soot, polycyclic aromatic hydrocarbons and proteins. Moreover, ROIs may contribute to the coupling of atmospheric and biospheric multiphase processes.

Apart from chemical aging of air particulate matter, long-lived ROIs might also participate in the formation and growth of secondary organic aerosols. In particular, surface interactions of long-lived ROIs may lead to the formation of multifunctional organic substances (acids, nitrates, sulfates, dimers/oligomers, etc.) with high molecular mass and low vapor pressure that are required for the nucleation and growth of new particles and may also influence their phase state (Virtanen et al. 2010). The experimental and theoretical information currently available suggests that long-lived ozone-generated ROIs play a central role in the multiphase chemistry of atmospheric aerosols.

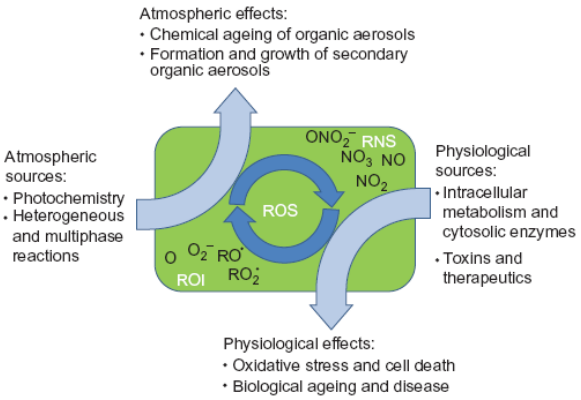

Figure 1. Illustration of the atmospheric and physiological sources, coupling and effects of reactive oxygen species(ROS), reactive oxygen intermediates (ROI), and reactive nitrogen species (RNS).

Ammonium nitrate aerosol exhibits highly scattering properties across the solar spectrum. Further to this, it displays hygroscopic tendencies (Tang, 1996), allowing enhanced water uptake for a given relative humidity. Consequently, its ability to scatter incident solar radiation is increased leading to an enhancement of the aerosol direct radiative forcing. Anticipated reductions in sulphur dioxide in polluted regions will result in an increase in the availability of ammonia to form ammonium nitrate as opposed to ammonium sulphate. Consequently, the relative importance of ammonium nitrate to the aerosol burden is likely to increase.

This paper presents an assessment of the contribution, properties and impact of ammonium nitrate upon the European aerosol burden. In-situ measurements of aerosol properties made onboard the UK Facility for Airborne Atmospheric Measurements (FAAM) BAe-146 aircraft will be presented. The aircraft employs a suite of aerosol instruments, which resolve the chemical composition, number size distribution, optical and hygroscopic properties of the in-situ aerosol population. This includes an Aerodyne Aerosol Mass Spectrometer (AMS) which measures the size resolved chemical composition of both volatile and semi-volatile particulate matter (Canagaratna *et al.*, 2007). The measurements were conducted as part of the EUCAARI-LONGREX (European Integrated Project on Aerosol Cloud Climate Air Quality Interactions–LONG Range EXperiment) and APPRAISE-ADIENT (Aerosol Properties, Processes and influences on the Earth's climate – Appraising the aerosol direct impact on climate) campaigns. Science flights were conducted across Europe, during predominantly clear sky conditions during 2008.

Ammonium nitrate was found to dominate in North-Western Europe during episodes of high pollution, reflecting the enhanced NO_x and ammonia sources in this region. Ammonium nitrate and organic matter were often observed to increase with altitude in the atmospheric boundary layer. This was attributed to partitioning of semi-volatile gas phase species to the particle phase at reduced temperature and enhanced relative humidity. Increased ammonium nitrate concentrations in particular were found to strongly increase the ambient scattering potential of the aerosol burden. During particularly polluted conditions, increases in boundary layer aerosol optical depth of 50-100% were estimated to occur due to the observed increase in secondary aerosol mass with altitude and associated water uptake. These enhancements significantly increase the direct aerosol radiative forcing. Such increases have major ramifications for regional climate predictions as semi-volatile components are often not included in aerosol models.

Our observations over North-Western Europe indicate that failure to include the semi-volatile behaviour of ammonium nitrate will result in significant errors in predicted aerosol direct forcing.

The ability of a sophisticated regional aerosol transport model to represent the complex spatial distribution of ammonium nitrate will be explored. This will include the observed horizontal spatial gradients in North-Western Europe and in particular the vertical distribution of the aerosol.

Predictions of Night-time Atmospheric Processes using a Coupled Model of Multi-phase Chemistry and Aerosol Microphysics

D. Lowe[1], S. Utembe[1], D. Topping[1,2], and G. McFiggans[1]

[1]Centre for Atmospheric Science, SEAES, University of Manchester, Manchester, UK, M13 9PL
[2]National Centre for Atmospheric Science, University of Manchester, Manchester, UK, M13 9PL
Keywords: aerosol modelling; multiphase chemistry; NOx

Aerosol particles play an integral part in the chemistry of the atmosphere – by acting as reaction surfaces for heterogeneous chemistry, as chemical sources, and by removing components through scavenging and dry deposition. They have an important influence on the lifetime of the nitrate radical (NO_3), which can be an important oxidant in polluted nocturnal atmospheres. NO_3 and NO_2 are in thermal equilibrium with N_2O_5, which acts as a reservoir species for NO_3. However N_2O_5 also provides an important loss pathway for NOx by conversion to HNO_3 via heterogeneous reactions on aerosol particles, the rates of which are dependent on aerosol composition, RH and T (Allan *et al.*, 1999, Davis *et al.*, 2008; Evans & Jacob, 2004). In order to properly predict the oxidative capacity of the nocturnal atmosphere we must understand the influence of aerosols on gas-phase chemistry.

This study uses a one-dimensional column model, built upon the sectional Microphysical Aerosol Numerical box-model Including Chemistry (MANIC) (Lowe *et al.*, 2009). Constructed using the Kinetic Pre-Processor (KPP, Damian *et al.*, 2002); all gas and condensed phase reactions, as well as gas-aerosol mass transfer, and gas and aerosol source and loss terms, within a single level of the column model are included into one system of ODE's, solved using a third-order Rosenbrock solver. In the condensed-phase we use the PD-FiTE (Partial Derivative Fitted Taylor Expansion) method for calculating the non-ideal activity coefficients for components of the H^+-NH_4^+-Na^+-SO_4^{2-}-HSO_4^--NO_3^--Cl^- system (Topping et al, 2009) and for a reduced complexity condensed organic phase consisting of 13 semi-volatile and 2 involatile species (Topping and Lowe, 2011). Other chemical species in the condensed-phase are treated as being in ideal conditions. Gas-phase chemistry is simulated using the CRI v2R5 scheme (Watson *et al*., 2008).

Here we present an investigation into the influence of size-resolved condensed-phase chemistry on the oxidant capacity of the troposphere with a range of pollutant loadings. The aerosol-phase for all studies consists of two externally mixed modes: one seasalt, the other non-seasalt. Each aerosol mode has been split into 8 size-bins. A vertical column model will be run along lagrangian trajectories through a range of different conditions (from clean marine, to polluted continental) – to investigate component variability within a parameter space which will be suitable for comparisons with FAAM 146 measurements.

We will present analysis of the evolution of the night-time nitrogen budget. This will consist of vertically-, temporally-, and size-resolved (for the condensed-phase) nitrogen species concentrations and trends. We will further identify the major production and loss channels for nitrogen processing, comparing the relative importance of the condensed- and gas-phase oxidised nitrogen reservoirs, formulating testable hypotheses for evaluation of the airborne measurements of reactive gaseous nitrogen and aerosol nitrate.

This work was conducted as part of the RONOCO (ROle of Nighttime chemistry in controlling the Oxidising Capacity of the atmOsphere) and RHaMBLe (Reactive Halogens in the Marine Boundary Layer) projects.

Phase transformation of evaporating solution droplets of immiscible polymers

V. Rajagopalan, E. A. Grulke and A. K. Ray

Department of Chemical Engineering, University of Kentucky, Lexington, KY 40506, USA
Keywords: polymer blend particle, multicomponent droplet evaporation, VOAG.
Presenting author email: akray@engr.uky.edu

Polymer blends have wide range of applications (e.g., opto-electronic devices, organic solar cells) that often require microparticles with uniform properties. In many cases, the polymers are incompatible with one another and thus separate into distinct phases. Conventional methods based on melt blending and miniemulsions can reduce the extent of phase separation in many polymer blends, but are limited to polymer pairs in certain property ranges. There is a need for a synthesis method that can blend immiscible arbitrarily polymer pairs. Blended microparticles produced by evaporating solution microdroplets, containing two immiscible polymers dissolved in a common solvent, are expected to exhibit a high degree of phase uniformity under conditions where the timescale of solvent evaporation is lower than that of polymer diffusion and self-organization. In such a situation, the phase separation is inhibited within the atto- to femto-liter volume of the droplet, and homogeneous blends of immiscible polymers can be produced.

We have examined multicomponent polymer particles produced from highly monodisperse micrordroplets that were generated using a Vibrating Orifice Aerosol Generator (Devarakonda et al. 1998; Gao et al. 2007). Equal proportions of two highly incompatible polymers, polystyrene (PS, Mw=280,000) and polyvinyl chloride (PVC, Mw=75,000), were dissolved in a common solvent, tetrahydrofuran (THF), to get a desired total polymer concentration in the solution in the range of 2 to 4 wt%. Droplets were generated from the homogeneous solution; in addition to THF, ethanol was added in varying amounts to reduce evaporation rates of the solution droplets. The morphology of the polymer blend particles produced from the droplets of various composition was studied by an SEM (Hitachi SEM-3200N). To obtain the distribution of each component inside the particle, samples were placed in Beem capsules, embedded in Spurr's resin, and kept under vacuum for 48 hours. They were then polymerized at 60^0C for 48 hrs, and finally, sliced thinly on a Reichert-Jung Ultracut E microtome. The thickness of the slices was about 60 nm. The slices were placed on copper grids and examined in the FEI Tecnai Biotwin 12 transmission electron microscope (TEM). An Energy Dispersive X-ray Analysis (EDS) (coupled with SEM) was performed for the presence of chlorine. All the samples were coated with a thin layer of Gold and Palladium before using them under the SEM.

The SEM micrographs of polymer particles show that the particles are of spheroidal shape and often have indentations. Even though the initial droplets generated by the VOAG have the same size, the final solid particles have varied morphologies. This is due to nonuniform drying conditions inside the experimental chamber. Surface hollows and indentations observed in the particles can be attributed to the rapid drying of the droplets. Even though the physical characteristics of the particles were not uniform, the objective was to study the extent of phase separation or the lack of it thereof. The elemental difference between PS and PVC is the presence of chlorine in PVC. This prompted us to do EDS on the thin slices of the blend particles that were prepared using the microtome. The slices were about 60 nm thick with diameter of about 12 μm. Each analysis was done over an area of 3x3 μm^2. The EDS spectra from various locations of a particle clearly show primary and secondary peaks of chlorine. For particles produced from solutions with THF as the sole solvent, chlorine peaks were observed to have approximately the same intensity. This suggests that the distribution of chlorine is more or less uniform throughout the cross-section. Thus, qualitatively, PVC and PS are dispersed uniformly in the particle.

The results of this study show that uniform polymer blend microparticles can be produced by rapid evaporation of microdroplets. The morphology of the final particles that form after the solvent evaporation depends on the initial droplet size, polymer concentration, solvent volatility, and temperature. Future studies would involve more quantitative measurements. The mapping of chlorine in the samples are needed to fully ensure that the particles produced are indeed uniformly blended microparticles.

Session 3D: PMx Data Interpretation

Mobile measurements of submicron particulate matter in Central Europe during wintertime inversions

R. Wolf, C. Mohr, M. Crippa, J. Slowik, A.S.H. Prévôt and U. Baltensperger
Laboratory of Atmospheric Chemistry, Paul Scherrer Institute, CH-5232, Villigen PSI, Switzerland
Keywords: Organic aerosols, Wood burning, Aerosol mass spectrometry, Source apportionment.
Presenting author email: robert.wolf@psi.ch

Wintertime inversions lead to an increase in concentrations of particulate matter. This phenomenon is of special interest because of the adverse effects of particles on health and visibility. During such episodes, aerosol mass concentrations are strongly influenced by local sources and topography. Recent studies (Weimer *et al.*, 2009, Alfarra *et al.*, 2007) indicate that both traffic and wood burning significantly contribute to particulate mass which accumulates in narrow Alpine valleys.

A mobile laboratory was deployed to determine the spatial distribution and the chemical composition of atmospheric aerosols during atmospheric inversion. The mobile unit contains a series of instruments including an Aerodyne quadrupole aerosol mass spectrometer (Q-AMS), a multi-angle absorption spectrometer (MAAP) and a fast mobility particle sizer (FMPS). The sampling was performed in both rural and urban areas along the Rhine Valley in Switzerland, Austria and Liechtenstein.

The main components of particulate matter and its sources were identified using Positive Matrix Factorization (PMF) (Paatero *et al.*, 1994). The organic fraction can be classified as primary (POA) or secondary organic aerosol (SOA). The primary organic aerosol classification includes contributions from wood burning and traffic. Local emissions of individual species were estimated by subtraction of SO_4-normalized background concentrations (Mohr *et al.*, 2011).

The results for the total mass concentration and the mean chemical composition are shown in Figure 1. It indicates a substantial difference in mass concentrations between the Austrian section (A) of the route ($\approx 53\ \mu g/m^3$) and the urban area of Chur in the southern Rhine Valley ($\approx 15\ \mu g/m^3$). According to Figure 2, the carbonaceous aerosol dominates the local contribution.

It can be concluded that the high amount of heavy-duty traffic and emissions from diesel powered cars in the Austrian part of the Rhine Valley lead to an increased concentration of organic aerosol and elevated emissions of black carbon (BC). In contrast, the local contribution of organic mass from wood burning, which can be attributed to domestic heating in this region, is lower (9 – 13 %).

We will present for this campaign and in addition the Mesolcina Valley with a higher ratio of wood burning the local and regional contributions to PM_1 and compare these with measurements in downtown Zurich.

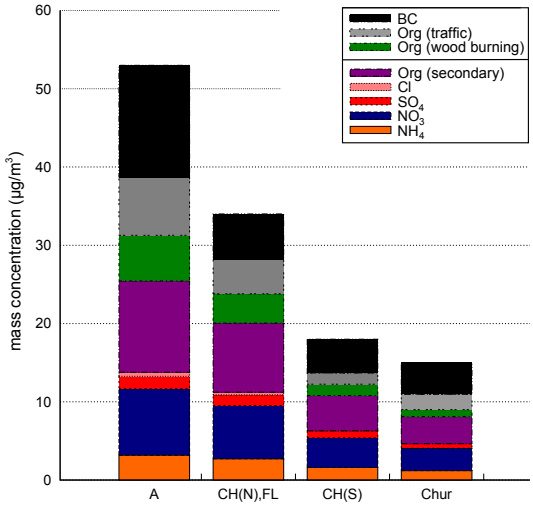

Figure 1: Mean chemical composition of PM_1 in the Rhine Valley at four different sections of the route (A Austria, CH(N) northern Switzerland, CH(S) southern Switzerland, FL Principality of Liechtenstein).

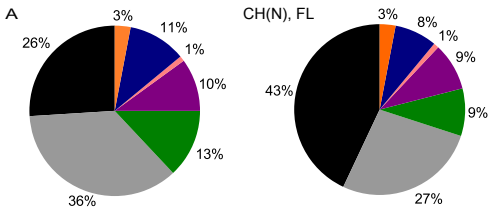

Figure 2: Relative local contributions after subtraction of the SO_4-normalized background concentrations of different species to PM_1 in the northern part of the Swiss Rhine Valley.

A GIS based approach to combine back trajectory statistics and land cover analysis for the source apportionment of aerosol constituents

D. van Pinxteren[1], E. Brüggemann[1], T. Gnauk[1], K. Müller[1], C. Thiel[2], H. Herrmann[1,*]
[1]Leibniz-Institute for Tropospheric Research, 04318 Leipzig, Germany
[2]University of Jena, Institute for Geography, Department of Earth Observation, 07743 Jena, Germany

Keywords: Source apportionment, Trajectory statistics, Size distribution, Chemical composition
Presenting author email: dominik@tropos.de

Source apportionment models have since long been used to elucidate the impacts of specific emissions on observed pollutant concentrations. Principal component analysis (PCA) and positive matrix factorisation (PMF) are popular examples of such receptor models.

Another common approach in source apportionment studies are trajectory statistical methods (TSMs, Stohl, 1998). The results of these methods are usually presented in the form of maps where possible geographic locations of source areas can be identified.

An alternative approach to back trajectory analysis was presented by Lammel et al., 2003. Rather than pinpointing geographic locations, the authors aimed at identifying ground surface types which determine the abundance of pollutants at a receptor site.

The present work aimed at further developing this approach. The proposed method based on the calculation of hourly back trajectories using the HYSPLIT model (Draxler, 2003) in the ensemble mode. In this mode, the air mass history of a 24 h aerosol sample is described by an ensemble of 648 trajectories, leading to a much better representation of possible air mass pathways as compared to the calculation of a few single trajectories.

The trajectories were intersected with freely available satellite-derived land cover data (GLC2000), by calculating an index $L_{ik}(P)$ for each back trajectory i within a sampling period P and for each land cover class k as follows:

(1)

where $j = 0,1,2,...,J$ corresponds to the hourly endpoints of trajectory i ($j=0$ is starting location and $J=96$ for 96 hours back trajectories as used here), F_{mnkj} corresponds to the area fraction F of land cover class k within grid cell (m,n) that is hit by the trajectory endpoint j and $w_j=1–j/J$ corresponds to a linear weighting function. Next, the index $L_k(P)$ is derived as the arithmetic mean of all $L_{ik}(P)$, i.e. the indices of all back trajectories that fall into the sampling period P. $L_k(P)$ thereby serves as a proxy for the age-weighted residence time above land cover class k within the sampling period P. Land cover classes under consideration in this work are: Marine areas, natural vegetation, agricultural lands, urban areas, and bare areas. In Figure 1 the cumulative residence times are shown for a dataset of 29 samples (see below).

The method has been implemented within a GIS-enabled database system to allow for an efficient processing of large datasets with low computational demands. To validate the modelled residence times and further calculated parameters (mean trajectory length, solar radiation along trajectory, and local height of the boundary mixing layer), a PCA was performed on a dataset including the modelled parameters and the concentrations of 10 particle constituents (inorganic ions and organic and elemental carbon) in 5 particle size ranges for 29 winter- and summertime samples, sampled during 2003 to 2005 at an urban background site in Leipzig, Germany.

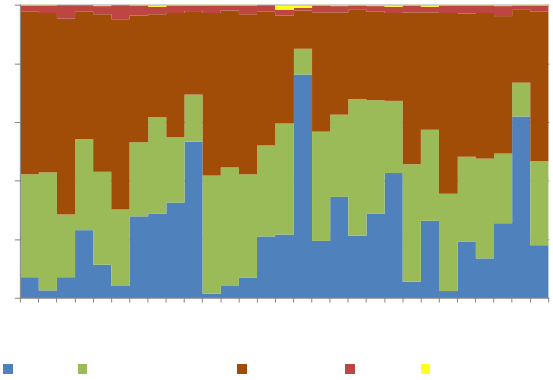

Figure 1: Cumulative residence times above the different land cover classes for all samples of the dataset

Six principal components could be extracted which together explained about 80 % of the total variance in the dataset. The factors could be attributed to the influence of meteorology on continental background pollution, secondary formation processes in polluted air masses, wood burning, aged sea-salt, local traffic, and long-range transported crustal material. Most of these factors have been frequently observed in previous European source apportionment studies (Viana et al., 2008), indicating the validity of the results. The modelled residence times and calculated meteorological parameters generally facilitated the interpretation of the extracted factors. The results proved that the intersection of trajectory data with land cover data by the presented method yields consistent and valuable additional information on the history of sampled air masses in the form of numeric indices which can readily be included into further data analysis.

To exceed, or not to exceed: are the air quality standards adequate to describe the particulate matter pollution?

A. Di Menno di Bucchianico, G. Cattani, A. Gaeta, G. Gandolfo and A.M. Caricchia.

ISPRA – Italian National Institute for Environmental Protection and Research, Via Brancati 48, 00144, Rome, Italy

Keywords: legislation and policy, air quality, urban pollution.

Presenting author email: alessandro.dimenno@isprambiente.it

Information to the public on air quality in urban areas and on the effects of atmospheric pollutants on human health is a common demand.

Some usual queries made by policy-makers or by the so-called stakeholders are if the compliance with limit values was ensured, or if air pollution levels were decreasing in a specific area. Besides, according to the European legislation (Directive 2008/50/EC) air quality plans should be developed for zones and agglomerations within which concentrations of pollutants in ambient air exceed the relevant air quality target values or limit values.

Nevertheless, it is not easy to describe air quality status of a macro-area only on the basis of the exceedances of fixed limit values registered by the urban monitoring networks. On the contrary, the simple reading of these data can lead misleading evaluations for a series of reasons. Limit values can be contradictory: it is well known, as an example, that European daily PM_{10} standard is considered more stringent than the annual average limit value (this ambiguity, introduced in the past Directive 99/30/EC, has been maintained in the new one), but it is less known that a similar discrepancy has been set up for the brand new $PM_{2.5}$ European standard. In few words, it is practically impossible to respect at the same time the three limit values for PM_{10} and $PM_{2.5}$. It must be remarked that a different, and more coherent, definition of particulate matter standards was not impossible, this can be clearly demonstrated looking at the US-EPA particulate matter standards. On the other hand $PM_{2.5}$ US-EPA, based on more complex application conditions (3-year and different sites average) can lead to opposite evaluations using the same data only with a simple variation in the averaging criterion (see case A vs. B in table 1).

Table 1. Example of attainment for US-EPA $PM_{2.5}$ annual standard (LV: 15µg/m^3; 3-year average).

	Year	Site 1	Site 2	Site 3	Site 4	Mean (Y)
	I	12.7	-	-	-	12.7
A	II	13.3	17.4	14.7	-	15.1
	III	12.9	16.7	12.3	20.1	15.5
[µg/m^3]				***limit not exceeded***		**14.4**
	I	12.7	-	-	-	
B	II	13.3	17.4	14.7	-	
	III	12.9	16.7	12.3	20.1	
mean (s) [µg/m^3]		13.0	17.1	13.5	20.1	**15.9** ***limit exceeded***

Nevertheless, analysing air quality data from different geographical areas in Italy, it clearly appears that PM_{10} levels identified different seasonal patterns in northern, central and southern regions and, consequently, an interesting incongruity emerges: two stations with the same annual mean and almost the same daily exceedances (see Fig. 1) can be characterized by a completely different distribution of daily concentrations and dissimilar 90.4 percentile values (the parameter that should be evaluated instead of the number of exceedances according to the Directive 08/50/EC). This is clearly shown by the cumulative frequency in Fig. 2.

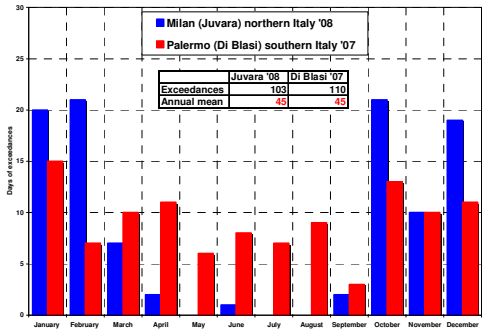

Figure 1. Northern and southern monthly distribution of PM_{10} daily exceedances in Italy.

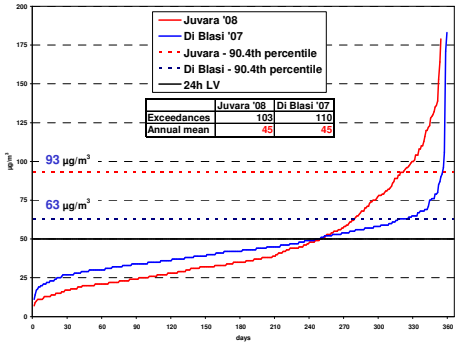

Figure 2. PM_{10} limit value and 90.4th percentile.

These evidences, if undervalued, can bring unexpected consequences: for example the fact that if the 24h PM_{10} European limit value were lower than 50 µg/m^3, on the basis of the same concentration data southern Italian cites could appear sometimes more polluted than northern cities; if limit were higher (just like in some non-European countries) southern cites never exceed the target so the PM_{10} pollution question could be easily and inexpensively solved for that area.

Long-term on-line measurement of non-refractory submicron aerosol in the city of Zurich

F. Canonaco[a], J. Slowik[a], A.S.H. Prévôt[a], U. Baltensperger[a]

[a]Laboratory of Atmospheric Chemistry, Paul Scherrer Institut, 5232 Villigen PSI, Switzerland
Keywords: AMS, PMF, ACSM
Presenting author email: francesco.canonaco@psi.ch

The role of aerosols in the atmosphere is of pivotal importance, because they affect climate (Forster *et al.,* 2007), human health (Peng *et al.,* 2005), ecosystems, e.g., acidification (Matson *et al.,* 2002), and visibility (Watson, 2002). These effects are controlled by particle concentration, composition, and size, which are in turn governed by sources and formation processes. Thus, the identification and quantification of formation mechanisms and sources is of high priority. However, this task is complicated due to the complexity of particle composition.

Long-term monitoring of aerosol composition provides a powerful tool for the analysis of the effects described above. This approach enables elucidation of the seasonal variability of different aerosol constituents, which is not possible with shorter-term campaigns. Long-term measurement records also allow for evaluation of emissions control strategies. Further, these measurements enhance epidemiological studies, permitting them to be carried out not only on the total aerosol concentration (Peng *et al.,* 2002) but on its components. Long-range, mesoscale, and local air quality models are improved through comparison with long-term datasets. Finally, the existence of long-term sampling records at a given site provides a framework for the interpretation of datasets from short-term intensive measurement campaigns.

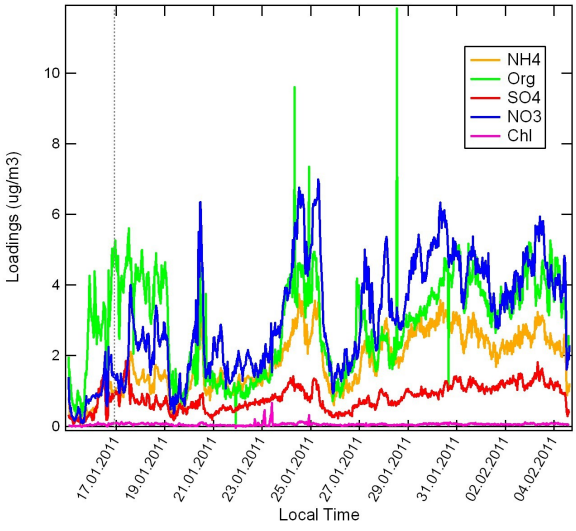

Figure 1. Preliminary results of the ACSM. The aerosol, SO_4, NO_3, NH_4, Cl and organics were measured.

We present measurements of submicron aerosol composition from an aerosol chemical speciation monitor (ACSM, Aerodyne Research, Inc.) deployed in downtown Zurich. The ACSM yields quantitative mass spectra of the non-refractory aerosol component with an averaging period of 30 minutes. As shown in Fig. 1, the ACSM is capable of resolving inorganic species such as NH_4, SO_4, NO_3, Cl, and the organic fraction. The mass spectra can be further analyzed by positive matrix factorization algorithm (PMF) or related techniques, which allow for identification and apportionment of the inorganic and organic fraction to important sources and processes.

Data from downtown Zurich collected during two weeks in January 2011 is shown in Fig. 1. PMF analysis of the organic component resolves the following factors: oxygenated organic aerosol (OOA), hydrocarbon-like organic aerosol (HOA) and biomass burning organic aerosol (BBOA). Mean concentrations for these components are shown in Table 1.

Table 1. Preliminary results of PMF applied to the organic portion. The algorithm allowed to deconvolve the organic data into three factors, i.e., OOA, HOA and BBOA.

factors	Loadings ($\mu g \cdot m^{-3}$)	Loadings (%)
OOA	2.40	52
HOA	1.40	26
BBOA	1.22	22

We will discuss identification and source apportionment of AMS and PMF data at an urban site over a six-month period (January to July 2011). Aerosol composition and source apportionment will be used to investigate the seasonal variability in the relative importance of specific emission sources and processes in the city of Zurich.

This work was supported by the Swiss Federal Office for the Environment (FOEN).

An intensive, one-year measurement campaign from August 2007 to August 2008 was carried out to determine the composition of PM_{10} and $PM_{2.5}$ at five locations in the Netherlands. The major goal of this study was to reduce uncertainties concerning composition, distribution and origin of particulate matter in the Netherlands. The work presented here was done within the framework of the Netherlands Research program on Particulate matter (BOP).

In the case of $PM_{2.5}$ the sum of all components measured in the collected filter samples explained 75-80%. Existing knowledge was used to partially close the remaining gap. After this procedure, 85-90% of the mass could be accounted for.

Generally, a considerable conformity in the chemical composition of $PM_{2.5}$ (and PM_{10}) is observed. In the case of $PM_{2.5}$, the secondary inorganic aerosol – the sum of sulphate, nitrate and ammonium - is the most dominant (42-48%). Higher contributions are measured at the rural locations. The second dominant contribution to PM2.5 comes from total carbonaceous matter and ranged between 22 and 32%. Sea salt, mineral dust and metals each comprises about 5% of total $PM_{2.5}$.

A detailed overview of the composition of the coarse fraction in the Netherlands could be presented. The chemical distribution shows a more even distribution among the components present in PM. Compared to the fine fraction, the presence of secondary inorganic aerosol and total carbonaceous matter become less dominant with contributions lower than 30%. Contributions of sea salt, mineral dust and metals are larger.

On days with high PM concentrations, all components except sea salt show higher concentrations. Relatively, the nitrate and unexplained contributions increase most on these types of days, while the relative contribution of the remaining components is mostly stable as function of PM level (figure 1). Sea salt maximises in marine air masses with clean air conditions.

From a literature study, the potential contribution from natural sources to the main components is estimated. The most important natural contributions came from sea salt and organic material. Although the analysis was rather pragmatic, it illustrates that the majority of PM in the Netherlands is of anthropogenic origin (Figure 2) being much higher than than originally assumed.

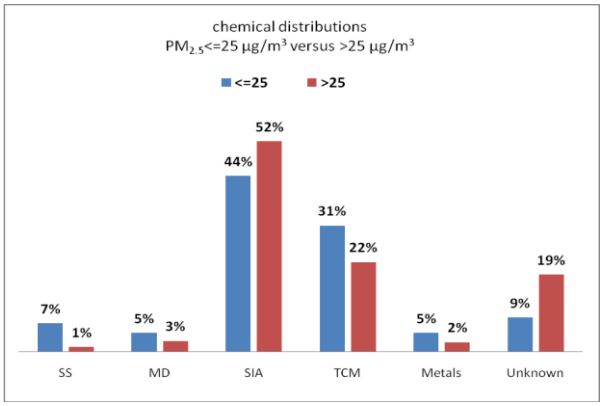

Figure 1. Change in chemical distribution in data substes for PM2.5 V<= 25 and PM2.5>2.5 µg/m^3.

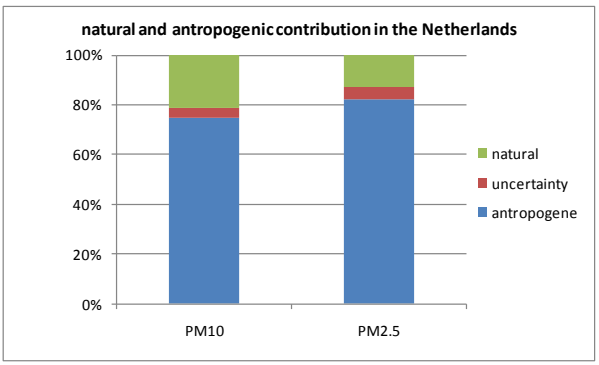

Figure 2. Natural and anthropogenic contributions to PM_{10} and $PM_{2.5}$ as estimated from the BOP data set.

The weekly cycle of ambient concentrations and traffic emissions of coarse (PM10-PM2.5) atmospheric particles

Presenting author email: andre.prevot@psi.ch

The aim of the study is to investigate the existence of a weekly cycle of coarse mode (PM10 – PM2.5) atmospheric particles, to compare this weekly cycle to the weekly cycle of PM2.5 and to compare the strength of the coarse mode weekly cycle in different seasons and different wind speed and precipitation conditions. In addition, an estimate of the contribution of traffic to the total ambient coarse mode particulate matter in urban areas is provided by estimating the weekly cycle of coarse mode emissions and by comparing it to the weekly cycle of ambient concentrations. The coarse mode data used in the study are the result of simultaneous daily measurements of PM10 and PM2.5 at seven sites located in Switzerland. The measurements cover a period of 7-12 years for six stations and 3 years for one station (Figure 1). It is found that a coarse mode weekly cycle is present in various types of urban and rural stations. Two examples are shown in Figure 2.
Ambient concentrations on weekdays are higher than on Sundays by a factor of 1.53 on average over all urban and suburban sites and by a factor of 1.32 on average over all rural sites. Moreover, the relative increase of coarse mode ambient concentrations on weekdays compared to Sundays was larger than the relative increase of PM2.5 concentrations by a factor of 2.7 on average over all urban and suburban sites whereas no considerable difference was found at the rural sites. A calculation of coarse mode traffic emissions for an urban scenario was carried out using traffic-induced dust resuspension and brake wear emission factors for light and heavy duty vehicles and traffic counts from urban areas in Switzerland. It is shown that coarse mode emissions on weekdays are greater than on Sundays by a factor of 1.73.

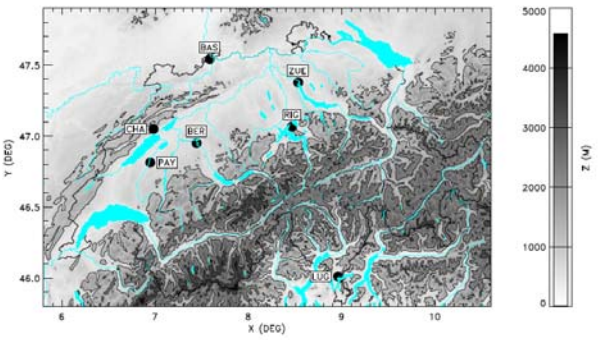

Figure 1: Locations of stations in this study. From West to East: Payerne, Chaumont, Bern, Basel, Rigi Zurich, Lugano

The contribution of traffic to coarse mode urban ambient concentrations was estimated to be 0.7 (0.52-0.9) on weekends and 0.8 (0.68-0.93) on weekdays.

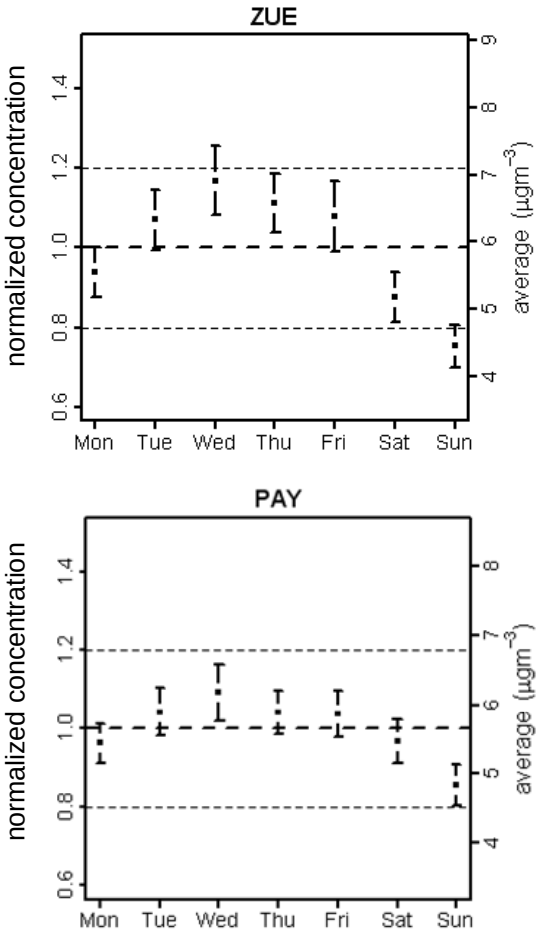

Figure 2: Weekly cycle of coarse particulate matter (PM10-PM2.5) for the urban background site Zurich and the rural site Payerne.

Jordan is a country under continuous development that faces a rapid increase in air pollution due to rapid increase in population density and industrial activities. Research on aerosols is rather sparse in Jordan. Very few studies have only focused on atmospheric aerosols because of the lack of air quality data as well as the absence of routine monitoring of ambient air pollution. However, previous research activities and studies have not focused on the capital city, Amman, neither they included measurements of particle number concentrations. Therefore, the purpose of this study was to investigate the number concentration of submicron particles in urban and suburban atmosphere of Amman during the spring season of year 2009. We specifically focused on the following aspects: (1) characteristics dispersion of submicron particle number concentrations at urban/suburban areas in the absence of dust episodes and (2) the influence of short-range transported dust episodes on the characteristics of submicron particle number concentrations.

We performed a measurement campaign at two sites (Hussein et al. 2011): suburban (University of Jordan campus) and urban (Al-Hashmi Al-Shamali). The aerosol measurements were performed with a portable Condensation Particle Counter (CPC, TSI model 3007).

Our findings confirmed that the particle number concentration of submicron aerosol particles is characterized by a daily pattern (Figure 1). This suggests that traffic emissions can be one of the main sources in Amman. Our speculations from both the measurement setup and with comparison with previous studies indicate that most of the submicron particles at the urban site were mainly in the Aitken and accumulation modes. The number concentration of submicron aerosol particles, which originated from the nearby highway, at the urban site decreased exponentially with the wind speed.

The dust loading in the atmosphere took several hours to build up and wash out before and after the air masses crossing over Amman region. In general, the total number concentration of submicron particles during a dust episode can be about 1/5 of what is typically observed during workdays without dust episodes. The low concentrations during dust episodes suggests that dust particles act as a coagulation sink for the submicron particles where their concentrations are reduces significantly, and thus, the total number concentration is also reduced. In addition, the wind speed during the observed dust episode was high enough to dilute the locally produced urban particles and disperse them efficiently. On the following days of a dust episode the number concentration gradually builds up in the urban atmosphere indicating the loading of aerosols from local sources within the city.

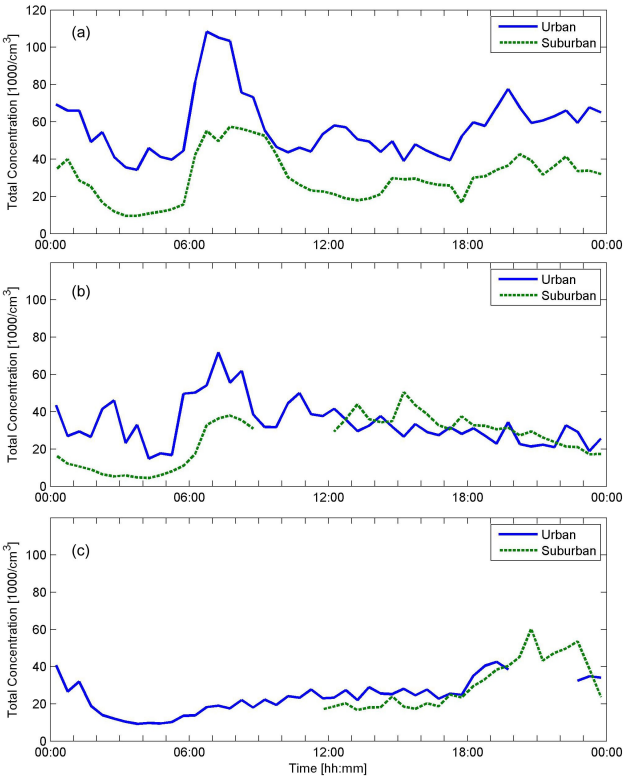

Figure 1. Daily patterns of the particle number concentrations (30-minutes means) at urban and suburban sites: (a) Saturdays–Wednesdays, (b) Thursdays, and (c) Fridays.

Presenting author email: anna.lahde@uef.fi

The copper nanoparticles and nanocomposites hold great promise for electronics, ceramics, optical (Takeda et al. 2002) and thin film applications (Baxter et al. 1995), and high surface catalyst (Karakhanov et al. 2010). However, metals such as copper are very susceptile to oxidation forming nonconductive oxides. In order to prevent the oxidation, a protective coating layer (e.g. SiO_2) is typically applied on the particle surface (Fotou et al. 2000).

In this paper, we present an atmospheric pressure chemical vapour synthesis method (APCVS) for the prepration of nanocomposite particles composed of Si/SiO_2 with Cu nanometer size core. Metal-organic Cu(I) complex, $[CuN(Si(Me_3)_2]_4$, was synthesized and used as a precursor in APCVS that enable continuous production of highly pure materials in one-stage. The particle formation is based on the decomposition of the precursor that leads to homogeneous nucleation of released Cu and Si species and subsequent formation of nanoparticles with narrow size distribution. Since the Si coated Cu particles are prepared in one-stage under inert atmosphere, the oxidation of ultrafine Cu particles can be avoided.

Figure 1 shows the number size distributions of particle prepared at the vaporization temperature of 200 ºC in inert (N_2) and reductive (H_2/N_2 10 v-%) atmospheres.

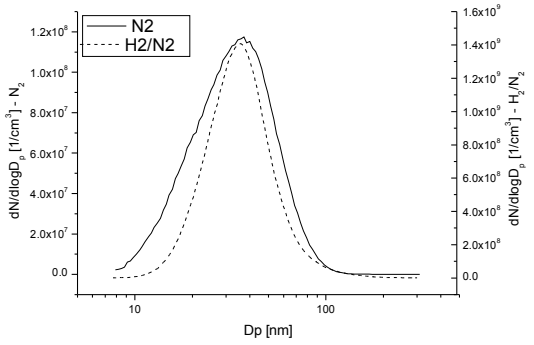

Figure 1. The number size distribution of Cu/Si particles prepared from non-purified precursor and vaporized at the heat bath temperature between 234-239 ºC. (Size distribution not dilution corrected, dilution ratio 1:19).

The geometric mean diameter of the particles was around 30 nm and the geometric standard deviation 1.3 in both cases. However, the total number of particles was baout nune times lower at N_2 ($N=6.2\times10^7$ 1/cm^3) compared at H_2/N_2 ($N=5.6\times10^8$ 1/cm^3) atmosphere. This is due to the enhanced decomposition of Cu(I) complex.The rapid decomposition lead also to a fast depletation of the precursor vapour and formation of copper film on the walls of the vaporisation flask.

The produced particles collected on the filter had reddish brown colour typical for metallic copper. Figure 2 shows the TEM images of the composite particles in inert (A) and reductive (B) atmosphere. The spherical coated primary nanoparticles were obtained when prepared under N_2. Since the components originated from the one precursor and not from the mixture of compounds, they were uniformly distributed in the gas phase resulting a uniform coating layer around the particles. Based on TEM/EDS analysis, the metallic copper was protected against oxidation with the shell consisting of Si/SiO_2. Under H_2/N_2 atmosphere, matrix type particles with ultrafine Cu particles embedded in SiO_2 were formed, see Figure 2B.

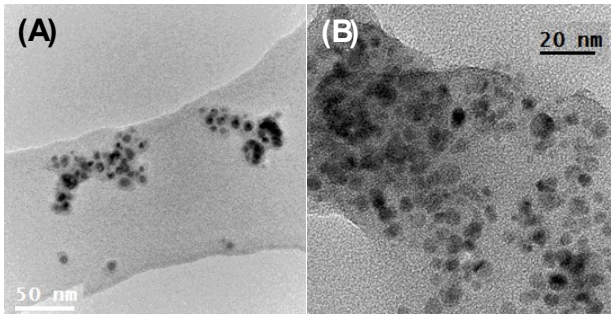

Figure 2. TEM images of Si/SiO_2 coated copper core particles formed at 800 (A) in nitrogen and (B) H_2/N_2 atmosphere.

Carbon nanotubes (CNTs) are a unique family of materials exhibiting diverse useful chemical and physical properties. The CNTs and especially single-walled CNTs (SWCNTs) were found to have exceptional mechanical, thermal and electronic properties. Among different routes to synthesize SWCNTs, an aerosol CVD method is one of the most promising. This method allows to grow high quality and clean SWCNTs with certain diameters and lengths. CNTs can be easily deposited onto practically any substrate, including temperature nontolerant polymers, so that time-consuming steps of CNT purification from the catalyst and support, dispersion and deposition processes are avoided. Supplementary advantages of the aerosol method are possibilities to on-line control of the CNT quality and separate individual and bundled CNTs. This continuous aerosol CVD process is one of the most promising and powerful methods for the high-yield synthesis at controlled conditions. (Nasibulin & Shandakov, 2010)

This paper reviews the latest results obtained by two different aerosol synthesis methods elaborated in our group. In the first method, catalyst particles were produced by evaporating catalyst material from resistively heated Fe wire (a hot wire generator, HWG method) (Nasibulin *et al.*, 2005). The second method is based on ferrocene vapor decomposition in carbon monoxide atmosphere (Moisala *et al.*, 2006).

We report the investigations of the mechanism of single-walled carbon nanotube formation (Anisimov *et al.*, 2010; Nasibulin *et al.*, 2006) and charging of CNTs in the gas phase due to the bundling process (Nasibulin *et al.*, 2008). The paper also discusses the discovery and growth mechanism of a novel hybrid material, NanoBuds (Nasibulin *et al.*, 2007), SWCNTs with covalently attached fullerenes.

Direct integration of the CNTs produced by the aerosol methods into different applications, especially for high-performance flexible electronics, is discussed. (Kaskela *et al.*, 2010; Sun *et al.*, 2011). Produced SWCNT/polyethylene composite films have exhibited excellent optical and electrical properties as well as high mechanical flexibility. It was found that the electrical conductivity of the SWCNT films could be significantly improved by ethanol densification and chemical doping. SWCNT/polyethylene thin films demonstrated excellent cold electron field emission properties. We have fabricated state-of-the-art key components from the same single component multifunctional SWNT material for several high-impact application areas: high efficiency nanoparticle filters with a figure of merit of 147 Pa^{-1}, transparent and conductive electrodes with a sheet resistance of 84 Ω/□ and a transmittance of 90%, electrochemical sensors with extremely low detection limits below 100 nM, and polymer-free saturable absorbers for ultrafast femtosecond lasers. Furthermore, the films are demonstrated as the main components in gas flowmeters, gas heaters and transparent thermoacoustic loudspeakers.

Cloud condensation nuclei (CCN) activity and oxygen-to-carbon elemental ratios following thermodenuder treatment of organic particles grown by α-pinene ozonolysis

M. Kuwata, Q. Chen and S. T. Martin

School of Engineering and Applied Sciences & Department of Earth and Planetary Sciences,
Harvard University, Cambridge, Massachusetts, 02138 USA
Keywords: CCN, secondary organic material, elemental ratio, volatility
Presenting author email: scot_martin@harvard.edu

Introduction CCN activity of aerosol particles is important as a regulator of cloud properties, including their brightness, lifetime, and precipitation. Although CCN activity of pure compounds is predictable from their chemical characters, CCN activity of secondary organic material (SOM) is not understood for quantitative prediction due to their complexity in chemical composition.

In the present study, we systematically controlled SOM chemical composition generated using the Harvard Environmental chamber (HEC) by (1) altering SOM concentration (M_{org}) in the HEC, and (2) increasing the thermodenuder (TD) temperature (T) connected to the HEC. SOM chemical composition was measured simultaneously with CCN activity. This experimental design allows us to relate CCN activity and chemical composition, as both M_{org} and T controls SOM chemical composition based on volatility.

Experiment The HEC is consisted of a 4.7 m^3 Teflon bag housed in a temperature controlled (25 °C) room. It was operated as a continuous stirred tank reactor, providing sufficient time to measure SOM. SOM was produced by dark ozonolysis of α-pinene (8 – 80 ppb) with the presence of 2-butanol as an OH scavenger. SOM concentration in the chamber ranged from 1.4 to 37μg m^{-3}, depending on α-pinene concentration. 30-nm $(NH_4)_2SO_4$ seed particles, those were provided from a differential mobility analyzer (DMA), were also continuously injected into the chamber. Ozone concentration and relative humidity were feedback controlled as 50 ppb and 40%, respectively.

SOM particles generated in the HEC were injected into a thermodenuder (TSI 3065), which was operated at bypass, 25, 60, 80, and 100 °C. The flow passed through the TD was split to three flows to measure size-resolved CCN activity (DMA-CCN counter(CCNC)), chemical composition (high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS), and number size-distribution (scanning mobility particle sizer (SMPS).

CCN activation curve measured by the DMA-CCNC was fitted by a sigmoid function to obtain dry activation diameter (d_{dry}) κ values, which is defined as $\kappa = i\, MW_{water}\rho_{org}/MW_{org}\rho_{water}$, were employed to represent CCN activity [i: van't Hoff factor, MW_x: molecular weight of x, ρ_x: density of x]. κ was iteratively calculated to reproduce d_{dry} obtained from size-resolved CCN spectra.

Results and discussion

We observed ~50% of decrease in M_{org} following TD treatment at 100 °C regardless of M_{org} in the HEC. This demonstrates that evaporation is the main process occurring in the TD. Elemental composition of SOM measured by the HR-ToF-AMS revealed that both M_{org} and T dependences are consistent in terms of volatility: oxygen-to-carbon (O:C) ratio increased for lower volatility compounds (lower M_{org}/higher T), while H:C ratio decreased for these conditions. This trend was further confirmed using a Van Krevelen diagram. All data points aligned on a straight line ([H:C] = -0.8 [O:C] + 1.8), including both M_{org} and T dependences. These results demonstrate that the main process occurring in the thermodenuder is evaporation of relatively volatile compounds.

κ did not depend on M_{org} at 25 °C, which may lead to predict that T also does not alter κ, considering the consistent dependences of elemental ratios on M_{org} and T. However, κ decreased at higher T. The magnitude of the decrease was significant (~20 % at 100 °C) at higher M_{org} (> 10μg m^{-3}), while the decrease was not significant at the low M_{org} (1.4μg m^{-3}).

These apparently contradicting results can be consistently interpreted as follows. TD evaporates relatively volatile materials, which cause decrease in M_{org} and changes in elemental ratios. At the same time, it enhances oligomer concentration in particles due to (1) evaporation of relatively volatile monomers, and (2) thermally induced oligomer formation reactions. These processes decrease κ, as oligomers have higher MW_{org} than original monomers. A variety of functional groups such as carbonyl groups is required for oligomerization reactions. Decrease in κ was significant at higher M_{org}, as relatively volatile carbonyl compounds could partition to particle phase due to higher concentration. This interpretation was supported by a model calculation employing master chemical mechanism coupled with SIMPOL vapour pressure prediction method, which predicted that carbonyl groups are depleted at lower M_{org}, while a variety of functional groups exist at higher M_{org}.

Surface tension of nanosized drops of mono- and bivalent metals

A. A. Onischuk, S. V. Vosel, P. A. Purtov

Institute of Chemical Kinetics and Combustion, Novosibirsk 630090, Russia
Keywords: surface tension, nanoparticles, homogeneous nucleation, nucleation rate.
Presenting author email: onischuk@kinetics.nsc.ru

The surface tension of nanosized drops is a rather sharp function of radius [1]. It is not possible to measure this quantity experimentally for radius of about 1 nm and numerical calculations are possible only for simple systems, like Lennard-Jones(LJ) fluids [2]. In this work we demonstrate the way to determine the small drop surface tension from the experimental nucleation rate.

The nucleation theory gives the rate of nucleation I (the number of critical nuclei formed per unit time per unit volume) as [3, 4]:

$$I = KSn_1^{sat}\beta Z \exp\left(-\frac{4\pi R_S^2 \sigma_S(R_S)}{k_B T}\right) \quad (1)$$

where S is the supersaturation, n_1^{sat} is the saturated vapor concentration, K is the translation-rotation free energy correction factor (arising due to the so-called replacement free energy [3]), R_S is the radius of the surface of tension, β is the collision frequency of the vapor molecules with the critical nucleus, Z is the so-called Zeldovich factor, $\sigma_S(R_S)$ is the surface tension of the critical nucleus referred to the surface of tension, k_B is the Boltzmann constant, T is the absolute temperature. The Classical Nucleation Theory (CNT) assumes that the drop surface tension is equal to that of a flat surface (σ_∞). This simplification results sometimes in an error in the nucleation rate of tens to hundreds orders of magnitude. Besides, it was put $K \approx 1$ in CNT, however, the direct numerical calculation have shown that $K \approx 10^9$ - 10^{13} (for the LJ systems) [3]. To obtain the rigorous analytical formula for the nucleation rate one should derive the formula for Zeldovitch factor Z accounting the dependence of drop surface tension on radius and an analytical expression for the correction factor K. Quite recently we obtained the analytical formula for the correction factor in the framework of the Frenkel's theory of liquids, Reiss theory accounting the fluctuations of the drop center of mass, and Kusaka theory of replacement free energy [4]. In the present work we derived the analytical formula for Zeldovitch factor in the framework of the Nishioka thermodynamic theory of non-critical drop [5]. Thus, the rigorous formula for the nucleation rate is

$$I = K\left(Sn_1^{sat}\right)^2 \sqrt{\frac{2m\sigma_S(R_S)}{\pi}} \frac{\varphi(x)}{\rho} \exp\left(-\frac{4\pi R_S^2 \sigma(R_S)}{k_B T}\right), \quad (2)$$

where ρ is the density of the liquid macroscopic reference phase (having the same chemical potential as the critical nucleus), m is the mass of molecule, $x=\delta/R_S$, δ is the Tolman length which is equal to $\delta = R_e - R_S$, R_e is the equimolar radius, $\varphi(x)$ is some function of x [6]. In this work we have analysed the nucleation rate from the supersaturated vapor of mono- and bivalent metals as measured in our laboratory (Zn Ag) and elsewhere (Li, Na, Cs, Ag, Hg, Mg) [7-11]. It was found from this analysis that the $\varphi(x)$ can be set as equal to unity with the accuracy of 10%. Then, accounting the analytical formula for the correction factor [4] the final formula for the nucleation rate can be written as:

$$I \approx 6 \times 10^2 \pi^{7/2} Sn_1^{sat} \frac{(u\rho)^3 R_S^9}{m^2 (k_B T)^{3/2}} \sqrt{\sigma_S(R_S)} \exp\left(-\frac{4\pi R_S^2 \sigma_S(R_S)}{3k_B T}\right) \quad (3)$$

where u is the sound velocity in the reference phase. If the nucleation rate is measured at some T and S, the surface tension and the radius R_S can be found by solving Eq. (3) together with the Kelvin equation. The surface tension thus found is shown in Fig. 1 for mono and bivalent metals. The plotted points are not dependences σ_S/σ_∞ vs. R_S, but there are three independent values σ_S/σ_∞ for each metal corresponding to three different temperatures and three values of R_S. All the metals considered can be divided into two groups Li, Na, Cs, Ag (monovalent metals) $\sigma_S/\sigma_\infty > 1$ and Mg, Zn, Hg (bivalent metals) $\sigma_S/\sigma_\infty < 1$. In all the cases the surface tension for drops of radius about 1 nm differs essentially from that of the flat surface, i.e. the surface tension is a strong function of size.

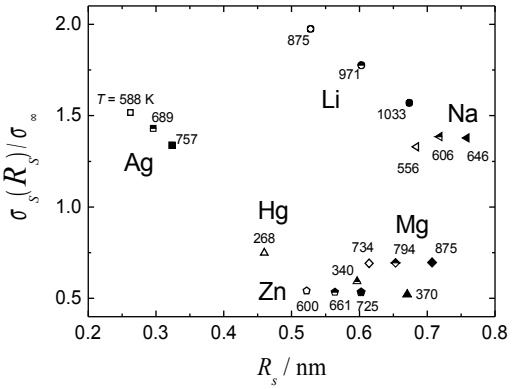

Fig. 1. $\sigma_S(R_S)/\sigma_\infty$ and R_S (T is shown in the plot).

Recent developments have led to significant reductions in the minimum size that can be detected with condensation particle counters (CPCs), allowing the detection of individual particles as small as 1 nm (Gamero and Fernandez de la Mora 2000, Jiang et al. 2011, Vanhanen et al. 2011)

While CPCs are widely used as particle detectors due to their high sensitivity and high signal-to-noise ratio, previous laboratory work shows that the activation efficiencies for particles smaller than 3nm are influenced by the chemical composition of particles and the condensing vapor, which lead to measurement uncertainties that are difficult to quantify.

On the other hand, in spite of the work on heterogeneous nucleation in the past decades, discrepancies between measurements and theory still exist.

In this study, we carry out experiments to explore the effects of nanoparticle chemical composition, electrical polarity (+1, 0, -1), and charge (+1, +2, +3, +4) on heterogeneous nucleation of several supersaturated vapors.

Particle materials studied include (NaCl, W, Ag, and polyethylene glycol). Several condensing vapors (water, n-butanol, and diethylene glycol) were investigated.

The comparison between the experimental result and the existing theories is discussed. This study not only enriches our knowledge of activation efficiencies of different CPCs, which are essential for aerosol scientists who work with them, but also serves as an attempt to explore the fundamental scientific mystery of heterogeneous nucleation.

Presenting author email: silvan.schmid@nanotech.dtu.dk

The use of engineered nanoparticles in commercial applications has increased and personal monitoring devices for the assessment of nanoparticle exposure doses are highly demanded (Nel, 2006). We present a micro sensor for the real-time measurement of the mass spectrum of airborne micro and nanoparticles for the implementation in a portable aerosol nanoparticle monitor.

The micro sensor is based on resonant strings, as shown in Fig. 1, and measures the particle mass spectrum of airborne particles with a mass range of up to 5 orders of magnitude. Every time a particle lands on the string it causes a resonant frequency shift. The frequency shift depends on the mass and landing position of a particle on the string. Based on an analytical mechanical model, both, the mass and position of individual particles can be calculated by measuring the shifts of the first two bending modes (Schmid, 2010). This method is fast and requires low computing power which is important for a the implementation in a portable device.

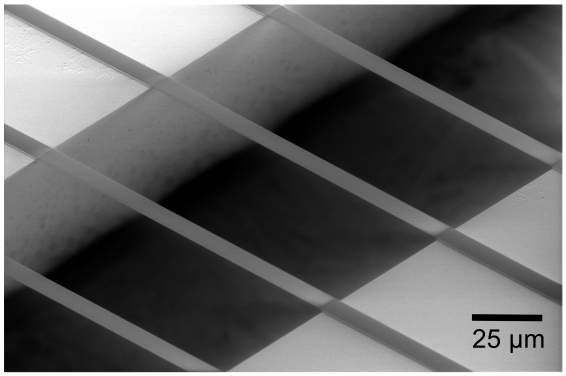

Figure 1. Scanning electron microscopy image of silicon nitride string resonators.

The sensor has been tested by distinctively measuring 3 different particles with weights Δm of 4.8±0.18 pg, 14.9±5.4 pg and 111.8±14.4 pg, respectively, with a 216 µm long and 340 nm thick silicon nitride string with a weight of m_0 = 0.6 ng. From the resulting particle-number versus particle-mass histogram, shown in Fig. 2, mean particle masses of 4.5±0.8 pg, 17.6±1.8 pg and 125.2±1.0 pg were obtained. The measured values are precise and correspond to the expected masses (see Fig. 3). The 4.8 pg particles caused an average relative frequency shift of 0.6%. At atmospheric pressure, the typical frequency resolution of micro beam resonators is approximately 4e-4% (Li, 2007) which gives a mass resolution in the femtogram range.

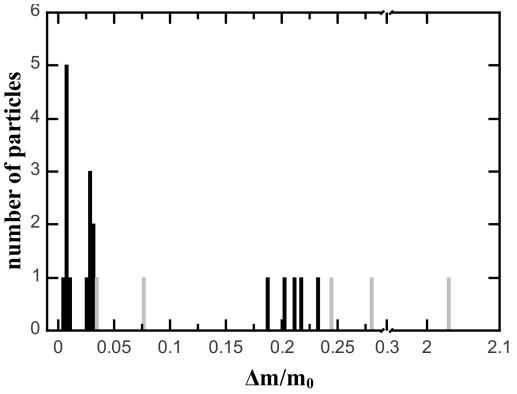

Figure 2. Histogram of number of particles versus mass ratio

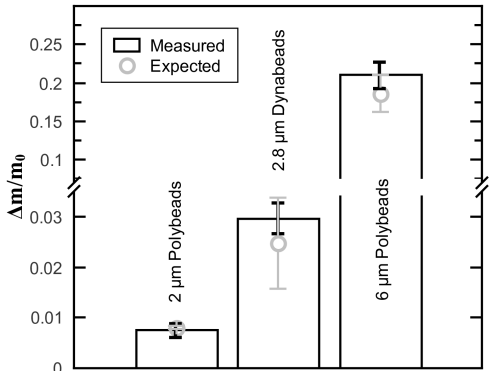

Figure 3. The average measured mass ratios for the three different types of micro particles compared to the expected values.

The sensitivity of the sensor can be increased by decreasing the string mass. With a string of one picogram, nanoparticles in the attogram range can be detected. In order to increase the sensor efficiency, beforehand unipolarly charged nanoparticles can be focused onto the string by an electrostatic lens. The presented micro sensor enables real-time mass spectrometry for portable personal aerosol monitoring devices.

Characterizing lengths and aerodynamic diameters of airborne glass fibers

Bon Ki Ku[1], Gregory Deye[1] and Leonid A. Turkevich[1]

[1]Centers for Disease Control and Prevention (CDC), National Institute for Occupational Safety and Health (NIOSH), Cincinnati, Ohio 45226, USA
Keywords: Glass fiber, length, diameter, screen.
Presenting author email: BKu@cdc.gov

Introduction

Historically, fiber-related research primarily grew out of health and manufacturing issues regarding asbestos. Current fiber measurement techniques also arose primarily due to health concerns over asbestos exposure. Fiber toxicity appears to be mostly a function of fiber concentration, dimensions (diameter and length) and durability in the lungs. During the past decade, airborne fibrous particles such as carbon nanotubes and carbon nanofibers have come under scrutiny owing to their asbestos-like appearance (Poland et al. 2008). This suspicion hinges on thin fiber-like structure of these particles and their presumed insolubility in the lungs, both attributes of harmful asbestos fibers. To better understand the toxicity of fibers, it is essential to classify fibers by length for toxicology studies. In this study we investigated how feasible it would be to use screens combined with asbestos sampling cassettes for length classification of fibers.

Methods

Glass fiber powder (GW1) supplied by the Japan Fibrous Material Research Association (JFMRA) was used as a surrogate of asbestos to generate airborne glass fibers by a vortex shaking method (Ku et al., 2006). The glass fiber sample had a geometric mean length 20.0 μm with geometric standard deviation (GSD) of 2.58 and geometric mean diameter 0.88 μm with geometric standard deviation (GSD) of 3.10 (Kohyama et al., 1997). Size distributions of the airborne glass fibers from the vortex shaker were measured by an Aerodynamic Particle Sizer (3321, TSI Inc.), and the airborne fibers were collected on a mixed cellulose ester filter (SKC Inc) in a 25 mm conductive cassette to measure length distribution of the fibers by a phase contrast microscope (PCM) with 40X and 10X magnifications. Nylon net screens with different screen mesh sizes (60, 20, and 10 μm) were used to examine the effect of screen size on length distribution.

Results and Conclusion

Figure 1 shows cumulative number concentration of glass fibers as a function of fiber length for different screen sizes. The red and blue lines in Fig. 1 represent mesh sizes of screen 20 and 60 μm. With no screen, the length distribution of the fibers is similar to the one reported in a previous paper. As screen mesh size decreases from screen 60 to 20, 50% cut-off length decreases from about 10 μm to about 7.5 μm. Compared to no screen case, using screens could give reduced lengths of fibers. It is worth noting that the 50% cut-off length for screen 10 is similar to the one for screen 60, but the slope of the cumulative curve for screen 10 becomes steeper, which means that the length distribution for screen 10 is narrower than the one for screen 60. The percentage of fibers longer than 20 and 60 μm for screen 20 and 60 is about 17 % and 3 %, respectively while the percentage of fibers longer than 10 μm for screen 10 is about 50 %,

APS measurements showed that fibers with no screen have bimodal distributions, with a primary aerodynamic diameter 1.5-2 μm and secondary aerodynamic diameter 7 μm. Using screen 60 and 20 slightly decreased primary modal diameters and significantly reduced the secondary mode. Screen 10 removed almost completely the second mode. The loading of fibers on the filter was also investigated. Using screens resulted in relatively uniform loading along the diameter of the filter.

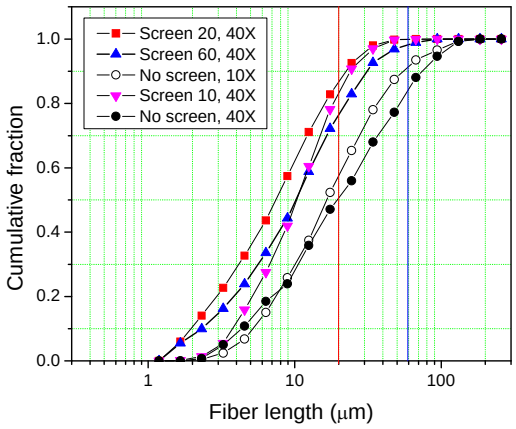

Figure 1. Cumulative fraction of fiber number concentration as a function of fiber length for different screen sizes. 10X and 40X mean magnifications used.

Acknowledgments

We would like to thank Dr. Ono-Ogasawara for sending us samples of glass fibers through the JFMRA in Japan, and Elizabeth Ashley for taking images of fibers and analyzing length distributions using the PCM. Session 3F: Thermal and Optical Effects

Using holographic optical landscapes to manipulate aerosol arrays, compare particle hygroscopicity and study aerosol coagulation.

R.M. Power,[1] J.S.Walker,[1] A.E. Carruthers[1] and J.P. Reid[1]

[1]School of Chemistry, University of Bristol, Bristol, BS8 1TS, United Kingdom

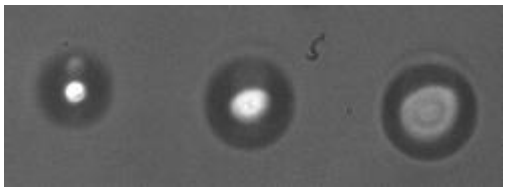
Keywords: Optical trapping & guiding, holographic optical tweezers, aerosol sampling & analysis, aerosol coalescence

Presenting author email: Rory.Power@bristol.ac.uk

Optical forces can be used to manipulate arrays of aerosol particles[1] in order to study their dynamics.[2] We demonstrate the use of multiple gradient force optical traps in studying the hygroscopic growth and coalescence of aerosol particles. These are two of the most fundamental processes that govern size distribution of aerosols a critical parameter for characterizing the role of aerosols in atmospheric science and drug delivery.

Aerosol particles can be confined in three dimensions by a tightly focused Gaussian laser beam. At the focus an optically induced gradient force several orders of magnitude larger than gravity acts to restore particles to the point of highest light intensity. This technique is referred to as 'optical tweezing'. Recently we have demonstrated the use of a spatial light modulator (SLM) in creating complex intensity patterns [2] in the optical trapping plane for the aerosol. By displaying a hologram onto the SLM the phase and intensity of light across the wavefront of the incident laser beam can be modified to produce the desired optical landscapes referred to as holographic optical tweezers (HOTs). A sequence of these holograms can be animated to produce a dynamically evolving optical landscape allowing complex manipulation of arrays of aerosol particles in three dimensions. [3]

Figure 1. An array of droplets trapped within an SLM generated holographic 'optical landscape'



HOTs can be used to manipulate particles of different size and composition independently in three dimensions. Optical barriers formed by the SLM can shield trapped droplets from the flow of free aerosol allowing additional droplets of chemically distinct composition to be added to the ensemble.[3] This can for example, allow an isolated droplet of known composition can be used as a probe of the gas phase conditions in an aerosol ensemble.

We will report two examples of the application of HOT aerosol arrays. The first application will examine the use of HOTs to perform comparative hygroscopicity measurements allowing validation of the aerosol diameter dependent equilibrium model (ADDEM) at high relative humidity (RHs approaching 100%). Such conditions are very difficult to replicate in the laboratory but are essential for understanding the activation of cloud condensation nuclei and the radiative forcing of atmospheric aerosol.

Cavity enhanced Raman scattering (CERS) allows droplet size to be determined with nanometre accuracy. [4] Using CERS in tandem with HOTs, we will show how the size of two chemically distinct droplets can be simultaneously measured, providing thermodynamic data on various aerosol species

In the second application we will show how aerosol HOTs can be used to study the factors governing particle interactions and coalescence. Tracking the position of a trapped particle from the brightfield image with millisecond resolution can be used to measure positional correlation of nearby particles and the interactions between them, providing information on droplet surface charge and the trapping forces. Further, measurements of elastic light scattering can provide information on the processes which occur over microsecond timescales during the coagulation event.

In conclusion, using novel HOT techniques we can gain considerable insight into the fundamental processes of aerosol coagulation and hygroscopic growth, processes that are responsible for controlling the evolution of aerosol size distributions in many complex environments.

Impact of Temperature Gradients on Brownian Coagulation

M. Arias-Zugasti[1] and D.E. Rosner[2]
[1] Dept. de Física Matemática y de Fluidos, UNED, Apdo: 60141, 28080 Madrid, Spain

Keywords: Coagulation; Fundamental aerosol physics; Aerosol modelling.
Presenting author email: maz@dfmf.uned.es

It has been recently shown that size-dependent particle thermophoresis, i.e. the movement of particles induced by a temperature gradient, provides a new coagulation mechanism [Rosner and Arias-Zugasti (2011)], which can either induce the coagulation of non-Brownian particles, or alter the coagulation frequency in the case of Brownian particles.

In the present work we consider this second scenario, in which an aerosol of Brownian particles evolves under the influence of both coagulation mechanisms: the well-known Brownian coagulation studied by Smoluchowski and the thermophoresis-induced coagulation. Rather than considering the addition of both coagulation frequencies, we derive a combined coagulation frequency based on a thermophoresis-modified formulation of the derivation of the coagulation frequency in the continuum limit by Smoluchowski. Hence, the Brownian-thermophoresis combined coagulation frequency is modeled in a way similar to the Brownian-sedimentation coagulation frequency [Simons (1986)], but with the gravitational sedimentation velocity replaced by the size-dependent thermophoresis velocity.

We show that the relative intensity of each coagulation process is given by a Peclet number, defined as the ratio of the characteristic coagulation frequencies: $\beta_{\mathrm{TP,ref}}/\beta_{\mathrm{B,ref}}$. Then, introducing the combined coagulation frequency as a kernel into a Smoluchowski-type population-balance integro-PDE, we perform a systematic parametric study of the time evolution of a coagulation aged, initially log-normal population, as a function of the control parameters of the problem: i.e. the aforementioned Peclet number (Pe) and the particle/gas Fourier thermal conductivity ratio k_p/k_g.

Our results show that in the long-time limit a quasi-self-preserving population is reached. The dependence of this quasi-self-preserving distribution function on Pe and on the particle/gas Fourier thermal conductivity ratio is analyzed. In this respect, we find that when the reference Peclet number is much smaller than, say 0.1, we recover the previously well-studied/characterized Brownian self-preserving populations. However, for intermediate Peclet-values characteristic distortions set in, corresponding to increased spread and skewness, and slightly smaller departures from log-normality. Ultimately (for Peclet-values larger than about 10 our quasi-self-preserving droplet size distributions become indistinguishable from our previously reported TP-dominated results [Rosner and Arias-Zugasti (2011)]. Remarkably, it has been observed that the dependence on the particle/gas Fourier thermal conductivity ratio reduces to a slight modification of the characteristic time and size scales (for $k_p/k_g > 10$), and hence the results for the self-similar normalized distribution function reached in the long-time limit are almost independent of the particle/gas Fourier thermal conductivity ratio in the whole range of values of the Peclet number. At the same time, our numerical results also show a non-trivial behavior of the quasi-self preserving particle size distribution for intermediate values of the Peclet number, which shows a non-monotonic behavior for some of its moments for values of the Peclet number of order unity (for instance the asymmetry-related skewness).

Photophoretic interaction of aerosol particles in rarefied gas medium

A.A. Cheremisin[1], A.V. Kushnarenko[2]

[1] Institute of Engineering Physics and Radio Electronics, Siberian Federal University, Krasnoyarsk, 660036, Russia

[2] Institute of Space and Information Technology, Siberian Federal University, Krasnoyarsk, 660036, Russia

Keywords: photophoresis, coagulation, heat and mass transfer

Presenting author email: aacheremisin@gmail.com, avkushnarenko@gmail.com

The main concepts underlying contemporary coagulation models have been known for a long time. This is Brownian motion of particles and interparticle interaction which occurs due to Van der Waalce forces and Coulomb electrostatic forces, if coagulating particles are charged.

The particles interaction that takes place as a result of gas-kinetic phenomenon – photophoresis has been investigated in this paper. The calculations are based on approximation of free molecular gas-kinetic regime and earlier developed Monte-Carlo algorithms (Cheremisin, 2010). In our previous work we have investigated the influence of gravito-photophoresis on aerosol stratification in the middle atmosphere (Cheremisin *et al*, 2005).

Photophoretic interaction forces of two spherical particles depending on particles sizes and distance between them under different ranges of gas medium pressure have been calculated. The example is shown on Figure1.

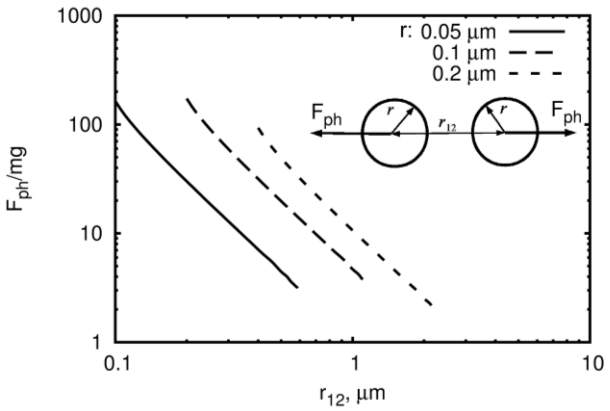

Figure 1. Relative photophoretic interaction force between two identical spherical particles of various sizes versus distance.

Here F_{ph} is photophoretic force and mg is gravity. The density of particles material is equal to 1000 kg per cubic meter. Accommodation coefficient for surface of each particle is equal to 0.5. Particles strongly absorb solar radiation, the optical properties are determined by the complex index of refraction, the value of which doesn't depend on wavelength and is equal to $1.95 - 0.66 \cdot i$, corresponding to soot optical properties. Absorption cross-sections have been calculated using Mie theory. Temperature of surrounding gas (air) is equal to 293K and pressure is 1220 Pa. The temperature of particles surfaces was calculated on the basis of requirement for thermal balance with flux of the solar and IR energy absorbed by particles, the flux of IR radiation emitted by particles, and the flux of molecular heat exchange taken into account.

We can see that repulsion photophoretic force occurs in condition of solar radiation with the pressure of about 0.1 atmosphere or less. These force is tens or hundreds times larger than gravity. Dependence of this interaction on distance between particles is similar to Coulomb type. The photophoretic force is important when the size of system of particles is smaller than the mean free path of the gas molecule, at distance where the value of Knudsen number is larger than 1.

Gas molecules continuously impact on the surface of aerosol particles and are reflected, the reflection can be specular and diffuse, with and without accomodation. For photophoresis accomodation is important. If the reflection is asymmetric a net force on each particle may result due to presence of the other particle. During reflection the molecules may pick up some energy and leave the surface with a higher thermal energy compared with the temperature of gas medium and then molecules may reach the surface of the other particle. Thus the particles with hot surfaces repulse due to gas molecule momentum exchange.

A higher radiation flux leads to increase in the particles temperature and, consequently, in interaction force value.

Photophoretic interaction forces have been calculated for laboratory vacuum chambers and for atmospheric conditions.

We estimated an impact of photoporetic interaction on coagulation constants. Photophoretic forces are capable of influencing aerosol particles coagulation depending on their size, optical properties, radiation and gas medium conditions.

Optical breakdown and detonation in aerosol systems

K.N. Volkov[1] and V.N. Emelyanov[2]
[1]Faculty of Engineering, Kingston University, London, SW15 3DW, United Kingdom
[2]Faculty of Physical and Mechanical Sciences, Baltic State Technical University, Saint Petersburg, 190005, Russia
Keywords: combustion aerosols, droplets, multiphase processes, aerosol fundamentals, CFD.
Presenting author email: k.volkov@kingston.ac.uk

The subject of the study stems from the increasing role of aerosol systems appearing in industry, technology and environment. Interaction of laser pulse with aerosols plays an important role in different areas (e.g., environmental monitoring of high-risk industrial objects and enclosed spaces, measurements of flammability and explosibility limits, propagation of laser radiation through explosive mixtures, laser ignition of volumetric explosion for application to fire mitigation). The role of particles and droplets in these applications is two-fold: particles and droplets may pose potential hazard for human activity (e.g., deposition of particles in human lungs) or can be successfully used in engineering solutions (e.g., to suppress acoustic instabilities of thermal processes). Processes that control transport and combustion of particles and droplets remain unresolved, and introduce significant uncertainties into modeling and simulation.

When a laser radiation interacts with a gas, the gas breaks down and becomes highly ionized. This process is accompanied by a light flash and generation of sound. The development of electron cascade requires the existence of initial free electrons in a gas. For every particle size of any material there is threshold intensity at which the particle material converts into the meta-stable condition and its intense evaporation leads to heat destruction of the particle. The injection of metal particles with low evaporation temperature and low ionization potential (e.g., aluminium) or liquid droplets decreases threshold value of optical breakdown on individual particle or droplet, and leads to drop of detonation minimum pulse energy (MPE). Vapour aureole around particle or droplet is a source of free electrons and optical breakdown in the gas-particle or gas-droplet mixture comes for lower energy of laser pulse than in pure gas (Emelyanov, 2007).

In this study, physical and mathematical models and up-to-date numerical methodology for computer modeling of optical breakdown are developed and validated. Laser-induced detonation in aerosol systems is studied, and advantages of the new methodology are demonstrated.

The mathematical formulation of the problem is divided into low-level models and high-level models. Low-level models correspond to the processes in the volume occupied by an individual particle or droplet induced by its interaction with a laser pulse. The high-level models correspond to the processes in the volume occupied by multiphase mixture due to energy supply to it. The data obtained from solution of low-level problem are used to calculate source terms in the governing equations describing high-level problem based on multi-velocity and multi-temperature continuum. It is assumed that particles and droplets are uniformly distributed in the domain. Some volume of the mixture depending on particle volume fraction is associated with each particle (individual reactor of a particle). The model of unsteady well-stirred reactor is used to calculate physical quantities in this volume. The solution of high-level problem provides volume fraction of particles and volume occupied by an individual particle or droplet. The numerical solution is based on finite volume method and splitting scheme on physical factors. Pseudo-gas of particles does not have internal pressure, so artificial pressure is introduced (Emelyanov, 2004).

The threshold value of optical breakdown and MPE of laser-induced detonation depending on total power and spot of laser pulse, mass fraction of particles and volume fraction of oxidant are computed. Some results are presented in the Figure 1 for fish-plate aluminium particles with size $50 \times 50 \times 5\ \mu m$ in the oxygen–acetylene mixture. Mass fraction of particles is 0.5 g/m^3. Wave-length of laser beam is 4.2 μm, radius of laser spot is 1.5 cm, and time of pulse is 2.6 μs. The results obtained are in a good agreement with the experimental data.

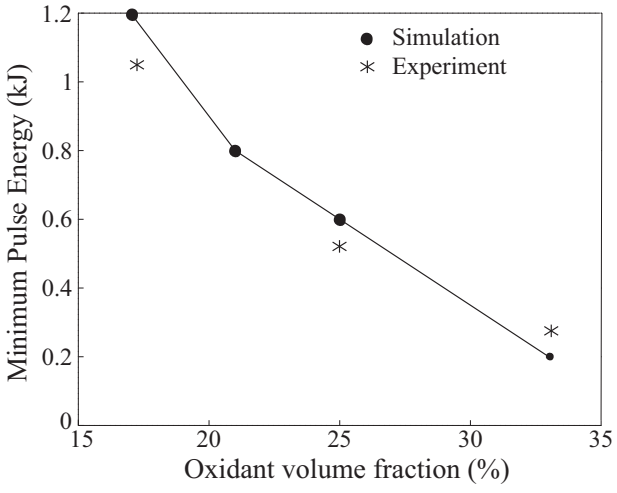

Figure 1. MPE of laser-induced detonation depending on oxidant volume fraction.

Thermophoresis of non-spherical particle: experimental prospect on soot particles

E. Brugière [1,2], F. Gensdarmes [1], F.-X. Ouf [1], J. Yon [2] and A. Coppalle [2]

[1] Aerosol Physics and Metrology Laboratory, IRSN, BP 68, 91192, Gif-sur-Yvette Cedex, France.
[2]UMR 6614 CORIA, Avenue de l'université, BP 8, 76801 Saint Etienne du Rouvray, France.
Keywords: thermophoresis, fractal aggregate, deposition.
Presenting author email: edouard.brugiere@irsn.fr

Thermophoresis is an important mechanism of micro-particle transport due to a temperature gradient in the surrounding medium. Extensive studies, both theoretical and experimental, have been carried out to understand the nature of this phenomenon which is well known for spherical particles contrary to non-spherical particles like soot particles. In fact, the soot particles are characterized by a complex morphology called "fractal" and, currently, the real impact of this morphology on deposition due to thermophoresis is not well known.

Thermophoresis of non spherical particles is more complex than the case of spheres. The theoretical solutions are more difficult and other parameters are needed, such as the diameter or the number of primary particles, the particle shape or orientation in the temperature gradient. The existing theory of the thermophoresis for non-spherical particles is limited and there are few solutions to formulate thermophoresis velocity in the continuum and the free molecule limits for several simple particle shapes. The reader is referred to a comprehensive review on thermophoresis of the two major categories, spherical and non-spherical particles, by Zheng (2002).

Mackowski (1990) analysed the thermophoresis of aggregates made of two-spheres in the near continuum regime. He shown that the aggregate thermophoretic velocity is not collinear to the temperature gradient. Moreover, Mackowski (1990) found that the thermophoretic force tends to rotate and aligns the aggregate along the temperature gradient.

Mackowski (2006) and Suzuki *et al.* (2009) demonstrated the influence of the number and the diameter of primary particles on the thermophoresis velocity of aggregates. On the one hand, Mackowski (2006) found in the free molecular regime that the thermophoretic velocity of an aggregate increases with the number of primary particles. On the other hand, Suzuki *et al*. (2009) found that thermophoretic velocity of an aggregate in the continuum regime is governed by the primary particle size and is much larger than those expected based on the size of aggregates and rather close to the velocity for particles in the free molecular regime. However, there is few reliable data to test the validity of these theories. Therefore, the influence of the particle shape and its orientation in a temperature gradient on the thermophoresis velocity are not mastered.

In order to show the particle orientation in the temperature gradient and the primary particle influence on the thermophoretic behavior, a new experimental device designed for the proposed experimental study is presented. This device called *SpectroMètre Thermique Circulaire* (SMTC) is based on the concept of a simplified version of the radial flow differential mobility analyser (DMA): the *Spectromètre de Mobilité Electrique Circulaire* (SMEC) developed by Pourprix (1989). The SMTC consists of a parallel arrangement of two circular plates (hot and cold). A schematic diagram is given in Figure 1; a sheath air flow (Qf) and an aerosol air flow (Qa) are passed between those two plates and for different flow rates and temperature gradients this new device will enable to determine with low uncertainties the mean thermophoresis velocity of spherical and non-spherical particles. In this presentation, the theoretical thermal study and the transfer functions of the SMTC will be presented. A comparaison between mean thermophoretic velocity of spherical and agregates particules having same mobility diameters will be proposed.

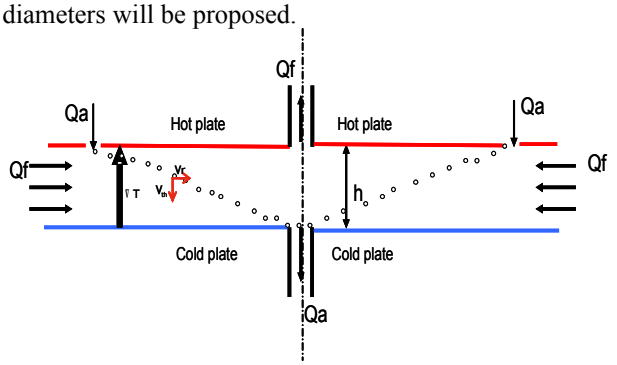

Figure 1. Schematic diagram of the SMTC.

Size measurement of dry ice particles in a jet flow using laser diffraction method

Yi-Hung Liu[1], Graham Calvert[2], Colin Hare[2],
Mojtaba Ghadiri[2], Shuji Matsusaka[1]

[1]Department of Chemical Engineering, Kyoto University, Nishikyo-ku, Kyoto 615-8510, Japan
[2]Institute of Particle Science and Engineering, University of Leeds LS2 9JT, UK
Keywords: dry ice, jet flow, size distribution, agglomeration.
Presenting author email: liu@cheme.kyoto-u.ac.jp

Dry ice blasting has been utilized as a dry cleaning method, which can be applied in many industrial fields, such as semiconductor, plastics, food, and pharmaceuticals, etc. The properties of dry ice particles, including size, shape, density, and hardness are thought to be important factors affecting the cleaning process (Spur *et al*., 1999). The agglomeration process of dry ice particles in the jet flow has been investigated (Liu *et al.*, 2010). It was shown that a chamber was effective for the generation of agglomerated dry ice particles. However, a precise measurement of the size of dry ice particles in the jet flow proved to be difficult due to the sublimation process. In the present study, the state of dry ice particles in the jet flow has been analyzed by an on-line laser diffraction method.

Dry ice particles were produced by rapid expansion of liquid carbon dioxide, based on Joule-Thomson effect. In this process, the temperature rapidly decreased by adiabatic expansion from the pressure of 5.5 ± 0.1 MPa to atmospheric pressure. The inner diameters of the nozzles used for expansion were 0.1, 0.2, and 0.5 mm. As an agglomeration chamber, ABS tubes, 50 mm in length and 2, 4, 6 mm in inner diameter, were attached to the nozzle outlet. The size of dry ice particles ejected from the nozzle or the ABS tube were measured by an aerosol analyzer (Spray-Tech, Malvern Instruments Inc.) based on the technique of laser diffraction. The laser beam and dry ice jet were both horizontal and oriented perpendicular to each other.

Figure 1 shows an example of the cumulative size distribution of dry ice particles in a steady state. For the distance from the nozzle $d \leq 40$ mm the median diameter was in the range from 1 to 2 μm and increased with the distance. As for $d = 50$ mm, the dry ice particles shrank to submicron size. A normal-like distribution can be ascertained at a short distance, i.e. $d \leq 40$ mm, while the distribution deviated as the distance increased ($d = 50$ mm). In the size distribution, two size regions were observed, i.e. a smaller diameter region of submicron and a larger diameter region around ten microns. It is found that the primary dry ice particles ejected from the nozzle still grew up and/or agglomerated up to a certain distance. When the distance was sufficiently large, two opposite phenomena, i.e. sublimation and agglomeration occurred. As a result, a bimodal distribution was obtained.

Figure 2 shows the cumulative size distribution of dry ice particles exhausted from the tube in a steady state. Comparing with Fig. 1, the particle size is remarkably larger, indicating that dry ice particles exhausted from the nozzle have already agglomerated in the tube. In addition, the median diameter decreased with increasing nozzle diameter.

Nucleation, condensation, agglomeration and sublimation processes all compete to yield the size distribution as measured. Among them, agglomeration is the most important in the tube (Liu *et al.*, 2010); i.e. dry ice particles of several micrometers are deposited on the tube wall and form a deposition layer; then, agglomerates are reentrained from the layer into the jet flow. The size of the reentrained agglomerates decreases with increasing flow velocity. In these experiments, the flow velocity increases with the nozzle diameter. This is considered as a reason for the trend of the results observed here.

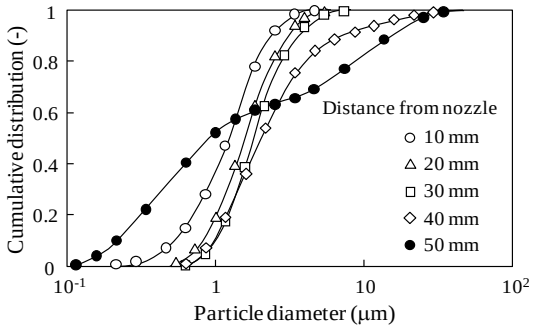

Figure 1. Cumulative size distribution of dry ice particles exhausted from nozzle (nozzle diameter = 0.2 mm).

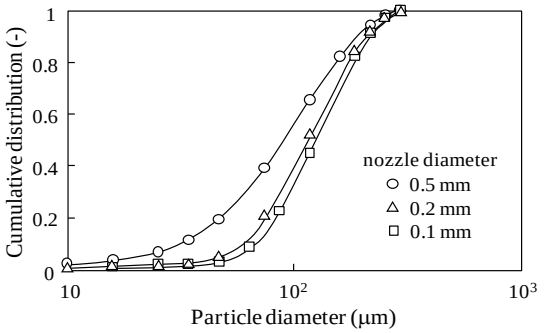

Figure 2. Cumulative size distribution of dry ice particles exhausted from tube (tube diameter = 6 mm, distance from the tube = 40 mm).

Plenary:

Aerosols for materials: medical and industrial applications and the role of nanotoxicology.

By Wendelin Stark

Aerosols for Materials: Medical and Industrial Applications and the Role of Nanotoxicology

Wendelin J. Stark

Department of Chemistry and Applied Biosciences, ETH Zurich, 8093 Zurich
Keywords: Chemical Aerosol Engineering, Metal Nanoparticles, Nanomedicine
Presenting author email: wstark@ethz.ch

This presentation will highlight how chemical and biological insight into aerosols opens above avenues as emerging scientific disciplines. Aerosol science has recently strongly contributed to the following large, emerging areas of research:

A) Materials Fabrication

Industrial aerosol processing has been chemically developed to extend traditional products (titania, silica and soot) to novel nanomaterials (Athanassiou et al., 2010). Reducing aerosol synthesis has taken flame synthesis from oxides to pure metal nanoparticle preparation and thereby opens access to technical use of metal nanoparticle aerosols. Using chemical understanding, we can design reactions inside aerosol producing reactors as to prepare salt and glass nanoparticles of complex composition in a single step process.

B) Aerosol Derived Nanomaterials

Whilst most aerosol research proceeds at low concentrations (mass and number conc.), the basics physics stays the same at high concentrations. Aerosols containing milligram to gram amounts of nanoparticles per cubic meter allow a technically attractive access to the production of advanced materials. Why are dry processes of particular attraction?

The alternative nanomaterial fabrication in the wet phase (precipitation reactions) always proceeds at moderate temperature and therefore cannot yield high temperature phases, complex glasses, and sintered, single nanoparticles. Latter are of particular interest for high performance applications like heterogeneous catalysts and ceramics and have become available easily by flame spray synthesis.

Reactive nanoparticles can be obtained from high temperature phases (e.g. amorphous particles) that allow preparation of nano-construction cements or injectable bone cements and dental materials (Hild et al., 2011).

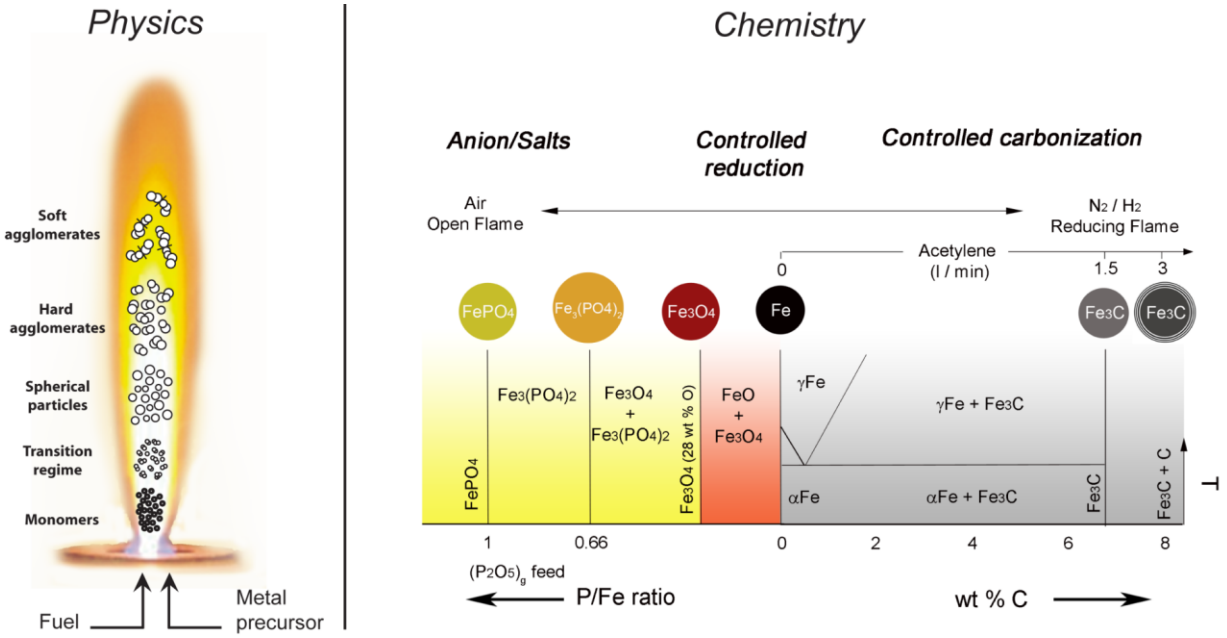

Figure 1: Physical understanding of particle formation in a gas stream (left) and the variety of chemical compositions (right) of nanoparticles (present example: iron) prepared by flame spray synthesis are shown.

C) Metal Aerosols for Nanometals

Classical flame aerosol synthesis uses combustion of a (limited) fuel in air. The aerosol reactor is then limited by the area of fuel combustion and the aerosol travels from the inside of the reactor (precursor) to the outside where gases are cooled down by mixing. As a result, only air-compatible materials are available.

Metal aerosols of non-air stable materials (e.g. iron, copper, cobalt…) can be obtained by inversing the flame reactor: If a limited amount of oxygen is injected together with fuel into a reducing atmosphere (e.g. nitrogen with 1% hydrogen), a special flame is obtained where the growing aerosol particle travels from the inside (precursor) through the combustion zone to the outside, where combustion gases cannot get enough oxygen for full combustion and the gas stays highly reducing (e.g. $CH_4 + O_2 => CO + H_2O + H_2$). As a result, aerosol reactors can also make reduced phases and metals.

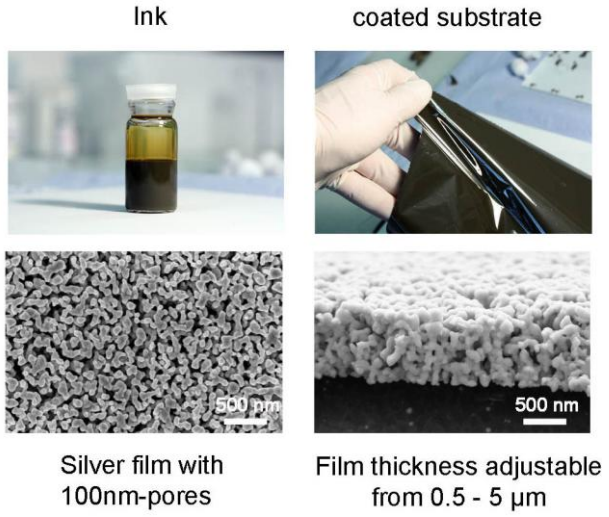

Figure 2: An ink consisting of aerosol derived metallic silver and calcium carbonate to produce a porous film that can be used for membrane filtration.

D) Biomaterials from Aerosols

Calcium phosphates and bioglasses are the prominent materials used in bone and dental medicine. Aerosol synthesis has enabled preparation of reactive particles which are not accessible otherwise, as a high temperature is needed to provide glasses (amorphous mixtures of silicate and phosphates) or non-crystalline phosphates. These aerosol derived materials are now used as parts of a number of preclinical medical devices, both for repair of broken bone, or infected teeth (Schneider et al., 2010; Mohn et al., 2010).

E) Nanoparticles and Organisms

The rapidly increasing use of nanoparticles in consumer products demands in depth understanding on the environmental and health effect of nanoparticles to numerous disciplines. The major route for nanoparticle uptake into an organism has been identified as over the lung. The intrinsic differences between a classical, molecular toxine ("classical chemicals") and a nanoparticle sample in terms of mobility (different diffusion coefficients), time dependent behaviour (agglomeration), chemical behaviour (surface related effects, catalysis) makes the design of relevant nanotoxicological experiments rather challenging (Stark, 2011). Particularly the concept of dose is changed (classical toxins are discussed in terms of a time and mass dose) and needs a clear definition of the relevant parameters (size, colloid stability, chemical activity etc.).

Nanomedicine and nanotoxicology can therefore be regarded as two viewpoints concerning the interaction between (aerosol-derived) particles and living organisms.

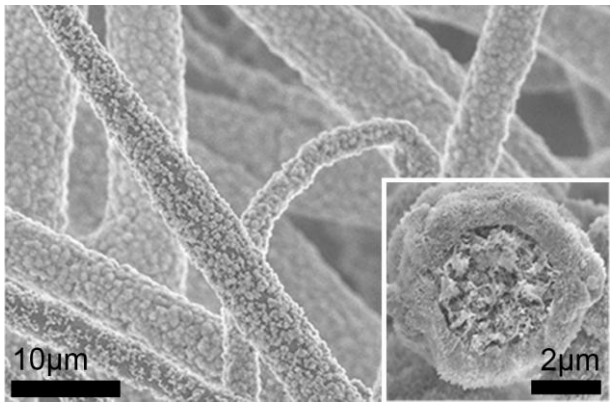

Figure 3: Aerosol derived calcium phosphates are smoothly incorporated in polymer fibres and showing a highly reactive phase.

Session 4P: Poster Session A: *Aerosol Chemistry*

Semi-continuous system for analysis of water-soluble fraction of metals in atmospheric aerosols

P. Mikuška, M. Vojtěšek, Z. Večeřa and K. Křůmal

Institute of Analytical Chemistry of the ASCR, v.v.i., Veveří 97, Brno, CZ-60200, Czech Republic
Keywords: atmospheric aerosols, metal, in-situ measurements, on-line measurements.
Presenting author email: mikuska@iach.cz

Metals released into air from both natural and anthropogenic sources are associated with particulate matter. Recent studies indicate that particulate metals are correlated with the pulmonary toxicity and for a lot of metals, their carcinogenic effects and/or their potential to attack the nervous system, are now well established.

The routine methods for the determination of metals in atmospheric aerosols involve aerosol sampling on filters with off-line analysis of filters in laboratory, which provides time averaged results. To obtain high time-resolved particle composition, the real-time methods have been developed such as mass spectrometry (Wood and Prather, 1998). Simple and cheap way of real-time measurement of chemical composition of aerosols can be obtained alternatively by application of aerosol collectors operating mostly on the principle of steam condensation (Khlystov et al, 1995; Poruthoor et al, 1998) or a Venturi scrubber (Belostotsky et al, 2001; Mikuška and Večeřa, 2005).

The new system for the in-situ determination of water-soluble metallic components of atmospheric aerosols based on the combination of continuous collection of aerosols and on-line analysis is described. Aerosol particles are collected in an Aerosol Counterflow Two-Jets Unit (ACTJU) (Mikuška and Večeřa, 2005) continuously from air (5 L/min) into a deionised water (1 mL/min) and the ACTJU concentrate is on-line analysed for the content of water-soluble fraction of selected particulate metals at collected aerosols. Metal analysis using a continuous flow system includes preconcentration, HPLC separation and chemiluminescent detection by the reaction with luminol (Fletcher et al, 2001).

Co^{2+}, Cu^{2+} and Fe^{3+} were selected as model metals to show a potential of the method for the analysis of water-soluble fraction of metals in atmospheric aerosols with high sensitivity and high time resolution. The system allows the determination of concentration of water-soluble fraction of particulate metals in real time with time resolution of 30 min. The detection limit of particulate Co^{2+}, Cu^{2+} and Fe^{3+} (S/N=3) is 0.3 ng m^{-3}, 37 ng m^{-3} and 65 ng m^{-3}, respectively. The whole system is sufficiently robust for the field application. The system was applied to the measurement of selected metals in urban aerosols in Brno in the Czech Republic (Figure 1).

Gaseous iodine as a substantial cause of new specific air ions

A. Luts, T.-E. Parts and U. Hõrrak

Institute of Physics, University of Tartu, Ülikooli 18, 50090 Tartu, Estonia
Keywords: aerosol chemistry, aerosol spectrometry, mass spectrometry, ion-induced nucleation.
Presenting author email: urmas.horrak@ut.ee

The observations have shown that new particle formation (NPF) depends on many factors, including the air gas-phase composition. Several studies concluded that iodine vapour is one, which can be responsible for the NPF. To study of the effect of iodine on negative air ions, we combined two simultaneous measurement methods: mass and mobility spectrometry (Sciex API-300 and AIS). We observed the noticeable MS peaks up to *m/z* 836. We modified the concentration of iodine vapour (by sublimation of I_2) and humidity. Iodine leads to enhanced concentration of the charged aerosol particles above 4 nm, which, in turn, decrease substantially the concentration of cluster ions due to ion-aerosol attachment. The concentration of 20 s old cluster ions decreases by about 90%. Work by Kärkelä *et al* (2009) demonstrated the results, which resemble our iodine effect: UV-radiation, ozone and gaseous iodine together induced almost instant burst of new particles.

After addition of iodine, major MS peaks were at *m/z* 381 $I^-(I_2)$ and 635 $I^-(I_2)_2$ (Fig. 1). Humid air favours the formation of pentaiodide $I^-(I_2)_2$. The gas-phase chemistry of iodides is not well known to explain such a result. More is known about the iodine reactions in aqueous solutions. In the present study no iodine solution was used, we recorded gaseous (complex) ions, which arouse due to sublimated iodine (I_2). We assume formation of iodine and iodide complexes surrounded by large number of water molecules. The assumption is supported by the AIS mobility spectra with numerous ions with the size above 4 nm, which could be just iodides and their agglomerates plus water molecules. The MS inlet could remove the water molecules and only iodide ions could be recorded by the MS. Numerous water molecules around iodide could make possible the reactions, known in aqueous solutions, where rapidly the equilibrium $I^- <> I_3^- <> I_5^-$ develops (Clough and Starke, 1985). Increased concentration of water vapour causes a larger number of iodine molecules to dissolve, which can shift the equilibrium of the process to the right, resulting in the increased formation of I_5^-. Also, it is known that pentaiodide molecules need H^+ to stabilize itself (Svensson and Kloo, 2003). The ionization of water molecules by radioactive source produces OH^- and the wanted H^+, which also favours the formation of I_5^-. We speculate that such reactions could result in the observed change in the balance of the peaks at *m/z* 381 and 635.

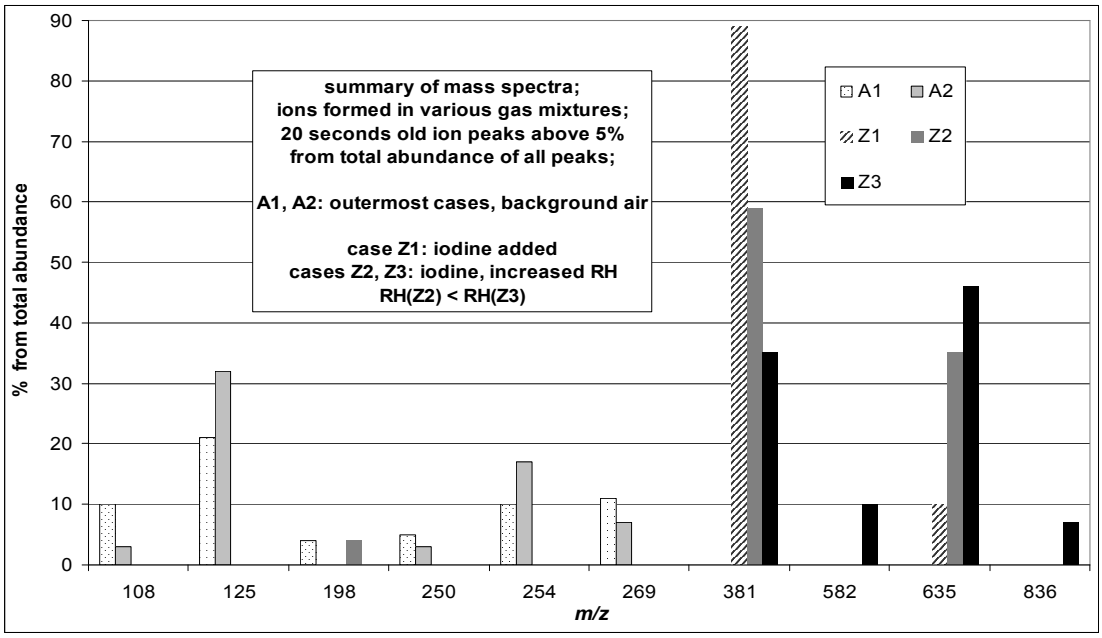

Figure 1. Main peaks, observed in the old ion mass spectrum evolved in the background air, and the effect of addition of iodine at the different humidities.

[2] German Biomass Research Centre, Torgauer Str. 116, D - 04347 Leipzig
Presenting author email: wuzhijun@tropos.de

Combustion of biomass is known to be a major source of gas- and particle- phase air pollution in the atmosphere and to be mainly made of a complex mixture of organics. To date, however, the atmospheric behaviours of these mixtures and their health effects are still largely unknown.

In this study, aging processes of different types of wood burning aerosols (see Table 1) are investigated. The wood burning aerosols are introduced into the IfT LEAK chamber (19 m^3, Iinuma et al. 2004) with and without ozone and /or UV lights simulating day- and night- times. Several online instruments including a Hygroscopic Tandem Differential Mobility Analyzer (H-TDMA), a Volatility Tandem Differential Mobility Analyzer (V-TDMA), a Multi-Angle Absorption Photometer (MAAP), a Scanning Mobility Particle Sizer (SMPS), and an Aerosol Mass Spectrometer (AMS) were used to measure the changes of physical and chemical properties of aerosols. In parallel to the physico-chemical study, modifications of the aerosols toxicity during the aging process were also investigated.

Table 1: Wood species and stoves

Wood	Stove
Spruce log	downdraught stove
Beech log	downdraught stove
WoodPellet	Pellet oven firing

In this abstract, the modifications in volatility and hygroscopicity of spruce burning aerosols via photochemical aging are presented as an example. Fig. 1 shows the comparisons of particle number size distributions before and after turning on the UV-lights. Fig. 2 and 3 display the temporal evolution of growth factor and shrink factor for different size particles, respectively. The growth factor is defined as the ratio of the wet particle mobility diameter D at RH=90% to dry diameter D0. The shrink factor is defined as the ratio of the particle diameter at a certain temperature (here, 120 and 300 °C) to the diameter at room temperature (25 °C).

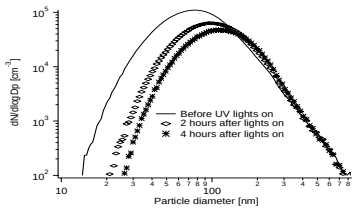

Fig. 1: Particle number size distribution

Before the UV-lights on, the growth factors for 50, 75, and 100 nm particles are within 1.3-1.4, and only 1.1 for 200 nm particles. This indicates that smaller particles are dominated by hydrophilic components, such as inorganic salts, while, larger particles are dominated by hydrophobic fraction, such as soot. After lights on, the growth factors of smaller particles decrease with time consuming. This means that more low hygroscopic organic species produced or condensed on the particles during aging process. But, no any changes in 200 nm particles were observed.

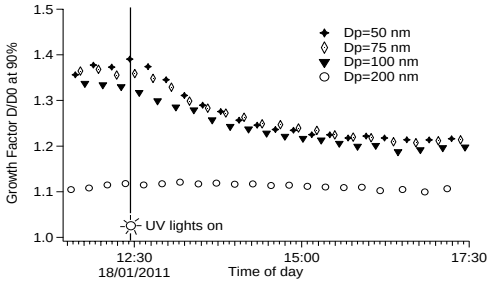

Fig. 2: Temporal evolution of hygroscopic growth

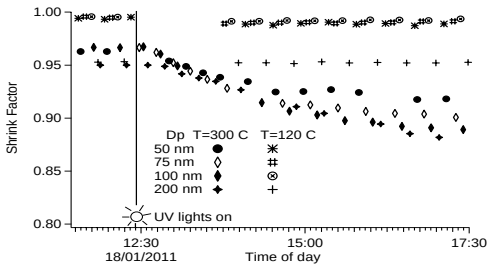

Fig. 3: Temporal evolution of volatility

At 120 °C, there is no any difference in shrink factor before and after UV-lights on, indicating that no high-volatile components, such as low carbon-number carboxylic acids, produced during chemical aging. At 300 °C, the particles freshly emitted with diameter of 50, 75, and 100 nm are non-volatile. After lights on, the aerosols are more volatile in contrast to primary particles. A detail study on the modifications in hygroscopicity and volatility of wood burning aerosols will be performed by combining the AMS data and filter measurements in the future work.

Morphology and phase transitions of internally mixed dicarboxylic acids/ammonium sulfate/water particles during hygroscopic cycles

Mijung Song, Claudia Marcolli, Ulrich K. Krieger, Thomas Peter

Institute for Atmospheric and Climate Sciences, ETH Zurich, Zurich, 8092, Switzerland.

Keywords: morphology, phase transition, hygroscopicity, dicarboxylic acids.
Presenting author email: mijung.song@env.ethz.ch

Tropospheric aerosols are complex mixtures of inorganic and organic substances. The phases and morphology of the aerosol particles are influenced by their chemical composition, hygroscopicity and size (Ciobanu *et al*., 2009). In particular, interactions between organic and inorganic compounds in aerosol particles may lead to liquid-liquid phase separations (LLPS) depending on relative humidity (RH) (Marcolli and Krieger, 2006). During hygroscopic cycles, particle morphology may also change (Kwamena *et al*., 2010). However, the physical state and morphology of atmospheric aerosol particles are difficult to derive from field measurements. Laboratory experiments are, thus, needed to gain insight into the possible morphologies and phase transitions of internally mixed organic/inorganic aerosol particles of atmospheric relevance and to further our understanding of aerosols.

Table 1. Investigated dicarboxylic acid mixtures, their measured solubility in dry weight percent and oxygen-to-carbon ratios.

Organic substances	Measured solubility (wt %)	O:C
C5		
Glutaric acid	58.8	
Methylsuccinic acid	32.0	0.8
Dimethylmalonic acid	10.5	
C6		
2-methylglutaric acid	52.7	
3-methylglutaric acid	45.3	0.7
2,2-dimethylsuccinic acid	8.3	
C7		
3-methyladipic acid	17.1	
3,3-dimethylglutaric acid	14.2	0.6
Diethylmalonic acid	19.5	

We investigated three representative model systems with ammonium sulfate (AS) as salt, namely C5/AS/H_2O, C6/AS/H_2O and C7/AS/H_2O using optical microscopy and micro-Raman spectroscopy in order to determine phase transitions and morphologies for mixtures with different organic-to-inorganic ratios (OIR) during a hygroscopic cycle. Table 1 presents the dicarboxylic acids that are mixed in equal weight ratios to yield the C5, C6 and C7 mixtures containing five, six and seven carbon (C) atoms leading to O:C ratios of 0.8, 0.7 and 0.6, respectively. These mixtures are increasingly hydrophobic with increasing carbon chain lengths.

Micrometer sized internally mixed particles of C5/AS/H_2O, C6/AS/H_2O and C7/AS/H_2O systems showed significantly different behaviors during RH cycles. In particles of C5/AS/H_2O, AS effloresced at 37.9 % RH and deliquesced at 77.5 % RH without LLPS. On the other hand, LLPS of C6/AS/H_2O particles appeared for an AS dry mass fraction of 0.1 to 0.8 at RHs between 70 % and 90 % (depending on OIR) when water was released. Depending on the OIR, it was induced by fundamentally different mechanisms like nucleation-and-growth, spinodal decomposition and growth of a second phase at the surface of the particle. Interestingly, after LLPS had occurred, the inner phase, confirmed to consist of aqueous AS by Raman spectroscopy, tended to move from the core toward the edge of the particle (Figure 1 (a)). Such partial engulfing structures have also been observed by Kwamena *et al.* (2010). LLPS in C7/AS/H_2O particles took place at RH as high as 90 % over a wider range of OIR both upon drying and moistening. Core-shell structure was the main configuration in these systems (Figure 1 (b)). Overall, the RH range of coexistence of two liquid phases and the processes resulting in LLPS depend on the chemical compositions leading to different O:C ratios and hydrophilicity of the particles. The observed morphologies of the investigated particles might very likely be present in the troposphere.

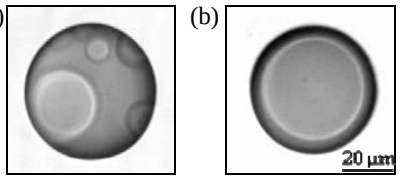

Figure 1. Optical images of morphologies of single particles of (a) C6/AS/H_2O and (b) C7/AS/H_2O for OIR =1:1 at 66 % and 89 % RH, respectively.

Influence of Existing Particle Surfaces on Formation of Secondary Inorganic Aerosols in Fine Mode

Mukesh Sharma[1, 2]*, and Sailesh N. Behera[1]

Centre for Environmental Science and Engineering, Indian Institute of Technology Kanpur, Kanpur 208016
Department of Civil Engineering, Indian Institute of Technology Kanpur, Kanpur 208016, India
Keywords: gas-to-particle conversion, rate constants, acid gases, existing particle surface, and ammonia
*Presenting author email: mukesh@iitk.ac.in

Reduction of ambient levels of particulate matter of diameter less than 2.5 µm ($PM_{2.5}$) is a common challenge to all air pollution control engineers because of the fact that 20–40% to $PM_{2.5}$ mass is formed in the atmosphere involving ammonia and acid gases (Baek et al., 2004 and Sharma et al., 2007). Specifically, ammonia produces secondary inorganic aerosols (SIA) in fine mode, which comprise ions of ammonium salts (i.e., NH_4^+, SO_4^{2-}, NO_3^- and Cl^-).

While the gas to particle conversion is now a common knowledge, role of surface provided by existing particles in formation of SIA needs investigations. This research attempts to examine the kinetics of formation of ammonium salts through interactions of precursor gases (NO_2, SO_2 and NH_3), primary aerosols and meteorology that can produce secondary aerosols. An outdoor environmental chamber facility (volume 12.5 m^3 made of FEP Teflon-film) was used for simulating multiple reactions concurrently. The chamber was checked for wall losses, leaks, solar transparency and ability to simulate photochemical reactions. Total 29 no of experimental runs were performed at elevated levels of precursor gases (concentration > 200 µg/m^3) with varying levels of existing $PM_{2.5}$ levels.

Reaction rate constants k_S, k_N and k_{Cl} for reactions R1, R2, and R3 (see below) have been estimated to address the issue of formation of SIA.

$$2NH_3(g) + H_2SO_4(aq) \xrightarrow{k_s} (NH_4)_2SO_4(aq) \quad (R1)$$

$$NH_3(g) + HNO_3(g) \xleftrightarrow{k_N} NH_4NO_3(s) \text{ or } (aq) \quad (R2)$$

$$NH_3(g) + HCl(g) \xleftrightarrow{k_{cl}} NH_4Cl(s) \text{ or } (aq) \quad (R3)$$

The estimated rate constants are: k_S = 2.68×10^{-4} (±1.38×10^{-4}) m^3/µmol/s, k_N = 1.59×10^{-4} (±8.97×10^{-5}) m^3/µmol/s, and k_{Cl} = 5.16×10^{-5} (±3.50×10^{-5}) m^3/µmol/s. It has been observed that the rate of formation of $(NH_4)_2SO_4$ was enhanced during daytime, while the rate of formation of NH_4NO_3 has been favored during nighttime.

Figure 1 illustrates the association between initial $PM_{2.5}$ concentration and rate constants for formation of $(NH_4)_2SO_4$, NH_4NO_3 and NH_4Cl (both for day and nighttime). The order of correlation coefficient (Figure 1) between initial $PM_{2.5}$ concentration and rate constants was: 0.71 for k_S; 0.59 for k_N and 0.42 for k_{Cl}. The significant positive correlations suggest that surface provided by initial aerosols augments condensation and adsorption of precursor gases that could facilitate enhanced formation of $(NH_4)_2SO_4$, NH_4NO_3 and NH_4Cl. In the cases of NH_4NO_3 and NH_4Cl, once formed on aerosols, backward reactions (in R2 and R3) are unlikely to occur and thus results in enhanced rates of formation of NH_4NO_3 and NH_4Cl.

It was an important conclusion of this study that in the urban environments having high background aerosol concentration, conditions become conducive for formation of SIA. A better control of primary aerosols is helpful in preventing formation of secondary fine particles.

Presenting author email: jose.ruiz-jimenez@helsinki.fi

Twenty one biogenic organic compounds, 9 dicarboxylic acids, 4 monocarboxylic, 3 polyols, 1 amine and 4 aldehydes, were determined in 61 atmospheric aerosol particle samples of different particle sizes (30 nm, 40 nm, 50 nm and TSP). The samples were collected in two different sampling sites (SMEAR II and SMEAR III) during different seasons of the year (Table 1). The validated methodology used for the collection, sample preparation, individual separation and determination of biogenic organic compounds has been recently described (Ruiz-Jimenez, 2011).

Table 1. Mean concentrations (ng m^{-3}) obtained for the target analytes

	All	SMEAR II	SMEAR III
N	61	39	22
Di acids	8.2	5.1	13.1
Mono acid	47.4	48.1	45.9
Polyols	18.7	6.7	39.8
Amines	2.0	1.8	3.4
Aldehydes	10.1	4.6	20.1
NNEV/NCD	0.5	0.6	0.3

Non-supervised pattern recognition techniques, such as Hierarchical Cluster Analysis and Principal Component Analysis, were used for the clarification of the influence of the collection place, the season of the year and the particle size on the concentration and behavior of the target compounds.

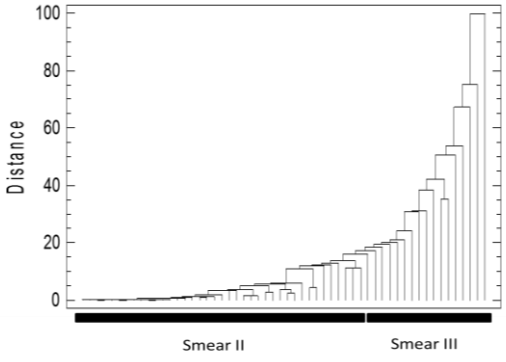

Figure 1. Influence of the sampling site on the composition of the aerosol particles.

The results achieved demonstrate the clear correlation of the sampling site, the season of the year and the particle size on the composition of the atmospheric aerosol particles. The explained data variation was over 88% in all the cases.

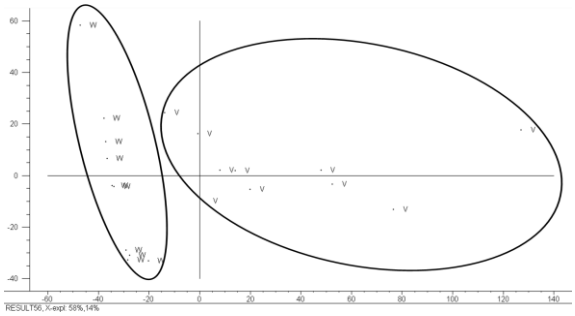

Figure 2. Effect of the season of the year on the composition of the aerosol particles. PCA models for samples collected at SMEAR III station.

Quantitative analysis methodologies, such as Partial Least Squares Regression and Principal Component Regression models, were used for the elucidation of the influence of the number of nucleation events on the chemical composition of the particles (Table 2).

Table 2. Statistical models developed for the study of the influence of the number nucleation event days in the composition of the atmospheric aerosol particles. (S, spring; A, autumn; V, summer; W, winter)

	GM	SMEAR II			SMEAR III		
	All	All	S	A	All	V	W
N	52	36	12	18	19	10	10
Model	PLSR	PLSR	PCR	PLSR	PLSR	PCR	PCR
R^2 pred.	0.71	0.65	0.80	0.71	0.77	0.69	0.82

Correlations were found between analyte profiles and the number of nucleation events during collection of the sample. Although the model was generated on the basis of the total profile of analytes, it was possible to clarify the influence of each individual analyte on the model.

Keywords: Comprehensive gas chromatography, nucleation, total suspended particles, ABOA station
Presenting author email: jose.ruiz-jimenez@helsinki.fi

Comprehensive two dimensional gas chromatography – time-of-flight mass spectrometry (GCxGC-TOF-MS) was used for the screening and semi-quantitation of volatile organic compounds, such as volatile and low-volatile compounds in total suspended aerosol particles (TSP). The samples were collected during the summer 2009 at the Finnish Antarctic Research Station (ABOA), and during the summer 2010 at the Station for Measuring Forest Ecosystem Atmosphere Relations (SMEAR II) at Hyytiälä (Finland).

The classification of the identified compounds was based on the main functional group or specific element present in the molecule (Figure 1).

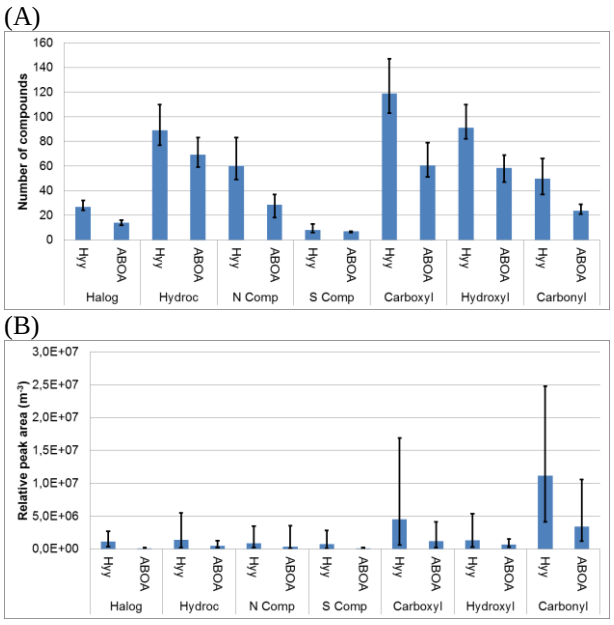

Figure 1. Chemical groups in different sized and TS particles as a function of A) number of compounds, B) relative peak areas.

The number of identified compounds and the relative peak areas were smaller in ABOA than in SMEAR II samples. The differences were clear especially in the case of acids and aldehydes. Totally different sampling site locations with different surroundings can explain these results.

The samples collected at the ABOA station can be divided into three groups as a function of the intensity of the nucleation events during the sampling —no-nucleation days (13 samples), normal nucleation days (4 samples) or very strong nucleation days (2 samples). Non- supervised pattern recognition techniques, such as Hierarchical Cluster Analysis and Principal Component Analysis were exploited for the clarification of the influence of the nucleation event on the particle composition.

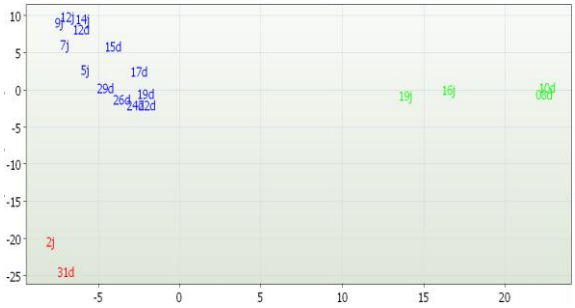

Figure 2. PCA models for samples collected in the ABOA station.

The clear differences revealed by the chemometrical analysis were confirmed by the use of time-series for the individual compounds leading to the classification of the compounds into six different trends, according to their concentrations in the different samples that can explain the differences in the particle composition associated to the nucleation events (Figure 3).

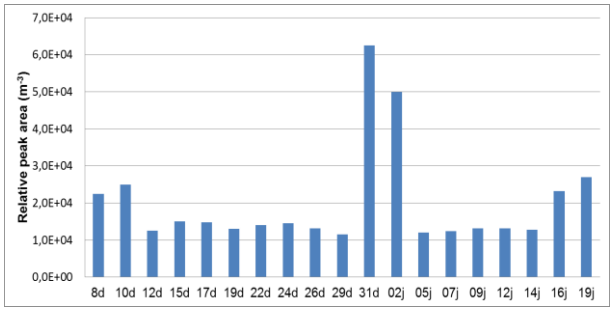

Figure 3. Time-series profile obtained for mevalonic acid, dithioerythriol, adipic acid and 1-hexanol.

Secondary aerosol formation is believed to account for the majority of particles in the atmosphere (Merikanto et al., 2009). Other studies have shown that the dominant mass fraction of organic aerosol has been produced secondarily (e.g. Hallquist et al., 2009). Volatile organic compounds (VOCs) are oxidized in several steps whereby the vapor pressure of the oxidation products can be reduced. This reduction in vapor pressure increases the ability of the product to either condense on to existing particles, or take part in the formation of completely new particles.

To better understand early steps of particle formation from VOCs it is therefore of importance to measure such vapors. The most volatile vapors are typically measured by e.g. PTR-MS or GC-MS techniques. The VOCs themselves and many of their high volatile oxidation products are available at high concentrations and do not easily stick to surfaces. However, as the oxidation of these compounds progresses, the concentrations and stability in the gas phase decrease, and neither of the above-mentioned techniques are capable of detecting such compounds. Chemical ionization mass spectrometry (CIMS) has evolved a lot during the recent decade, and is able to measure both inorganic and organic acids in the gas phase down to sub-ppt levels.

The study of naturally charged ions with the atmospheric pressure interface time-of-flight mass spectrometer (APi-TOF; Junninen et al, 2010) has been shown to be very sensitive to acidic, highly oxidized atmospheric molecules (Ehn et al, 2010). Though the instrument cannot directly give quantitative estimates of the neutral compound concentrations, it is to our knowledge the most sensitive instrument available to detect many acidic trace compounds. With the addition of a chemical ionization source in front, the instrument can also be converted into a CIMS, sacrificing some of the high sensitivity and selectivity for quantitative measurements.

The APi-TOF has been deployed at a boreal forest site in Hyytiälä, southern Finland, where several typical ions were identified. During nucleation events, H_2SO_4 dominated the negative ion spectra, but during evening and night when the particles continued growing, the H_2SO_4 signal decreased significantly, and other organic peaks became visible.

To get a better understanding of the processes forming these organic species, and their role in new particle formation and growth, plant chamber measurements were conducted with both real tree emissions and single compound precursors.

Many features of the ion spectra were reproduced in the chamber experiments, both with real plant emissions from a mix of boreal species, and by using pure alpha-pinene as a precursor. Several ions typically found in Hyytiälä, lacking a conclusive identification (Ehn et al, 2010) were also detected in the chamber studies during experiments with alpha-pinene and ozone, i. e. at low OH concentrations (Fig. 1). The peaks are believed to be nitrate-containing, highly oxidized organic molecules with an O:C:H ratio close to 1:1:1. The plotted mass/charge region shows the dominant peaks in the Hyytiälä spectra, however, in the chamber also larger ions, not visible in ambient air, were detected. Additionally, observations of sulfuric acid and its clusters up to the trimer were detected during new particle formation events both in the chamber, and in the field. However, much stronger nucleation events could be produced in the chamber with only small H_2SO_4 signals, indicating the importance of organic precursors in the formation process.

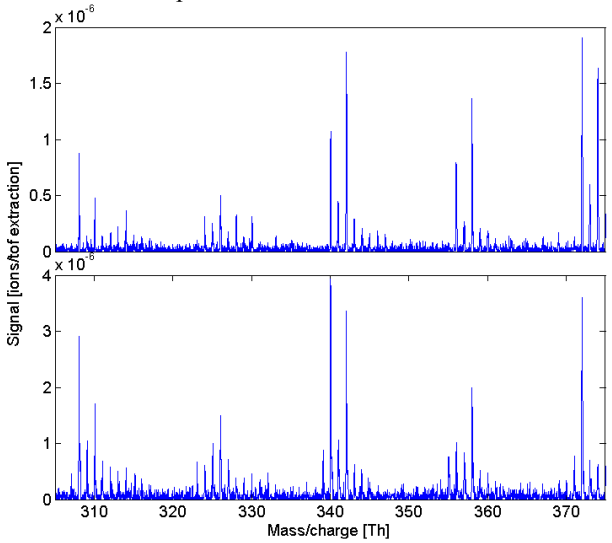

Figure 1. Ion spectra of alpha-pinene oxidation products in the JPAC plant chamber (top), and night-time ion spectrum in Hyytiälä, Finland (bottom).

Quantitative and qualitative characterisation of ultrafine particles emitted by laser printing devices

M. Barthel, S. Seeger, O. Hahn, O. Wilke, W. Horn and O. Jann

BAM Federal Institute of Materials Research and Testing, Division 4.2 Environmental Material and Product Properties, Unter den Eichen 87, 12205 Berlin, Germany
Keywords: Aerosol measurement, indoor aerosols, chemical composition, XRF, GC-MS.
Presenting author email: mathias.barthel@bam.de

Among the main sources for indoor ultrafine particle aerosols are electronic devices with laser printing function (LPDs) (Seeger *et al.*, 2006; Destaillats *et al.*, 2008, Schripp *et al.*, 2008). The characterisation of particles emitted by LPDs and the investigation of formation processes involved has been the subject of recent research (Morawska *et al.*, 2009; He *et al.*, 2010). In this work the quantitative and qualitative characterisation of ultrafine particles originating from 10 different laser printers is presented.

The experiments were carried out in stainless steel emission test chambers to ensure constant and reproducible conditions. In order to study the effect of chamber volume on particle agglomeration two chambers with different volumes (1 and 5 m^3) were used. The particle number concentration was measured using an Engine Exhaust Particle Sizer (*TSI*) and different types of condensation particle counters (*Grimm, TSI*) with subsequent calculation of the emission rate PER(t) and total number of emitted particles TP.

For qualitative analysis the particles were sampled with a 13 stage low pressure cascade impactor (*Dekati DLPI 10*). The samples were examined by the use of both µXRF and thermal desorption GC-MS. Depending on the method different substrates (Al or Polycarbonate foils) were used in order to minimize background signals.

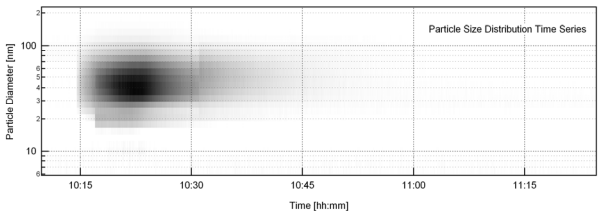

Figure 1. Particle Size distribution time series of particles emitted from a laser printer into an environmental test chamber during and after printing.

It could be shown that the variation in chamber volume (1 and 5 m^3) has no effect on particle emission rates and total particle numbers provided that particle loss factors are considered properly in the calculations. Furthermore data from different particle counting devices (CPC, EEPS) are in good agreement. To ensure working order of the instruments as well as repeatability and comparability of the measurements a standard operational procedure (ECMA, 2010) was worked out.

The results from the µXRF- and GC/MS-analysis of sampled particles reveal their chemical composition. Comparison of particle spectra with those from materials involved in the printing process, such as paper, toner and printer assemblies (e.g. fuser unit) are used to identify the sources of the particles.

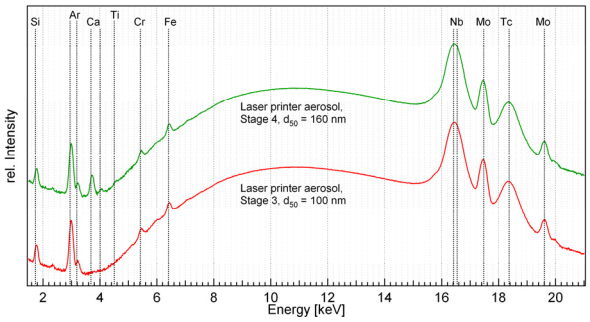

Figure 2. Qualitative analysis of size-resolved printer aerosol deposited on polycarbonate substrate using µXRF.

Among other results the presence of a Si-peak in the µXRF spectrum in combination with the absence of siloxanes in the GC-MS spectra indicates that non-volatile Si-compounds, such as SiO_2 play a role in particle formation. This thesis is supported by the results of evaporation experiments carried out using a thermo diluter.

The above findings allow for conclusions being drawn considering particle formation mechanisms relevant to the generation of indoor aerosols. Furthermore the chemical identification of some components of the emitted particles will contribute to an evaluation of potential health risks related to indoor aerosols.

A significant portion (up to 60%-70%) of atmospheric fine particles can be comprised of secondary organic aerosol (SOA). Therefore, a detailed understanding on the formation, properties and transformation of SOA is essentially needed to evaluate its impact on atmospheric processes, climate and human health. However, a significant progress in SOA research in recent years, the formation and properties of SOA are not fully understood, which poses a major research challenge in atmospheric science (Hallquist *et al.*, 2009). Biogenic volatile organic compounds (BVOC) are major SOA precursors. Among the BVOCs limonene can potentially yield high SOA depending upon the atmospheric conditions (Griffin *et al.*, 1999). One key feature not yet explored in details for the limonene oxidation is the thermodynamic property, e.g. volatility. In this study, the effect of reaction temperature on the volatility behaviour of SOA from limonene ozonolysis was investigated. The results from these flow tube reactor experiments were compared to previous smog chamber studies.

Experiments were carried in a flow-reactor named G-FROST (**G**öteborg- **F**low **R**eactor for **O**xidation **S**tudies at low **T**emperatures; Jonsson *et al.*, 2008). The average reaction time was kept constant (238 s). Generally system was maintained at 30-50% RH. SOA was created using limonene and ozone. Cyclohexane (CH) was used an OH scavenger (OHS). Some experiments were also conducted in presence of aldehyde/ketone (Pinonaldehyde (PA); Nopinone (NP)). The experimental scheme is presented in Table 1.

Table 1: Experimental conditions

Reaction Temp (K)	SOA	SOA +OHS	SOA+ Aldehyde	SOA+ Aldehyde +OHS
298	Lim+O_3 +CH	Lim+O_3 +CH	Lim+O_3+ NP/PA	Lim+O_3+ CH+ NP/PA
273	Lim+O_3 +CH	Lim+O_3 +CH	Lim+O_3+ NP/PA	Lim+O_3+ CH+ NP/PA
253	Lim+O_3 +CH	Lim+O_3 +CH	Lim+O_3+ NP	Lim+O_3+ CH+NP

SOA volatility was measured using the Volatility Tandem Differential Mobility Analyzer (VTDMA), which consists of two differential mobility analyzers (DMA1 & DMA2) in tandem with a set of 8 controlled heating ovens. Size selected monodisperse aerosol (75nm) using DMA1 were fed to the heated ovens (298K-525K). The volume fraction remaining (VFR) of the aerosol feed was subsequently measured by DMA2 and the VFR normalized to that at 298K was estimated.

Results

Figure 1 shows the change in SOA volatility curves corresponding to different reaction temperatures in the experimental system in comparison to data from the AIDA chamber (Saathoff *et al.*, 2009 and Salo *et al.*, 2011). Any change in volatility may signify the variation in the distribution of reaction products at different temperature due to change in reaction kinetics etc. In general, the SOA volatility increased with decrease in reaction temperature in the two systems except for the 253K in the G-FROST system, which was lower than that for 273K. The two experimental systems showed difference in SOA volatility at the same reaction temperature e.g. the volatility at 273K in the G-FROST was higher than that in the AIDA chamber. A number of factors are addressed including fresh-aerosol in the G-FROST vs few hours aged in the AIDA chamber, chamber wall effect etc. Detailed results and analysis on the effect of OHS and impact of aldehydes/ketones on the partitioning and volatility of SOA at different reaction temperature will be presented.

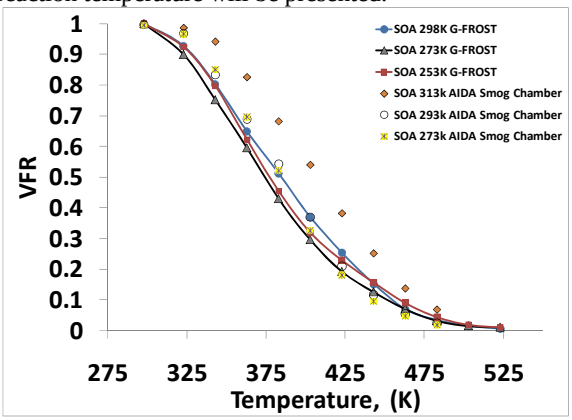

Figure 1: Volatility of SOA formed at different reaction temperatures in the two experimental set-ups

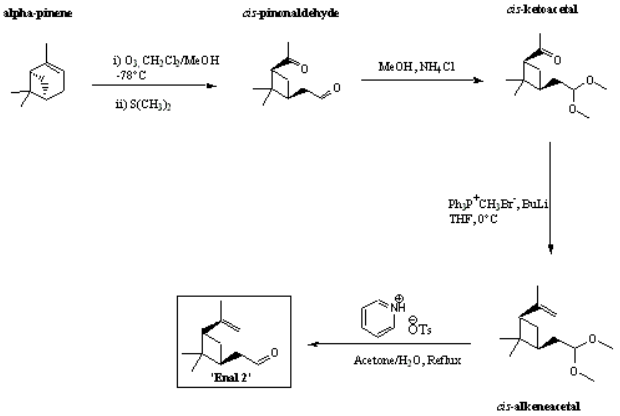
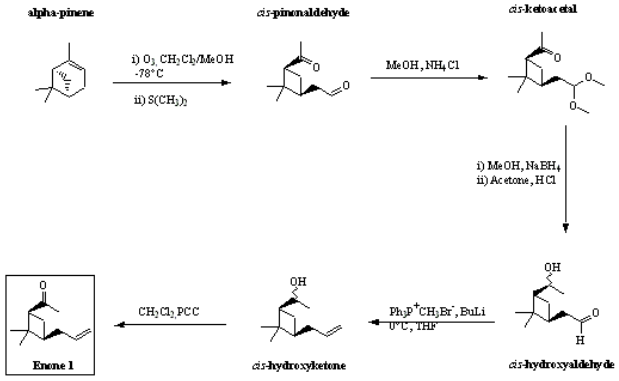
The Formation of Secondary Organic Aerosol from Intermediates in the Ozonolysis of α-pinene.

I.D. Hoare, D.J. Stewart, G. Brittan, A.T. Russell, S. Almabrok, M.V. Ghosh, C. Pfrang and G. Marston.
Department of Chemistry, University of Reading, Whiteknights, PO Box 217 Reading, RG6 6HA
Presenting Author email: i.d.hoare@reading.ac.uk

The oxidation of volatile organic compounds (of which α-pinene is an important species) in the atmosphere is important for a number of reasons. Oxidation products, both closed shell (carbonyl species) and radicals (OH, HO_2 and RO_2) have a major importance in the chemistry of the troposphere (Johnson and Marston, 2008). Modelling studies have shown that the reaction of ozone with alkenes could be the dominant source of HO_x in polluted urban environments as well as being a significant contributor in less polluted rural locations (Paulson and Orlando, 1996). The oxidation of VOCs can also contribute significantly to the nucleation and production of aerosol particles in the atmosphere (Went, 1960; Marti *et al.* 1997), which has a significant effect on air quality, global climate (Twomey *et al.* 1984; Charlson *et al.* 1992), cloud formation (Novakov and Penner, 1993) and also has important impacts on visibility and human health (Donaldson *et al.* 1998).

The oxidation of α-pinene by ozone is known to proceed *via* the initial production of two reactive Criegee Intermediates (CIs), it is now well established which final chemical products of the reaction are produced from which CI (Ma *et al.* 2007a, 2007b, 2008); however, it is still uncertain which of the chemical species resulting from which CI are responsible for the formation of secondary organic aerosol. In order to elucidate which CI produces the products responsible for SOA formation "enal" and "enone" compounds structurally related to α-pinene but which on ozonolysis will give only one of the Criegee Intermediates have been synthesized using the procedures below.





In static chamber experiments the aerosol yields from the "enal" and the "enone" will be compared to the aerosol yield from α-pinene to ascertain which reaction pathway is dominant in SOA production. This is the first attempt to elucidate the mechanism of SOA formation from α-pinene oxidation in this way.

Simulating secondary organic aerosol (SOA) formation over Europe using the volatility basis-set approach (VBS) in the online coupled model COSMO-ART

Eleni Athanasopoulou[1], Heike Vogel[1], Max Bangert[1], Christoph Knote[2], Bernhard Vogel[1], Ben Murphy[3], Alexandra Tsimpidi[4], Spyros Pandis[3,4]

Presenting author email: eleni.athanasopoulou@kit.edu

COSMO-ART is a recently developed regional model that couples meteorological and air quality processes online (Vogel et al., 2009). Comparisons of aerosol predictions against measurements suggested an underestimation of the total aerosol mass, which was attributed mainly to low organic aerosol (OA) predictions (Knote et al., 2010). This finding became the stimulation for revising SOA treatment within COSMO-ART, presented in the current study.

Previous research suggests that the models' inability to reach OA observations is strongly related to gas-particle partitioning of all (thousands) organics emitted and formed into the atmosphere, but not in simulations. An efficient way to incorporate this chemical evolution of organics into modelling (aging), is their group treatment by saturation concentrations (VBS) (Donahue et al., 2006).

Recent model applications using VBS confirm model's improved efficiency in predicting OA mass (Murphy and Pandis, 2009; Tsimpidi et al., 2010 etc). According to their results, SOA can represent more than 50% of total OA mass, while their absolute values can reach more than 5μgm^{-3}, which seems promising for improving COSMO-ART performance (Fig. 1).

In the framework of this study, COSMO-ART is modified to include the VBS treatment of SOA. Nine biogenic and anthropogenic SOA precursors (higher alkanes and alkenes, terpenes, isoprene) are grouped into 4 surrogate species with effective saturation concentrations of 1, 10, 100, 1000 μgm^{-3}, modified according to the spatial-temporal variation of temperature (Clausius-Clapeyron eq.). Aerosol yields after each precursor's oxidation to OH, O_3 and NO_3^- alter with its condensation effectiveness and are a combination of the low and high NOx mass yields used in Murphy and Pandis (2009). Further oxidation of surrogate species decreases their saturation concentration by 1 order of magnitude (aging) and increases their mass by 7.5% (to account the oxygen added).

The VBS approach is then coupled with the existing gas-particle partitioning module and with the chemical mechanism RADMKA (Regional Acid Deposition Model Version Karlsruhe). The simulation domain covers Europe with an horizontal grid size of 14km and 40 vertical layers up to a height of 20km. The meteorological initial and boundary conditions are achieved from the IFS model of ECMWF for May 2008. COSMO-ART results by applying the prior (SORGAM) and the current (VBS) SOA module are inter-compared and evaluated against field measurements of OA collected during the EUCAARI campaign for selected stations.

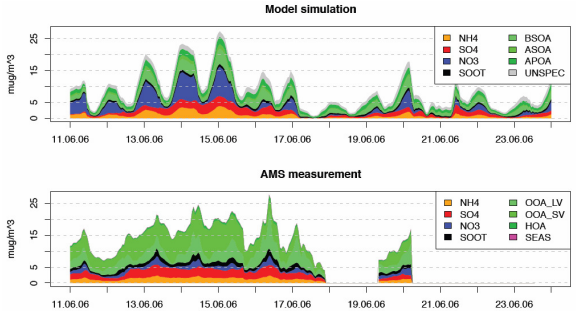

Figure 1. Evaluation of COSMO-ART aerosol composition AMS campaign measurement (PSI) in Payerne (CH) (Knote et al., 2010)

A similar grouping and aging approach used in global applications, showed an effect on CCN concentrations, due to the enhanced condensation and particle growth (Yu, 2011). The fully coupled approach used by COSMO-ART, gives to this study the opportunity to investigate the feedback of the VBS approach on cloud formation. Results will be presented during the conference.

An explicit chemical mechanism model (GECKO-A, detailed in Aumont *et al.* 2005) was applied to over 150 gas-phase anthropogenic species with up to C22 (taken from the emissions inventories AIRPARIF and CITEPA), to describe the formation of SOA in the city of Paris and the chemical composition evolution during several days of reactivity. Some biogenic compounds (i.e. isoprene and α-pinene) were also included to account for nearby rural emissions.

The resulted chemical mechanism was coupled to a two-layer box-model which includes anthropogenic and biogenic emissions of VOCs and NOx and dry deposition. Variations of emissions were considered throughout day and night with temperature and light following parameterisations described in Aumont *et al.* (2003). Compounds are exchanged between the two layers during the growth and the decay of the continental boundary layer.

To our knowledge, this is the first time that such a detailed chemical scheme including hundreds of thousands of secondary VOCs is evaluated for its potential to form SOA.

First modelling results are presented with the assessment of SOA concentrations and chemical speciation, identification of major SOA contributors and analysis of Van Krevelen diagrams (H:C vs. O:C) at different time sets, recently acknowledged as a valuable tool to graphically interpret the mass spectrometric measurements (Heald *et al.* 2010).

Results from the model are evaluated with typical observed concentrations from the MEGAPOLI project with special focus on the representation of SOA formation.

Keywords: aerosol chamber, aerosol chemistry, aerosol modelling, OH radicals, SOA

OH radicals are the most important agents for oxidation of atmospheric constituents and they play an important role in formation and aging of atmospheric aerosols e.g. secondary organic aerosols (SOA). Since the influence of temperature on aerosol formation and aging is one of the major uncertainties for understanding aerosol transformations (Tsigaridis et al., 2005) we investigated SOA aging by OH radicals in the large temperature controlled simulation chamber AIDA (Saathoff et al., 2009).

As a dark source of OH radicals we employed controlled ozonolysis of 2,3-dimethyl-2-butene (TME). The OH radical concentrations generated in the AIDA simulation chamber were calculated by comparing the results of master chemical mechanism (MCM 3.1) with the measured evolutions of all trace gases measured. SOA was generated by ozonolysis of alpha-pinene with an excess of ozone under simulated tropospheric conditions in the AIDA chamber on time scales of up to 30 hours and at temperatures between 253 and 313 K. Various instruments were used to measure the time evolutions of hydrocarbons (PTR-MS, FTIR), ozone (UV-Absorption), aerosol particle mass & size (TOF-AMS, SMPS) and number concentrations (CPC). The experimentally determined values were analysed using the aerosol behaviour code COSIMA (Naumann, 2003), supplemented by a SOA module.

The model calculations can reproduce the observations based on known rate coefficients and the measured trace gas concentrations. Generating the OH radicals in the order of 10^6 to 10^7 molecules cm^{-3} in the presence of SOA from ozonolysis of alpha-pinene resulted in additional formation of SOA mass in the order of 10-35% within two hours or less. The additional mass formed is smaller for lower temperatures. The model analysis takes into account the wall losses of semi volatile SOA compounds and also the impact of the OH radicals formed already during the terpene ozonolysis.

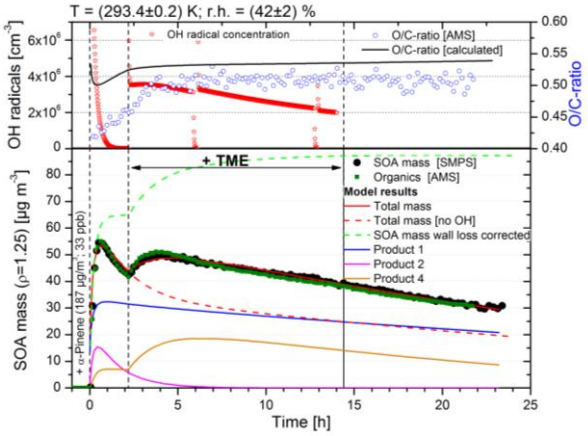

Figure 1. Evolution of SOA mass and composition during ozonolysis of α-pinene and aging with OH radicals from TME oxidation at 293.4 K.

Figure 1 shows the evolution of the measured SOA mass and O/C-ratio compared to model results including SOA composition (4 different products assumed) and OH radical levels. Please note that already during ozonolysis of the terpene OH radicals are formed which strongly influence yield and properties of the SOA particles.

This paper will present quantitative results on the OH radical induced aging of alpha-pinene SOA for simulated tropospheric conditions.

Gas-to-particle conversion in biogenic aromatic aldehydes and their complexes with heavy metals: a contribution into the biogeochemical cycles of elements

S.N. Dubtsov[1], G.G. Dultseva[1,2],
[1]Institute of Chemical Kinetics and Combustion, SB RAS, Novosibirsk, 630090, Russia
[2]Department of Natural Sciences, Novosibirsk State University, Novosibirsk, 630090, Russia
Keywords: organic aerosols, particle formation, photochemical properties
Email: dubtsov@kinetics.nsc.ru

Biogenic aldehydes emitted into the atmosphere by vegetation often contain aromatic fragments and/or double bonds, which makes these compounds potential participants of nucleation both under the action of sunlight and through chemical reactions with such atmospheric minor gases as ozone or nitrogen oxides. The contribution from biogenic aldehydes into atmospheric aerosol of the nanometer size scale remains poorly investigated due to the experimental difficulties connected with identification of trace amounts of very reactive species. The occurrence of metals in the form of complex compounds with aldehydes in the emissions of vegetation, though reliably detected in field observations, remains a subject to be studied more thoroughly under laboratory conditions to exclude the effect of numerous uncontrollable factors existing in natural atmosphere.

The present work deals with the investigation into the mechanisms of photonucleation, atmospheric oxidation and gas-to-particle conversion of biogenic aromatic aldehydes and their volatile complexes with heavy metals (of soil origin). Many green plant species when growing on soil with increased heavy metal content, either of natural or anthropogenic origin, are able to release such complexes; this is a kind of detoxication for plants but brings about the danger of atmospheric pollution with the breathable nanometer-sized metal-containing aerosol. We studied the kinetics and mechanism of photonucleation of aromatic aldehydes alone and in complexes with heavy metals under laboratory conditions in a flow photochemical reactor under UV irradiation. Analysis of major and minor intermediate and final products was carried out using UV, IR, NMR, EPR spectroscopy, GC-MS, chemical analysis for functional groups, and HPLC. Both the gas-phase products and the particulate matter formed under irradiation were analysed. The concentration and size distribution of the particulate matter formed under UV irradiation were studied using the diffusion spectrometer of aerosol (DSA) designed and built at the Institute of Chemical Kinetics and Combustion, Novosibirsk.

Special attention was paid to the part played by water vapour, ozone and nitrogen oxides as the participants of the general gas-to-particle conversion process. The initial stages of cluster formation preceding nucleation were modelled using the previously developed approach (Dultseva *et al.*, 2008) based on semiempirical estimations. It was demonstrated that the presence of additional functional groups, for example OH (in salicylic aldehyde) creates additional possibilities for clustering and thus routes the process to quite different products. Benzaldehyde and salicylic aldehyde exhibited quite opposite dependences of photolysis and photonucleation kinetics on water vapour concentration Figure 1 shows the dependences of photolysis constants for both aldehydes on water vapour concentration.

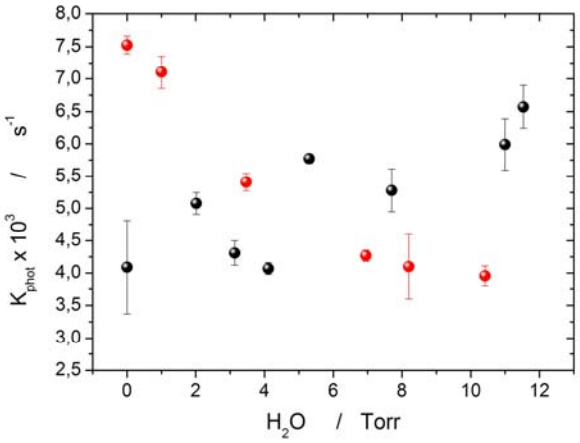

Fig. 1. Dependence of photolysis rate on water vapour concentration: black dots – benzaldehyde, red dots – salicylic aldehyde.

Investigation of the participation of short-lived free radicals was carried out using the spin trapping procedure and showed that no free radicals appear during the photolysis of salicylic aldehyde, though benzaldehyde under photolysis gives rise to phenyl radicals that take part in further transformations. Complexes of aldehydes with metals under photolysis did not give rise to the formation of spin adducts, so it may be supposed that no free radicals are formed in this case and intramolecular processes are prevailing.

The yields of particulate matter measured under laboratory conditions allow us to suppose that gas-to-particle conversion may be an efficient process forming a link in the biogeochemical cycles of heavy metals by bringing them from soil into plants and then into the atmosphere, where photonucleation turns these compounds into solid particles. The results obtained in the investigation prove the significance of plant-mediated flux of elements into the atmosphere.

Email: dubtsov@kinetics.nsc.ru

Aldehydes are important minor components of urban air that possess the aerosol-forming potential. The mechanisms of gas-to-particle conversion in the atmosphere include a large number of elementary stages starting from the photochemical decomposition under the action of sunlight and finishing with the formation of nanometer-sized particles. We studied the processes of this kind in detail under laboratory conditions, with noble gases or air as carrier gases, and discovered that even the simplest aliphatic aldehydes (formaldehyde, acetaldehyde) are able to form particulate matter under UV irradiation (Dultseva et al., 2001). Results obtained under laboratory conditions suggested that the presence of oxygen has a crucial effect on the process mechanism. So does the presence of some other minor atmospheric gases such as nitrogen oxides and ozone. In the present work we studied the kinetics and mechanisms of photonucleation of aldehyde vapour in the presence of nitrogen oxide, nitrogen dioxide, and ozone.

Among the important products of aldehyde photolysis in the presence of nitrogen oxides, peroxyacylnitrates are of special ecological significance. We studied the mechanisms of gas-to-particle conversion in the system {aldehyde + nitrogen oxides} both experimentally in the photochemical reactor and theoretically by means of kinetic modelling at the level of elementary stages. The effect of ozone was also evaluated. Analysis of the intermediate and final products, both gaseous and particulate ones, was performed using HPLC, NMR, GC-MS, short-lived free radicals were identified by means of EPR spectroscopy using the spin trapping procedure. The concentrations and size distribution of the particulate matter formed in the process were determined with the help of the diffusion spectrometer of aerosol (DSA) designed and built at the Institute of Chemical Kinetics and Combustion, Novosibirsk.

The role of ozone was evaluated with special focus on its gas-phase reactions with organic species participating in the process. Ozone is known to be formed in polluted air through the addition process $O_2 + O \rightarrow O_3$; where O is generated by the photolysis of NO_2 under sunlight. Atmospheric organic compounds play an essential part in $NO \rightarrow NO_2$ conversion ($RH + OH + O_2 \rightarrow RO_2$; then $RO_2 + NO \rightarrow RO + NO_2$) thus making their contribution into the formation of NO_2 and therefore ozone in polluted atmosphere. Thus formed ozone interacting with organic species gives rise to peroxy radicals, peracids, hydroperacids, organic peroxides and many other oxygenated species that are able to undergo gas-to-particle conversion. Moreover, ozone itself can be consumed in the reactions taking place at the active surface of freshly formed particles. This very complicated mechanism can hardly be understood in detail without the kinetic simulation. Simulation results were tested with kinetic measurements. An example is shown in Fig. 1.

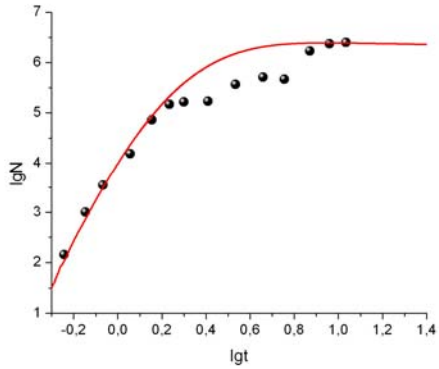

Fig. 1. Time dependence of particle concentration formed in benzaldehyde photolysis. Points – experiment, line – simulation.

It was demonstrated that the concentration of peroxybenzoyl nitrate can reach 10^9-10^{11} cm^{-3}, which generally agrees with the values obtained by measurements in urban atmosphere. Simulation suggests and experiment proves that among the aldehydes present in urban atmosphere (formaldehyde, acetaldehyde, acrolein, benzaldehyde etc.) the major contribution into the formation of organic particulate matter is made by acetaldehyde and benzaldehyde (Dubtsov et al., 2006). So, the aerosol-forming potential of organic compounds, even so reactive ones as aliphatic and aromatic aldehydes, in the presence of oxygenated species can be evaluated by means of experimental measurements and kinetic simulations of the process mechanism at the level of elementary stages with permanent intercomparison of theoretical results with the experimental ones.

Observation of decreased final product volatility in the gas ozonolysis of unsaturated carboxylic acids in the absence of oxygen

C. Keunecke, T. Zeuch

Institut für Physikalische Chemie, Georg-August-Universität, Göttingen, 37077, Germany
Keywords: SOA, Ozone, Carbon oxidation, Organic acids.
Presenting author email: ckeunec@gwdg.de

In the past decades large efforts have been made in laboratory studies to elucidate the secondary organic aerosol (SOA) formation mechanism. Critical issues have been studied such as reaction product formation and the influence of relative humidity, temperature, presence of additional organic matter and seed aerosol. However, the mechanism of organic nucleation is still controversial. Consequently significant uncertainty remains in closing the gap between laboratory experiments, theoretical predictions and nucleation rates observed in field studies. In a recent study we could show that (besides volatility considerations of detected reaction products) SOA formation during alkene ozonolysis experiments depends also on kinetic parameters and is linked to intermediate species like peroxy radicals (Wolf *et al*., 2009, 2011).

To obtain an acceptable compromise between controlled reaction chamber filling and minimized aerosol wall losses during laboratory SOA experiments (e.g. a large reaction volume to surface ratio), we constructed a 64 L stationary reaction cell with ozone / alkene premixing chambers, FTIR spectroscopy for gas phase species analysis and a SMPS system for measuring particle size distributions in the submicron size range. With the new reactor we achieve a well controlled mixing within a few seconds allowing a controlled variation of process parameters including reaction pressure (Wolf et al. 2011).

Due to atmospheric relevance we use unsaturated acids, as possible oxidation products of biogenic emitted terpenes, as well as unsaturated alcohols, which are released by plants after leaf damage (Kesselmeier *et al*., 1999) as reactants.

With our comparative studies we can show the influence of reaction parameters, such as reaction pressure and presence or absence of O_2, on the ability to produce low-volatile oxidation products or condensation nuclei during the ozonolysis of different functionalized respectively oxidized alkenes.

As Fig. 1 shows, the presence of various amounts of oxygen in the reactive mixture influences the observed aerosol yield of organic acids.

Our approach is to illuminate the dependency of aerosol formation, both on oxidation state of the alkene and on the relative distance between the double bond and the oxygenated carbon atom in the backbone. The influence of arborisation can be of interest as well, due to different (kinetic) behaviour of substances with otherwise identical atomic composition.

Whereas the aerosol yields during the ozonolysis of unsaturated acids are considerably reduced in the presence of oxygen, they are enhanced in case of alcohols (not shown).

The influence of molecular oxygen can be interpreted as follows:

During the ozonolysis alkyl radicals are formed either by external H atom abstraction by OH radicals or by internal H atom abstraction in the hydroperoxid channel of Criegee intermediates. In synthetic air O_2 is added immediately to the radicals forming peroxy radicals. Our results suggest that in case of the acids the fate of the peroxy radicals is to a significant degree C-C bond fission increasing the volatility of products and reducing the observed aerosol yields.

The same reaction regarding unsaturated hydrocarbons and alcohols leads to a reduction of volatility and a noticeably growing aerosol yield with the amount of oxygen enclosed in the reactive mixture.

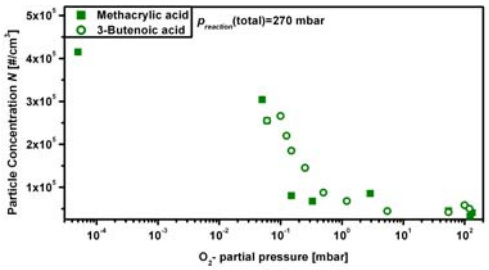

Figure 1. This figure illustrates the dependence of the total particle concentration on the amount of oxygen in the reactive mixture. Constant quantities of reactants were converted: $p_{0,\,acid}$=5 Pa, $p_{0,\,ozone}$=0.1 Pa for 3-Butenoic acid, $p_{0,\,ozone}$=0.2 Pa for Methacrylic acid.

Emission of biogenic volatile organic compounds (BVOCs) by vegetation in the boreal forest and subsequently atmospheric oxidation leads to the formation of secondary organic aerosol (SOA). Oxidation of the BVOCs produces a variety of mostly unidentified organic species. Dependent on the volatility of the products, they partition between gas and particle phase. Seen from this perspective, organic acids are of particular importance for the particle phase, since the higher oxidation state and molecular mass, compared to the corresponding terpenes or aldehydes, is accompanied by a much lower volatility. However, very little is known about intermediate volatility organic compounds (IVOCs) which are residing almost entirely in the gas phase and generate efficiently lower volatility products by further reaction with atmospheric oxidants or by oligomerization (Donahue et al., 2006).

Here we show the high potential for gaining new insights into gas-to-particle-partitioning of individual organic acids by measuring them in both phases with the same instrument. This was achieved by coupling a miniature Versatile Aerosol Concentration Enrichment System (mVACES) as described by Geller et al. (2005) with an Atmospheric Pressure Chemical Ionization Ion Trap Mass Spectrometer (APCI-IT-MS; Hoffmann et al., 2002). The benefits of the on-line APCI-IT-MS are soft ionization with nearly no fragmentation, high time resolution and less sampling artifacts than in the common procedure of taking filter samples, extraction and detection with LC-MS. Furthermore the ion trap allows to perform MS/MS-experiments by isolation of single m/z ratios of particular ions. By subsequent addition of energy, the trapped ions form characteristic fragments which enable structural insight on the molecular level.

The sophisticated aerosol concentrator mVACES is a necessary unit for operation of the APCI-IT-MS in the field. It improves the limit of detection by concentrating particles without lowering the time resolution. Physical and chemical alteration of the particles, especially the change of gas-particle partitioning, was evaluated.

Field measurement during HUMPPA-COPEC10 campaign

The setup mVACES coupled to APCI-IT-MS was tested successfully in the laboratory and afterwards used during the large HUMPPA-COPEC field campaign at the SMEAR station in Hyytiälä, Finland in summer 2010. The comprehensive instrumental equipment of gas and particle phase measuring instruments during the campaign made it possible to compare the APCI-MS-data with a variety of different techniques. Especially the comparison between APCI-MS and the c-ToF-AMS (compact Time of Flight Aerosol Mass Spectrometer) of the University of Helsinki is predestinated, since these two instruments were connected to the same aerosol inlet line. Very good correlation coefficients between APCI-MS and AMS for sulfate (R^2=0.93) and for total organics (R^2=0.94) in particle phase have been determined. Furthermore organic acids were measured by filter sampling and subsequent analysis with LC-MS in order to resolve possible isobaric interference of the APCI-MS technique. For the first time in a field measurement in situ MS/MS-experiments for chemical characterization of the major abundant organic acids have been carried out. Results show similar pattern to those MS/MS-experiments in laboratory generated secondary organic aerosol.

However, not only comparison to different instruments and techniques revealed interesting results, but also the temporal behavior of specific compounds allows interpretation possibilities. For example fast mixing processes in the atmosphere (e.g. boundary layer processes) show a strong influence on the concentration levels of IVOCs. These short-term processes can only be monitored by an on-line technique. In addition we could show that gas-particle-partitioning of single organic compounds is not only driven by the molecular mass but most notably by the oxidation state of the regarded species. This means there exist highly oxidized organic acids with a relative small molecular mass which contribute more to particle mass than other organic acids with higher molecular masses.

Abstract

Based on the studies of Haagen-Smit and Went, new aerosol particle formation by biogenic terpene oxidation products has been proposed. This certainly has remarkable atmospheric effects, since vegetated areas are extensive in space but diverse in composition and emission of reactive volatile organic compounds (VOCs). So far independent pathways from sulphuric acid derived nucleation have not been formulated and accepted. Here we aim to explain the observed nucleation process by a purely organic algorithm obtained from laboratory investigations, which we could perform successfully. The important role of organic radical (RO_2) formation by monoterpenes was elucidated, which activated the sesquiterpene derived nucleation core. Therefore both terpene groups and their reactivity with respect to ozone and OH are important for new aerosol particle formation in a non-linear system.

Methods

We focus on two controlled greenhouse experiments a) at Frankfurt University in June 2010 and b) at Max-Planck Institute for Chemical Ecology in Jena, in December 2010. While the first measurements were done in a greenhouse with changing light and temperature conditions, the second set of measurements were run at a constant temperature T of 24°C and constant illumination. The used three different tobacco plant types provided three different emission patterns with respect to sesquiterpenes, i.e. (i) one wild type and two genetically modified ones emitting (ii) a mixture of two sesquiterpenes (α-farnesene and α-bergamotene) or (iii) α-farnesene only.

In Frankfurt plant incubation was done using a Teflon bag while in Jena each plant was incubated in a single plant cuvette and was treated with different ozone stress intensities between 400 and 833 ppb_v.

Total particle concentration was measured by a condensation particle counter (UCPC 3776, TSI) with a lower cut-off size of 2.7 nm. All measurements have been conducted on the 13th-18th of December 2010 at the Max-Planck Institute in Jena.

Nucleation mechanism assumed

Based on the laboratory investigation on new particle formation by alkenes and ozone (see other presentation), the following mechanism was assumed:

1. Formation of stabilised Criegee intermediates (sCI) by sesquiterpenes and ozone
2. Formation of reactive secondary ozonides (SOZ) from sCI and available carbonyl compounds.
3. Activation (reaction) by monoterpene and OH derived large organic peroxy radicals (RO_2).

Taking into account the inhomogeneity of the cuvettes and the uncertainty of the radicals, a reasonable match between observation and calculation was obtained. As a conclusion it can be stated: The reaction rate constants of sesquiterpenes and of monoterpenes with O_3 and OH affect the entire nucleation process and the system is non-linear.

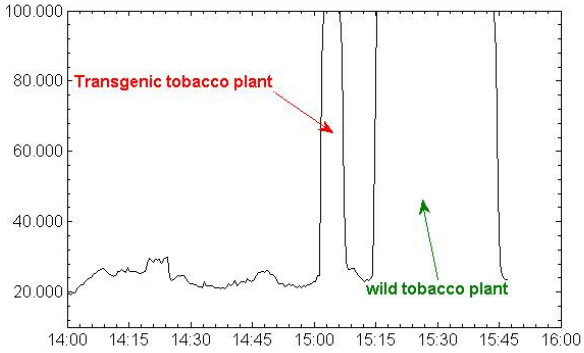

Figure 1. Effect of sudden rise in provided ozone. Particle number and sesquiterpenes concentrations rapidly increased in Frankfurt.

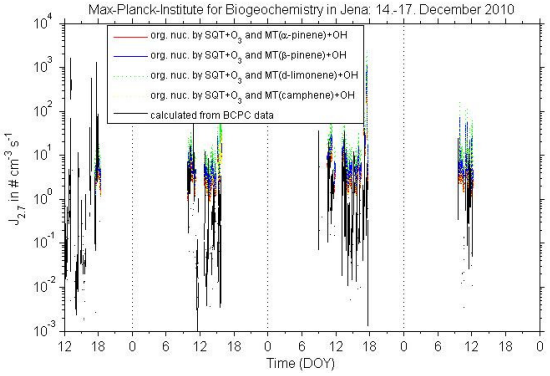

Figure 2. Simulated and measured nucleation rates for experiments performed at Jena.

Oxidation of nopinone - Influence of relative humidity and particle acidity on particulate products

A.Mutzel, Y. Iinuma, O. Böge, A. Kahnt and H. Herrmann

Leibniz-Institut für Troposphärenforschung, Permoserstr. 15, Leipzig D-04318, Germany
Keywords: VOCs, SOA, Aerosol characterization
heinolda@tropos.de

The oxidation of biogenic volatile organic compounds (BVOCs) leads to the formation of low volatile compounds. Especially, the formation of secondary organic aerosol (SOA) from the oxidation of monoterpenes has been investigated extensively in the past years (see a review paper by Hallquist *et al*., 2009). The first generation oxidation products of monoterpenes are still volatile and are further oxidized in the gas phase to form a wide range of products that contribute to SOA formation. Although, a spate of studies report SOA products from monoterpene oxidation, little is known about the influence of relative humidity and seed particle acidity on the formation of monomeric and oligomeric compounds from the first generation oxidation products.

In the present study, we conducted a series of chamber experiments to study the influence of the reaction conditions on the formation and composition of SOA in the OH radical reaction of nopinone (Table 1). Nopinone is one of the first generation products that orginates from β-pinene oxidation. Three different reaction parameters were examined: seed particle acidity, relative humidity and NO_x mixing ratio. Each set of experiment was performed using two different OH sources: the ozonolysis of tetramethylethylene and the photolysis of methylnitrite in the presence of nitrogen oxide.

Table 1. Conditions for the oxidation of nopinone. (Initial mixing ratio 50 ppb, temperature 20±1°C)

Relative humidity [%]	Set 1 (0.07M)	Set 2 (0.076M/0.003M)	Set 3 (0.04M)
0	Na_2SO_4	$(NH_4)_2SO_4/H_2SO_4$	NH_4HSO_4
50	Na_2SO_4	$(NH_4)_2SO_4/H_2SO_4$	NH_4HSO_4
75	Na_2SO_4	$(NH_4)_2SO_4/H_2SO_4$	NH_4HSO_4

The formed particulate products were collected using a denuder/PTFE filter sampling device. The filter were extracted and analyzed using HPLC/(-)ESI-TOFMS. The analysis of the particle-phase revealed a number of monomeric and oligomeric compounds.

The major monomeric products were detected at the mass to charge ratios (*m*/*z*) 157, 171, 185, 203 and 231 corresponding to terebic acid, terpenylic acid (Claeys *et al*., 2009), pinic acid, 3-methyl-1,2,3-butanetricarboxylic acid (Szmigielski *et al*., 2007) and diaterpenylic acid acetate (Iinuma *et al*., 2009). These compounds are not influenced by relative humidity or particle acidity but their yields decreased in the presence of NO_x.

A decrease in the yield of monomeric compounds and the associated decrease in SOA mass in the presence of NO_x can be explained by the favoured production of more volatile compounds such as aldehyds over low volatile acidic compounds due to the reaction of the alkylperoxyradical (RO_2) with NO (Kroll and Seinfeld, 2008).

The analysis of the higher molecular weight compounds indicates two major oligomeric products with *m*/*z* 357 and 371, corresponding to $C_{17}H_{25}O_8$ and $C_{18}H_{27}O_8$, respectively. Both compounds showed an influence of NO_x levels and particle phase acidity though only *m*/*z* 371 compound was influenced by relative humidity. In the presence of NO_x the formation of both compounds was reduced. The highest amount of the *m*/*z* 371 compound was observed under higher relative humidity and in the presence of strongly acidic particles, indicating that this compound is likely formed through acid catalysed accretion reaction. Surprisingly, an opposite behaviour was observed for the *m/z* 357 compound, which decreased in the presence of acidic particles. This observation gives a hint that the formation of this compound is either not related to acid catalysed accretion reaction or decomposed in the presence of strong acidity.

Outside urban areas, oxidized organic aerosols (OOA) dominate the composition of the organic atmospheric particulate matter. In the frame of the EUCAARI (European integrated project on Aerosol Cloud Climate Air Quality Interactions) project, the submicron aerosol chemical composition in Cabauw, Netherlands, was characterized by means of proton-Nuclear Magnetic Resonance (^{1}H-NMR) spectroscopy with aim of organic aerosol characterization and source apportionment. The analysis was applied to water-soluble organic aerosols (WSOA),which is a proxy for OOA.

The experiment was conducted throughout May 2008 during a period of prolonged stable anticyclonic conditions, which favoured the accumulation of pollutants over western/central Europe, interrupted by an outbreak of Atlantic air masses between 17th and 20th May. A set of 25 PM1 filter samples were analysed by ^{1}H-NMR spectroscopy and the resulting collection of spectra was processed using a suite of chemometric techniques, including PCA, cluster analysis and factor analysis (Positive Matrix Factorization or PMF, Non-negative Matrix Factorization or NMF, Multivariate Curve Resolution-Alternating Least Squares or MCR-ALS) aiming to identify recurrent spectral profiles. The contributions of the identified factors to total NMR-detected organics were used to trace the temporal variations of the various organic aerosol types at the sampling location and to identify different prevalent sources.

Factor analysis identified three factors with characteristic spectral profile: (a) OOA associated to metanesulphonic acid (MSA), (b) humic-like substances (HULIS) and (c) other complex OOA enriched in aliphatic acids. The analysis of metadata (meteorological variables, concentrations of nitrate, sulfate, ammonium, potassium, black carbon, and air masses origin), shows that the MSA-containing OOA factor is associated to northerly marine air masses, the HULIS are carried by polluted continental air masses, whereas the aliphatic-rich OOA have no clear dependence on wind direction.

The comparison of these results with those of Positive Matrix Factorization (PMF) applied to a parallel AMS dataset showed a good agreement between NMR "HULIS"-factor and one type of AMS "LV-OOA" (a-type).

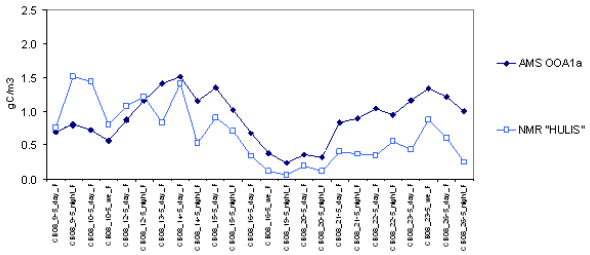

Fig. 1: Comparison between contributions (μgC/m^3) of NMR "HULIS"-Factor and AMS "LV-OOA" a-type at Cabauw during May 2008 EUCAARI IOP

Additional measurements performed at other European EUCAARI stations during May 2008 shows that the HULIS factor characterized the OOA composition in the polluted boundary layer air at the regional scale. Nevertheless, the aliphatic-rich OOA of Cabauw were not found in the central European stations and it can be related to different sources of oxidized organic aerosols active at that time in the North Sea area with respect to continental Europe.

This work has been supported by European Commission 6th Framework program project EUCAARI, contract no 036833-2 (EUCAARI).

Determination of organic compounds in ultrafine particles

S. De Pieri[1], J. Coppola[2], E. Morabito[1], C. Barbante[1,2] and A. Gambaro[1,2]

[1] Department of Environmental Sciences, Informatics, and Statistics, University Ca' Foscari, 30123 Venice, Italy

Keywords: nanoparticles, PAH, organic compounds, pollution.
Presenting author email: depierisilvia@unive.it

Nanoparticle emissions are associated with cardiopulmonary health impacts and increased mortality. The emission and, evolution, and exposure-uptake of particles with diameters equal to or less than of these particles, 100 nanometers and smaller in diameter, are fundamentally quantified by their by the number concentration as a function of particle size. Nanoparticle number distributions are widely variable and rapidly change fast changing as their concentrations are strongly influenced by local environmental conditions .

In this work four sampling campaigns were conducted under differing meteorological conditions. We collected ultrafine particles on the roof of the university in Venice using a low-pressure impactor (DLPI DEKATI). The impactor classifies 13 size fractions from 0.03 to 10 μm.

The literature, many authors (Di Filippo et al., 2009) suggests that the fraction of particles collected on impactor-stages 1–3 (Dp < 0.1 μm) is defined referred to as the ultrafine fraction, while the portions on impactor-stages 4–8 (0.17 μm < Dp < 1.0 μm) and on impactor-stages 9–13 (Dp > 1.0 μm) are respectively referred to as the fine and the coarse fractions.

The samples were analyzed for PAHs, PBDEs, PCNs and PCBs. Ultrafine particles were recovered from aluminum filters. The filter were extracted by ultrasonic bath in a mix Dichloromethane:Hexane 1:1 (v:v) for ten minutes, and their volumes were reduced to 500 μL under a gentle nitrogen flow.

The concentrations of organics compounds were determined by high-resolution GC-High Resolutions MS. PAH identification were as performed by comparison of the sample chromatograms with PAH certified mixtures. Before the extraction the samples were spiked with 13C-labeled standard.

Quality control of the analytical procedure was conducted carried out by controlling blanks control, and by evaluating detection limits, recoveries, accuracy. The LOD was quantified as the mean concentration in the blank plus three times the standards deviation (IUPAC, 1978). The LOD for PAHs ranged from 1.17ng for Naphtalene to 0.02ng for Acenaphtalene. The recovery of nanoparticles-PAH determination was tested by spiking the filters with known amounts of PAH and subsequent extraction and analysis using the procedures reported above. The accuracy of "nanoparticles-PAH" determinations were estimated by analyzing five different filters. The means of accuracy are approximately estimated around to 90% for Naphtalene and Acenaphtalene. The accuracy ranges between to 2% for Phenantrene, to 20% for Benzo(a)Antracene.

The preliminary results demonstrated that the main contributors to the total concentration in the ultrafine fractions are Pyrene and Anhthracene. In the fine fraction the main contributor are represented Anthracene and Fluorene while in the coarse fraction is dominated by congeners with m/z 178.1. These preliminary results represent the first effort to estimation of the concentrations of organic contaminants in the Venice lagoon nanoparticles; and will be compared with the measurements which are still in progress.

The project MEGAPOLI-PARIS, elaborated in a European regulation context, aims at gaining an increasing comprehension of major processes affecting the abundance of particulate matter in a polluted atmosphere so as to better assess primary sources of carbonaceous aerosols, secondary sources of organic aerosols through gas-to-particle conversion and to evaluate and improve process and air quality models. To reach these objectives, an experimental campaign in the Paris agglomeration, a major anthropogenic emission source surrounded by rural areas, has been conducted during summer (from 01 to 31 July 2009) and winter (from 15 January to 15 February 2010).

The project MEGAPOLI-PARIS, elaborated in a European regulation context, aims at gaining an increasing comprehension of major processes affecting the abundance of particulate matter in a polluted atmosphere so as to better assess primary sources of carbonaceous aerosols, secondary sources of organic aerosols through gas-to-particle conversion and to evaluate and improve process and air quality models. To reach these objectives, an experimental campaign in the Paris agglomeration, a major anthropogenic emission source surrounded by rural areas, has been conducted during summer (from 01 to 31 July 2009) and winter (from 15 January to 15 February 2010).

In order to develop effective control strategies for fine particulate air pollution abatement, knowledge of the relative importance of the various sources that contribute to the particulate matter concentrations at the ambient air monitoring sites is required.

Chemical analyses have been carried out for major anions, trace metals, OC/EC, and for individual organic marker species including n-alkanes, hopanes, PAHs, levoglucosan, organic acids, sterols, phtalates, tetrols and other secondary organic markers. Source apportionment has been performed using the US EPA chemical mass balance (CMB) model.

This study was conduced in two sampling sites in Paris : one urban supersite (LHVP) and one suburban supersite (SIRTA). The contributions of up to 5 primary fine particles source types can be separately identified in ambient samples based on this method. In summer, the organic aerosol is mainly from secondary origin and the largest primary source contributors to fine particle mass concentrations in Paris are found to include mainly diesel engine exhaust, with smaller contribution from vegetative detritus as combustion aerosol. In winter, the main primary source emission is wood combustion.

Cyanobacteria are a small group of photosynthetic-planktonic bacteria, which produce a large group of potent hepatotoxin, microcystins.
Past research was conducted to determine the microcystins' concentration in drinking waters, marine waters and foods but few studies were focus on identification and quantification of microcystins in marine and urban aerosol.

Algae cells, bacteria, and waterborne toxins can be aerosolized by a bubble-bursting process. It is demonstrated that respiratory symptoms are associated with exposure to higher levels of cyanobacteria during recreational activities (Paddle, 2003). Aerosolized toxins may be absorbed through the skin, inhaled into the lungs or enter the gastrointestinal system after being deposited in the major airways or following ingestion of food and water.

Bisphenol A is an industrial chemical used as an intermediate compound in the production of epoxy resins and carbonate plastics. Many studies have demonstrated that bisphenol A is an ubiquitous pollutant (Staples et al. , 1998; Fromme et al., 2002; Wilson et al., 2001; Matsumoto et al., 2005) and has toxic proprieties, including estrogenic endocrine disruption and promotion of tumorigenic progression (Keri et al., 2007).

The aim of this work is the development of a comprehensive analitical procedure for the determination of six microcystins (LA, LR, LW, LF, LY, YR), the toxin nodularin and bisphenol A in the aerosol of the Venice Lagoon. Instrumental analysis employed an Agilent 1100 series HPLC system (Agilent, Waldbronn, Germany) coupled to an API 4000 triple quadrupole mass spectrometer (Applied Biosystems/MDS SCIEX, Toronto, Ontario, Canada). In this work leucine enkephalin acetate and bisphenol A $^{13}C_{12}$ are used as internal standard for the quantification of toxins and bisphenol A, respectively. The analytical procedure was validated: the accuracy, precision and recovery have been evaluated.

In order to apply this method, 8 samples collected in Venice on the Sacca San Biagio Island near Venice harbor from June to July 2007, were analysed. Three toxins (LA, LW and LF) were observed; LA: average concentration 275 fg/m^3 (with a range between 90 and 706 fg/m^3), LW average concentration 230 fg/m^3 (177 - 250 fg/m^3) and LF average concentration 221 fg/m^3 (130 - 369 fg/m^3)
To our knowledge this is the first time the presence of microcystins is observed in the Venice Lagoon.

Research demonstrates the presence of bisphenol A in Venice Lagoon waters (Pojana et al., 2004) but this is the first research to investigate the presence of bisphenol A in the urban aerosol of Venice Lagoon. We demonstrate that bisphenol A was present in the urban aerosol of Venice Lagoon with an average concentration 0.65 pg/m^3 (with a range between 0.16 and 1.92 pg/m^3).
The preliminary results of our study suggest that further research should be conducted to better define the temporal trend of microcystins and bisphenol A , in the aerosol of the Venice Lagoon.

$PM_{2.5}$ emissions from wood combustion in a fireplace and a woodstove: carbon content and inorganic speciation

Célia Alves, Cátia Gonçalves, Ana Patrícia Fernandes, Luís Tarelho, Casimiro Pio
Centre for Environmental and Marine Studies (CESAM), Department of Environment, University of Aveiro, 3810-193 Aveiro, Portugal
Keywords: woodstove, fireplace, $PM_{2.5}$, biomass burning, water-soluble ions, metals
Presenting author e-mail: celia.alves@ua.pt

Residential wood burning is known to be a significant source of particulate matter in many regions worldwide. Several studies have been carried out to characterise the organic composition of wood smoke particles (e.g. Fine *et al*., 2004; Schmidl *et al*., 2008). However, only limited information exists on the combustion-related trace elements and water-soluble ions, which are biogeochemically active species and may represent a substantial portion of the toxicity of particles.

Wood from seven species of trees grown in the Portuguese forest and briquettes produced from forest biomass waste were burned in a fireplace and in a woodstove to determine the chemical composition of fine particle ($PM_{2.5}$) emissions. Samples were analysed for organic and elemental carbon (OC/EC), water soluble ions (Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, NO_3^- and SO_4^{2-}) and 67 elements, using a thermo-optical transmission technique, ion chromatography and ICP-MS, respectively.

The fireplace was the combustion appliance with the highest $PM_{2.5}$ emissions. Organic carbon contributed to about 50% of the fine particle mass in the emissions from every wood species studied (Table 1). The water-soluble ions accounted for about 1 to 14% of the $PM_{2.5}$ mass. The Golden wattle wood smoke showed a much higher ionic content than the emissions from the other wood types. Trace elements represented 0.4 to 2.5% of the $PM_{2.5}$ mass with an average total emission of 110±64 mg kg^{-1} wood burned. Among these, K, Pb, Al, Mn and Sr were present in all samples.

The water soluble potassium (K^+) comprised 77±20% and 71±30% of the analysed inorganic ions in particles emitted from the fireplace and the woodstove, respectively. The water soluble potassium (K^+) comprised 77±20% and 71±30% of the analysed inorganic ions in particles emitted from the fireplace and the woodstove, respectively. A good correlation between the potassium levels determined by ICP-MS and the water-soluble form of the element was found ($K_{water\ soluble}=0.73\times K_{ICP\text{-}MS}+0.06$; $r^2=0.89$). Thus, most of the potassium observed in the wood smoke emissions of this study is water-soluble, as indicated by the high K^+/K ratios: 0.80±0.19. Watson *et al.* (2001) reported K^+/K ratios ranging from 0.1 in geological material profiles to 0.9 in vegetative burning emissions. The elemental potassium accounted for 0.87±0.52 wt % of $PM_{2.5}$, representing 0.092±0.058 g kg^{-1} wood burned.

Table 1. Fine particulate emission factors and chemical composition of selected Portuguese biomass fuel types.

Appliance	Biomass type	$PM_{2.5}$ emission factor (g kg^{-1} fuel burned, dry basis)	OC (wt % of $PM_{2.5}$ mass)	EC (wt % of $PM_{2.5}$ mass)	Water soluble ions (wt % of $PM_{2.5}$ mass)	Metals (wt % of $PM_{2.5}$ mass)	Σ of chemical components (wt % of $PM_{2.5}$ mass)
Fireplace	Maritime pine	14.2	43.2	7.5	1.8	0.392	91.8
	Eucalyptus	20.2	43.2	2.2	2.9	0.835	82.8
	Cork oak	13.4	51.8	2.6	0.64	0.510	98.5
	Golden wattle	10.0	38.7	6.6	11.3	2.48	84.6
	Olive	9.9	48.5	4.2	0.98	0.981	95.9
	Portuguese oak	19.1	48.0	2.5	1.87	1.27	92.2
	Holm oak	16.0	53.0	2.2	0.75	0.540	99.9
	Briquettes	15.3	47.7	5.4	2.7	0.596	96.4
Woodstove	Maritime pine	16.3	49.2	3.9	1.7	0.179	95.6
	Eucalyptus	6.7	48.0	3.7	3.2	1.35	94.6
	Cork oak	15.1	53.6	1.9	0.53	0.394	100
	Golden wattle	11.7	45.0	2.0	13.6	1.97	87.6
	Olive	6.2	45.6	7.7	1.4	1.49	97.5
	Portuguese oak	9.8	49.4	3.9	1.6	1.26	97.3
	Holm oak	10.2	53.4	2.2	1.82	0.610	101
	Briquettes	4.2	47.1	3.9	9.1	2.17	94.7

Σ chemical components = $OC\times1.8 + EC + NH_4^+ + Cl^- +$ Metals

The application of cluster analysis to the individual smoke composition indicated that emissions from the cork and Holm oak combustion, whether in the fireplace or in the woodstove, can be grouped into the same composite source profile, while those from the Portuguese oak should be separated into another profile, which also may include the emissions from eucalyptus. Emissions from the combustion of maritime pine in both appliances may also be averaged to obtain a single profile. The comparison of emissions from this study with literature data showed dissimilarities, confirming the need of obtaining specific values for the combustion of Mediterranean biomass fuels in order to appropriately use these profiles in source attribution studies.

Characterizing lengths and aerodynamic diameters of airborne glass fibers

Bon Ki Ku[1], Gregory Deye[1] and Leonid A. Turkevich[1]

[1]Centers for Disease Control and Prevention (CDC), National Institute for Occupational Safety and Health (NIOSH), Cincinnati, Ohio 45226, USA
Keywords: Glass fiber, length, diameter, screen.
Presenting author email: BKu@cdc.gov

Introduction

Historically, fiber-related research primarily grew out of health and manufacturing issues regarding asbestos. Current fiber measurement techniques also arose primarily due to health concerns over asbestos exposure. Fiber toxicity appears to be mostly a function of fiber concentration, dimensions (diameter and length) and durability in the lungs. During the past decade, airborne fibrous particles such as carbon nanotubes and carbon nanofibers have come under scrutiny owing to their asbestos-like appearance (Poland et al. 2008). This suspicion hinges on thin fiber-like structure of these particles and their presumed insolubility in the lungs, both attributes of harmful asbestos fibers. To better understand the toxicity of fibers, it is essential to classify fibers by length for toxicology studies. In this study we investigated how feasible it would be to use screens combined with asbestos sampling cassettes for length classification of fibers.

Methods

Glass fiber powder (GW1) supplied by the Japan Fibrous Material Research Association (JFMRA) was used as a surrogate of asbestos to generate airborne glass fibers by a vortex shaking method (Ku et al., 2006). The glass fiber sample had a geometric mean length 20.0 μm with geometric standard deviation (GSD) of 2.58 and geometric mean diameter 0.88 μm with geometric standard deviation (GSD) of 3.10 (Kohyama et al., 1997). Size distributions of the airborne glass fibers from the vortex shaker were measured by an Aerodynamic Particle Sizer (3321, TSI Inc.), and the airborne fibers were collected on a mixed cellulose ester filter (SKC Inc) in a 25 mm conductive cassette to measure length distribution of the fibers by a phase contrast microscope (PCM) with 40X and 10X magnifications. Nylon net screens with different screen mesh sizes (60, 20, and 10 μm) were used to examine the effect of screen size on length distribution.

Results and Conclusion

Figure 1 shows cumulative number concentration of glass fibers as a function of fiber length for different screen sizes. The red and blue lines in Fig. 1 represent mesh sizes of screen 20 and 60 μm. With no screen, the length distribution of the fibers is similar to the one reported in a previous paper. As screen mesh size decreases from screen 60 to 20, 50% cut-off length decreases from about 10 μm to about 7.5 μm. Compared to no screen case, using screens could give reduced lengths of fibers. It is worth noting that the 50% cut-off length for screen 10 is similar to the one for screen 60, but the slope of the cumulative curve for screen 10 becomes steeper, which means that the length distribution for screen 10 is narrower than the one for screen 60. The percentage of fibers longer than 20 and 60 μm for screen 20 and 60 is about 17 % and 3 %, respectively while the percentage of fibers longer than 10 μm for screen 10 is about 50 %,

APS measurements showed that fibers with no screen have bimodal distributions, with a primary aerodynamic diameter 1.5-2 μm and secondary aerodynamic diameter 7 μm. Using screen 60 and 20 slightly decreased primary modal diameters and significantly reduced the secondary mode. Screen 10 removed almost completely the second mode. The loading of fibers on the filter was also investigated. Using screens resulted in relatively uniform loading along the diameter of the filter.

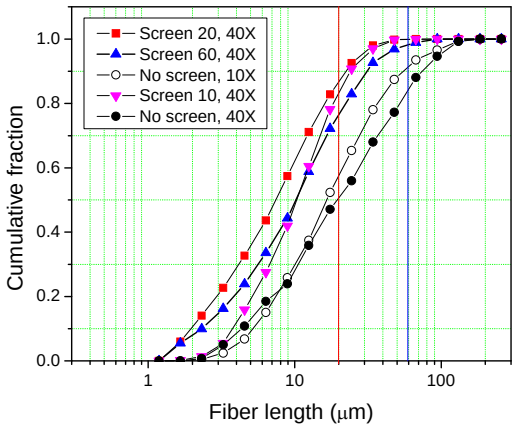

Figure 1. Cumulative fraction of fiber number concentration as a function of fiber length for different screen sizes. 10X and 40X mean magnifications used.

Acknowledgments

We would like to thank Dr. Ono-Ogasawara for sending us samples of glass fibers through the JFMRA in Japan, and Elizabeth Ashley for taking images of fibers and analyzing length distributions using the PCM. Atmospheric aerosol particles meet a growing interest in today's environmental concerns because of their potential impact on the global radiative budget. In the context of the global warming assessment, combustion aerosols are extensively studied as they originate from industrial and transport activities for a large part. They usually are in the form of more or less compact aggregates made of primary particles. The compactness of these clusters is commonly quantified in terms of fractal dimension (Samson, 1987).

The aim of this study is to compare different methods reported in the literature for determining the fractal dimension (D_f) of aggregates from Transmission Electron Micrographies. Two classes of methods may be identified. The first one is based on the statistical study of an assembly of aggregates and the power law dependence of characteristic quantities of each aggregate like N_{pp} the number of primary particles, L_{2D} the maximal projected length, A_{2D} the projected area and P the perimeter. The fractal dimension is determined for the whole set of investigated aggregates. The second class of method focuses on the scale law of each individual aggregate with the nested squares method or the covering set method (Cleary, 1990) providing the fractal dimension of each of them.

The reported work is based on bidimensional projection images of soot aggregates generated by a CAST burner (soot generator mini CAST 5201^{TM}) and emitted by an aircraft combustion chamber (Figure 1). Three major issues are addressed. First, similar fractal dimensions come out from the various statistical approaches based on parameters sensitive to the inner content of the aggregates (e.g. N_{pp}, A_{2D}, see Table 1) whereas deviations are observed when using parameters related to the contour of the object (e.g. P). Then the relationship between the fractal dimension of an assembly of aggregates of various sizes and the averaged fractal dimension of single aggregates studied at different scale sizes is investigated as a second issue. This work is discussed with the previous study of the fractal dimensions of quartz grains by Takahashi and Nagahama (2003) where they showed that the fractal dimensions of individual quartz grains converge to the fractal dimension of the population composed by these objects when the size of these latter increases. This characteristic has never been studied for soot aggregates. The last issue investigated concerns the bandwidth limits to consider (smallest and largest sizes of the aggregates) in the fractal dimension determination. These limits have to respect the sizes of primary particles and of the considered aggregates to bring an analysis that is consistent with the physical structure of the objects.

The three issues investigated in this study should bring clues on the understanding of the methods developed to determine the fractal characteristic of environmental objects that are not fractals (in the mathematical sense) and their uses.

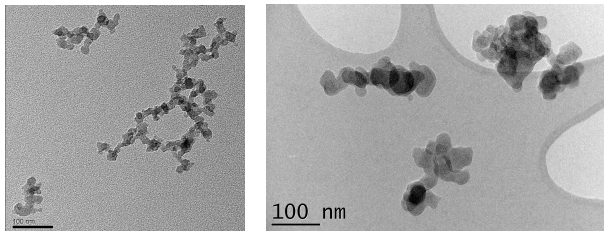

Figure 1. TEM pictures of soot aggregates emitted by a CAST burner (left) and an aircraft combustion chamber (right).

	$A_{2D} \propto P^{\frac{2}{D_f}}$	$A_{2D} \propto L_{2D}^{D_f}$	$N_{pp} \propto \left(\frac{L_{2D}}{d_p}\right)^{D_f}$
D_f	1.4	1.8	1.8

Computationally efficient methods for computing the free molecular and continuum friction factors of non spherical aerosol particles.

Thaseem Thajudeen, Christopher J Hogan Jr
University of Minnesota, Twin cities
thaju001@umn.edu
Keywords: Monte Carlo Simulations, Agglomerates, Aerosol Fundamentals

Without appropriate drag models, non-spherical aerosol particle mobility/friction factor measurements allow for little inference of particle size and shape. Efficient computational models are therefore necessary to calculate the drag on aerosol particles in both the continuum and free molecular regimes, from which more relevant physical descriptors of non-spherical particles can be inferred from drag measurements. In this work we modify two previously developed methods to calculate the friction factors of non spherical aerosol particles in continuum and free molecular regimes, respectively.

Computational Methods

We first adopt algorithm of Zhou et al. (1993) to determine the drag on non-spherical particles in the continuum regime. This algorithm was originally developed to determine the diffusion controlled reaction rate on an arbitrarily shaped particles in liquid solvent. Specifically, Brownian dynamics simulations are utilized to compute the capacitance of nonspherical objects, which is found, to an excellent approximation, to be well correlated the hydrodynamic radius of the particles. Calculated hydrodynamic radii (R_h, the relevant size parameter in the continuum regime) are shown for fractal agglomerates with a varying number of primary particles per agglomerate and fractal dimension in Figure 1. These fractals were generated randomly using a sequential algorithm, which can produce effective mimics of agglomerates generated by a diffusion limited aggregation (DLA) process for ~50 primary particles or less. Although the larger agglomerates are less representative of those produced by DLA, they nonetheless serve as suitable test particles for our continuum drag/friction factor calculation method.

In the free molecular regime we modify the method developed by Nakamura & Hidaka (1998), which was utilized for drag calculation on non-spherical extraterrestrial particles (e.g. asteroids). In the modified approach we employ, trajectory simulations of the diffuse scattering (in angle, while kinetic energy conserved, mimicking a rough specular molecule surface) of point mass gas molecules with a non-spherical aerosol particle in a low velocity flow are used to determine the momentum transfer to the aerosol particle. This momentum transfer rate is compared to the momentum transfer rate to a sphere of known diameter colliding with the same gas molecules, but with perfectly specular scattering between the sphere and point masses. As the collision cross section (Ω) of the sphere is known, the ratio of the net momentum transfer to the non-spherical agglomerate to the net momentum transfer rate to the sphere gives Ω of the agglomerate.

Results

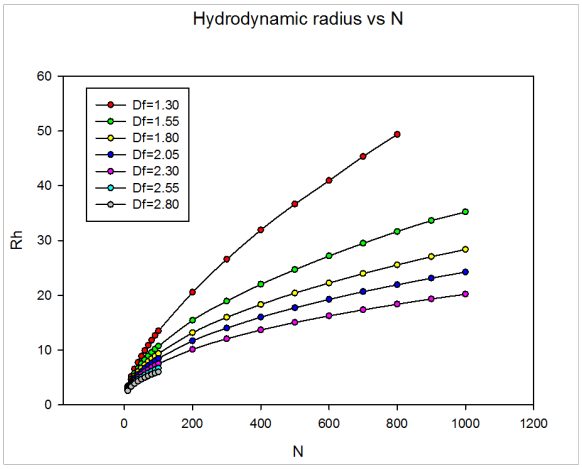

Fig 1. Variation of hydrodynamic radius, R_h, with fractal dimension and number of primary particles.

Overall, these new computational methods allow for calculation of R_h and Ω for any non-spherical particle. These two parameters are the revelant descriptors of any particle with regards to momentum transfer in the continuum and free molecular regimes respectively. Future work will involve determination of how these parameters influence transition regime momentum transfer, which would allow for inference of R_h and Ω from mobility measurements.

In this work, ionic molecular clusters that were generated in a commonly used ^{241}Am neutralizer are characterized with respect to mass and electrical mobility at the same time. The ions are produced by the ionizing radiation occurring during the alpha decay of ^{241}Am. The measurements were performed using a Vienna type high resolution DMA (UDMA, Steiner et al. 2010), running in a closed loop arrangement for the mobility classification and with a novel high resolution atmospheric pressure interface time-of-flight mass spectrometer (APi-TOF, Junninen et al. 2010) for the mass determination in terms of m/q ratios.

The detailed processes governing the generation of the molecular ions within a charger are still somehow uncertain, but the general idea is that the ionizing radiation forms primary ions that will subsequently combine with polar molecules present in the carrier gas to form larger clusters. Therefore, special attention was paid to the purification of the carrier gas led through the ^{241}Am charger, as already very small amounts of trace gases and/or contaminants will strongly alter the species of the generated ions (Steiner et al. 2009).
For the experiments, high purity nitrogen, (N_2 5.0) was used as carrier gas which was additionally purified by means of two silica gel diffusion dryers, two active carbon filters and a hepa filter. The tubing from the purifying equipment to the DMA and APi-TOF was chosen to be either of PTFE or stainless steel to avoid any contaminations.

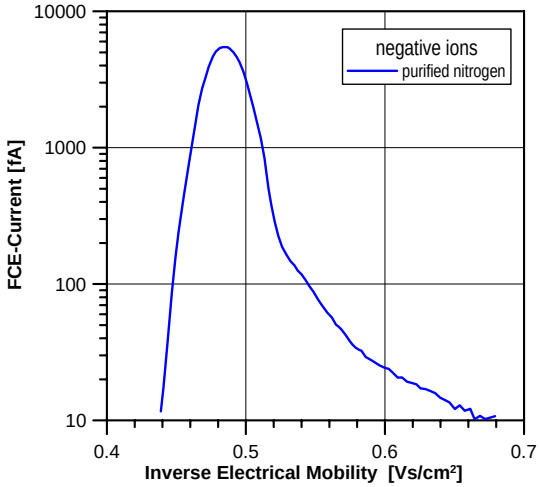

Fig.1 Mobility distribution of negative ions

The resulting mobility distribution of negatively charged ions is shown in Fig.1. For very clean and dry conditions, the ion mobility spectrum is reduced from several to one single peak with a small shoulder facing towards lower mobility/larger size.

The UDMA is continuously classifying the molecular clusters and feeding them to the APi-TOF which allows the identification of the chemical composition of the investigated ion clusters. The mass spectrum of negatively charged ion clusters is dominated by approximate m/q ratios of 46 (NO_2^-), 62 (NO_3^-, nitric acid) 80 $(H_2O{\cdot}HNO_3)^-$ and 125 $(HNO_3{\cdot}NO_3^-$, nitric acid dimer); (Fig.2). Similar experiments were performed for positive ion polarity.

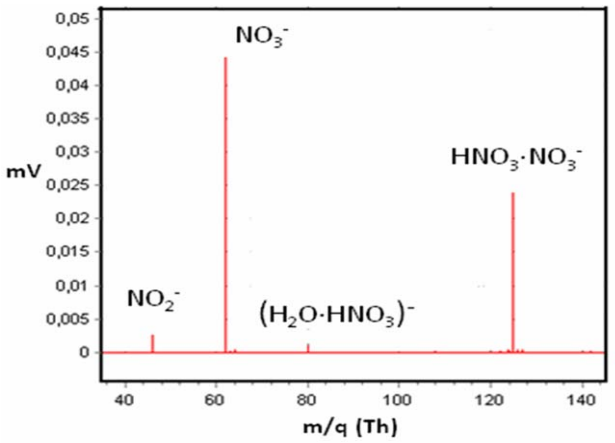

Fig.2 Mass spectrum of negative ions with dominant m/q (Th) peaks

Optical cloaking and agglomerated fractal clusters

V.V. Maksimenko [1] and V.N. Ignatov [2]

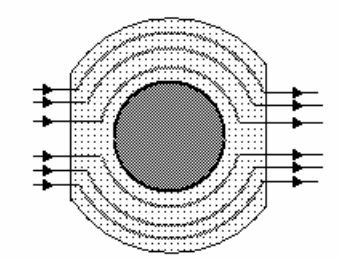
Keywords: fractals, cluster, nanoparticles, agglomerates
Presenting author email: wmaksim@mail.ru

An idea to make a macroscopic object invisible for external observer is now one of the most exciting problems of modern optics. Recent interest to this problem is related to the discovery of so-called meta-materials with negative dielectric and magnetic permeability at certain frequency range (Sarychev & Shalaev, 2007). In this case, light can circulate around an object just as a laminar fluid flux circulates around a cylinder (see Fig. 1)



These ideas were successfully realised in experiments performed in centimetric range of the wave lengths. Typical covering meta-material used were solid matrixes containing a large number of ordered thin metal wires and rings with size comparable with wave-length of the incident radiation. In principle, such systems can also be created in optical spectrum, but sizes of these heterogeneities inside the matrix must be submicron. The latter is extremely hard to do. Moreover, the problem of reflection from boundary of these materials also exists. One should remember about considerable weight of such covering.

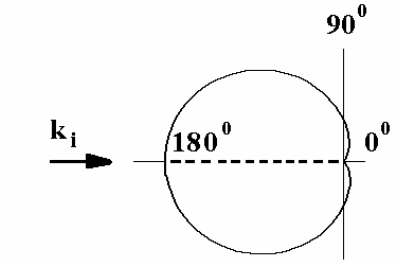
It is desirable to create a covering which entirely absorbs any radiation without any reflection. But this is impossible as we know. Absorbed irradiation heats the object and it re-emits on any wave-length. Nobody could violate the heat radiation rules.

However, the possibility to create a system capable to trap incident radiation without its dissipation and re-emission exists. In this case, the trapped photons move along closed trajectories inside the system on nonabsorbing scatterrers without heating the system. This phenomenon is called the light localization. The most appropriate object for the realization of this aim is a covering consisting of agglomerated fractal clusters containing nonabsorbing nanoparticles.

The localization of light is concerned with closed loops on a photon trajectory. If a photon moves along a closed loop, the phase shift of the wave function of the photon is equal to zero. The probability amplitudes corresponding to both possible ways of the loop passing (clockwise and counterclockwise) interfere constructively. Each loop means indispensable return to the starting point. Due to the increase of the probability of the loop generation (because of above mentioned interference) the flux of light scattered into the back hemisphere also increases. This, in turn, stimulates production of new loops on the photon trajectory, and so on. The photon localization in a finite space region results from such self-sustaining process.

Localization is a purely interference phenomenon, but it can be easily interpreted as the appearance of a bound state of pair of virtual photons passing the closed loop on the photon trajectory by two alternative ways. This phenomenon is analogous of the effective interaction of electron-hole pair due to its scattering on the same impurities in lattice. The latter, as is known, is the reason for the Anderson localization.

The cross section of the photon elastic scattering by an agglomerate of fractal clusters containing nonabsorbing nanoparticles is calculated. It is shown that a photon scattered in the forward direction is not localized, i.e. its life time inside the system is equal to zero. At the same time, every photon scattered at a non-zero angle is trapped by the system. Its life time in the system is of the order of $N^2 \exp(N^2)T$, where T is the period of the incident electromagnetic wave and N is the number of correlated particles inside a separate fractal cluster inside the agglomerate.



In Fig. 2 angular distribution of the intensity of p-polarized light scattered by fractal a cluster is presented. The enhanced scattering to the back hemisphere, in comparison with Rayleigh's indicatrix of an isolated particle is just the physical reason for photon cycling in a cluster (Maksimenko et. al., 2009)

Non conventional indoor model for submicron particulates

Lyons Russell

Radiation Health Unit, Environmental Health Branch, Queensland Health, Brisbane, 4000, Australia

Keywords: submicron, particulates, deposition, indoor, aerosol, modelling.

Abstract

This paper describes the mechanisms of deposition and particle exchange. The term particle exchange in this paper refers to the movement of particle into and out of an enclosure due to the movement of air into and out of an enclosure. At low concentration coagulation is expected to be small in comparison to deposition and particle exchange.

This model seems to have the ability to produce quick and accurate predictions for particle deposition loss and the gain or loss of particles due to particle exchange. Thus this model has the potential to be a powerful tool to aid in further understanding of the phenomenon of coagulation.

Introduction

The deposition component of the model was derived from a non conventional theoretical modelling of the probability of a collision of particles with the walls of the enclosure. Since the particle concentration of the aerosol in the enclosure changes with time, due to the deposition and particle exchange, the model needs to predict these changes and looped the predictions back into the model for the next calculation. This process is repeated for each second.

The model was used to predict the size distribution after ~106 minutes for tobacco smoke. The model appears to give a very accurate prediction as shown in figure 1. Figure 1 graphically compares the actual measured data after 106 minutes and model's prediction after 6360 iterations.

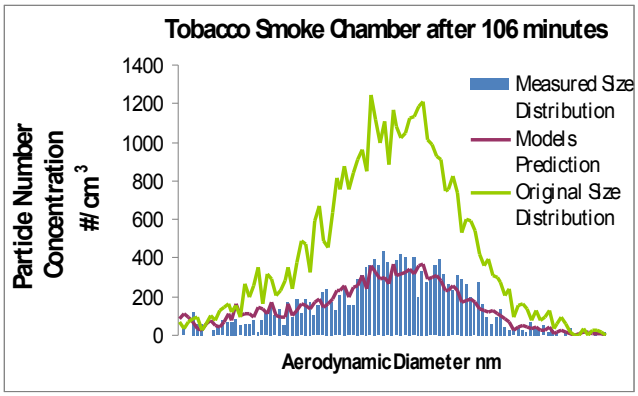

Figure 1. This figure illustrates good agreement between theories and experiment data after 106 minutes (International Lab. For Air Quality and Health, QUT)

The original aerosols distribution in the enclosure is also shown in Figure 1 to give perspective of the particle changes.

The indoor particle model for deposition and particle exchange used is Figure 1 is given below

$$N_x^t = N_x^{t-1} - \frac{AreaN_x^{t-1}}{4\times Volume}\times\left\{\sqrt{\frac{4kTC_{cx}}{3\pi\eta d_x\times 10^{-9}}}\right\} + \frac{f\times\left(N_x^{Outside} - N_x^{t-1}\right)}{Volume\times 10^6}$$

Nomenclature

Area	internal surface area	m2
Volume	internal volume	m^3
f	flow rate	cm^3
k	Boltzmann Constant	
T	Temperature	K
Cc	Cunningham Slip correction factor	
η	dynamic viscosity of air	kg.m-1 s-1
N	Particle concentration	$\#/cm^3$

This paper describes the theoretical development of this indoor particle model used for predicting the changes of total particle number concentration of a decaying aerosol and its changing size distribution over extended time period, for an indoor environment under natural ventilation conditions.

The model used only the following input data for predicting the changes in number concentration; the original size distributions, which is the aerosol size distribution concentration, in the enclosure (after the source has been extinguished) and outside the enclosure, the flow rate into the enclosure, the surface area and volume of the enclosure.

Characterization of sulphuric acid aerosols in industrial processes

L. Brachert[1], S. Sinanis[1] and K. Schaber[1]

[1]Institute of Technical Thermodynamics and Refrigeration, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany

Keywords: Absorption, Homogeneous nucleation, Industrial aerosols.

Presenting author email: leonie.brachert@kit.edu

The formation of volatile sulphuric acid aerosols is a phenomenon which emerges frequently in industrial processes such as absorption, mixing and cooling. An important domain is the absorption-based flue gas cleaning in power plants using fossil fuels. The formation of aerosols during absorption and quenching of acids in general and its possible harm to downstream equipment have been exposed by Schaber (1995). The formation of aerosols contributes to an increased emission of the pollutant as the droplets are carried with the gas stream. As a consequence, expensive facilities for aerosol precipitation have to be installed. For this reason, it is very important to have an instrument to investigate the formation of aerosols and subsequently to provide conditions which prevent their formation.

The absorption of several acids such as HBr and HCl has already been examined in a pilot plant for flue gas cleaning at the institute (Wix, 2008).

A simulation tool (AerCoDe) has been developed which used a monodisperse model for heterogeneous nucleation in the beginning (Ehrig et al, 2002) and recently has been extended for homogeneous nucleation, based on a polydisperse model (Wix *et al*, 2010). The latter is needed when the nucleation of sulphuric acid aerosols is investigated. The reason for this is the occurrence of high supersaturations during the absorption of sulphuric acid as a result of the extreme phase equilibrium of the binary system "sulphuric acid – water.

The results of the simulation yield small aerosols (<200 nm) and high number concentrations up to 10^{16} m^{-3}. The dependence of the number concentrations on the H_2SO_4 inlet concentration of the flue gas is illustrated in Figure 1, which shows lower number concentration at high inlet concentrations of H_2SO_4 in the flue gas. This can be explained by the two competing mechanisms for the depletion of supersaturation: nucleation and growth. At low inlet concentrations, the binary system H_2SO_4-H_2O reveals a steep descent of the saturation pressure with increasing concentration of H_2SO_4 (and subsequently high supersaturations). Hence, at low inlet concentrations the driving force for nucleation is high, whereas there is not much substance in the gas phase which would enforce growth. The higher the inlet concentration, the higher is the driving force for growth and the number concentration of aerosol decreases.

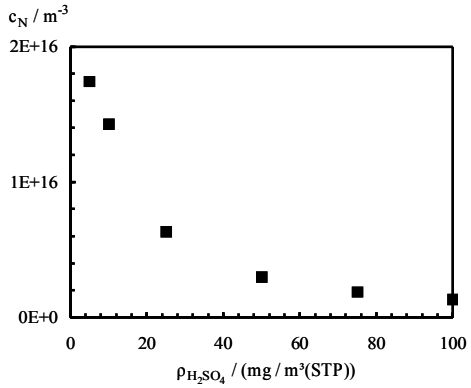

Figure 1. Total number concentration of all droplet classes in the quench column outlet as a function of the H_2SO_4 inlet concentration (Wix 2008)

Because of the expected small diameters, there is currently no in-situ measuring method known which could be used to verify the simulation by experiments. Therefore, a condensation particle counter (CPC) combined with a dilution cascade is used in experiments in order to investigate this correlation in ongoing experiments. As a result of the measuring method, the information about the size distribution of the aerosol is lost.

The combination of simulation and experiments could provide a possibility to fully characterize the aerosols formed during the absorption process in terms of number concentrations, size distribution and contents of acid of the droplets. This could serve as a base for the improvement of absorption processes in industrial applications.

Experimental work on particle motion inside a differentially heated cavity

J. Kalilainen[1,2], T. Lind[2], A. Auvinen[1], P. Rantanen[1], A. Dehbi[2], S. Güntay[2] and J. Jokiniemi[1,3]

Presenting author email: jarmo.kalilainen@vtt.fi

In the case of nuclear reactor severe accident, fission products can be released from the core into the containment. In the presence of temperature gradients inside the containment, natural turbulent convective flows will occur, inducing turbulent flow which can affect aerosol particle deposition rates on containment walls.

The phenomenon of particle deposition in differentially heated cavity (DHC) was investigated in a PhD work with direct numerical simulation (DNS) (Puragliesi, 2010). Also, ongoing PhD work at Paul Scherrer Institut (PSI) uses large eddy simulation (LES) to study the same process. DNS work provided information, such as flow field and temperature profile (shown in Fig. 1), for three-dimensional closed cubic cavity with turbulent Rayleigh number of 10^9. The objective of the LES work is to be able to simulate turbulent conditions with Rayleigh number 10^{10}.

The main aim of this investigation is to experimentally determine the fluid motion, temperature fields, and particle motion inside a differentially heated cavity. Special emphasis is to enable validation of models used in LES, as well as enable comparison with earlier computational work using DNS..

First part of the experimental work is the design and manufacture of the DHC facility. The DHC facility will be a cube with side length no more than 0.8 m. Rayleigh number inside the facility will be varied between 10^9 and 10^{10} by altering the gas composition in the cavity atmosphere. The facility has a heated and a cooled wall for thermal gradient between the walls, and four adiabatic walls. In order for the Oberbeck-Boussinesq approximation, used in the simulation work (Puragliesi, 2010), to be valid the heat difference between the walls must remain below 50 K. Also, the facility must allow optical access for different laser-based measurement devices used to determine the flow properties. This means that besides the heated / cooled walls, all other walls must be at least partly made of transparent material, such as quartz glass.

The facility will be designed to allow geometrical modifications after the first set of tests. For example, the ratio of the cavity height to its width will be varied to better simulate aspect ratios of real containment geometries.

Particle Image Velocimetry (PIV) will be used for measuring the fluid flow velocities. Especially, fluid motion in the boundary layer close to heated / cooled wall must be measured with high resolution.

Particle concentration inside the facility will be measured using Laser-Induced Incandescence (LII). In addition, aerosol instrumentation, such as Condensation Particle Counter (CPC) and Tapered Element Oscillating Microbalance (TEOM) can be used to measure particle number and mass concentrations, respectively. Particle depletion inside the facility due to different mechanisms is investigated by using different particle sizes. In the DNS work, the particle diameters used were 15, 25 and 35 µm. In the experimental work, also smaller particles with diameter close to 1 µm are used in order to investigate the effect on particle depletion of different forces such as turbophoresis. Monodisperse particles will be used in all experiments.

As a result of this work, improved models for fluid and particle motion may be developed and implemented to analytical tools. Based on the experimental results, correlations for particle depletion within DHC will be determined using the validated DNS-LES simulations. These correlations are to be transferred to a CFD code, e.g., Fluent. Particle concentration within DHC will be then modeled with CFD applying the new and improved correlations for turbulent convective flow.

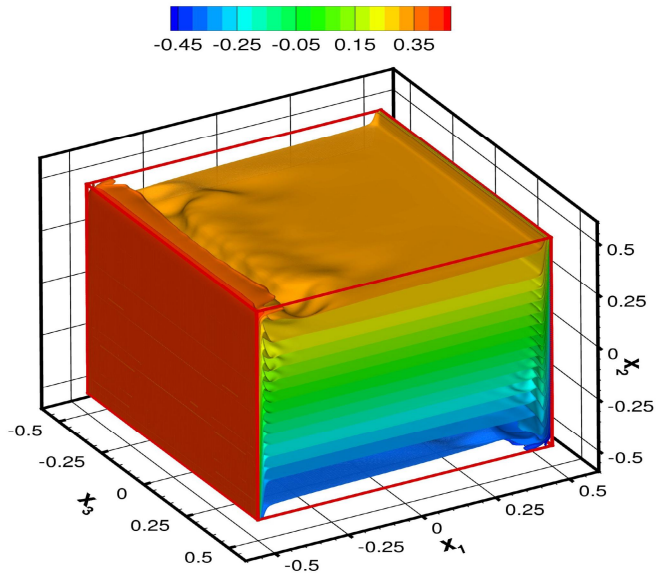

Figure 1. Time-averaged dimensionless temperature profile of DHC, acquired with DNS (Puragliesi, 2010).

Agglomerate drag in continuum and rarefied flow regimes

P. Vainshtein and M. Shapiro

Faculty of Mechanical Engineering, Technion-Israel Institute of Technology, Haifa, 32000, Israel
Keywords: agglomerate, fractal, mobility, rarefied.
Presenting author email: merpeva@tx.technion.ac.il

Submicron particulates emitted from automotive engines oftentimes have a fractal agglomerates structure. The fractal relationships have one of the following forms $N_p = k_f (d / d_p)^{D_f}$ or $N_p = k_g (d_g / d_p)^{D_f}$, where N_p is the number of primary particles per aggregate, d_p is the diameter of the primary particles, D_f is the fractal dimension, k_f, k_g are the prefactors; d, d_g are the outer and gyration diameters.

Drag acting on moving agglomerates can be specified by the Knudsen number, which is a mean free path of the medium molecules, λ, divided by a characteristic sizes of the agglomerate; for instance the outer diameter d and the size of the primary particles d_p (Vainshtein and Shapiro, 2005).

The developed model for calculation of hydrodynamic drag and mobility of fractal aggregates in the transition flow regime employs an adjusted sphere diameter (Dahneke, 1973) and is based on the knowledge of the continuum and vacuum mobility diameters. In the continuum regime the model accounts for internal flow rarefaction and porous fractal structure and their effects on the apparent viscosity and effective permeability of agglomerates. It employs the Stokes equations outside the agglomerate, the Brinkman equations inside the agglomerate and continuity of momentum and stress on the interface. In the free-molecular regime the model uses a semi-empirical relationship for the vacuum mobility diameter of Koylu et al. (1995). The spherically symmetrical model also includes the effects of agglomerate non-sphericity on the drag by assuming agglomerate spheroidal shape (Vainshtein et al., 2004).

We compare our results with those obtainable by Rogak et al. (1993), who used a similar interpolation assuming in addition that the mobility diameter in the continuum regime equals the gyration diameter. Their model thus does not account for internal flow rarefaction and agglomerate porous structure. These phenomena, however, are of importance for determining agglomerate drags especially for large-number agglomerates.

The obtained results on the continuum and transition mobility diameters are compared with the existing experimental and theoretical data. Figure 1 provides an example of such a comparison. The model predicts the ratio between the mobility diameter and gyration diameter about 20% lower than the experimental points. The non-sphericity factor when introduced in the model leads to increasing of the diameters' ratio thereby allowing rationalization of the experimental data.

The large-number colloid RLCA and DLCA aggregates in the continuum regime (Wiltzius, !987; Wang and Sorensen, 1999) behave as oblate spheroids, whereas small-number aerosol DLCA aggregates in the transition regime (Schmidt-Ott, 1988; Cai and Sorensen, 1994; Park et al., 2004; Katzel et al., 2008) behave as prolate spheroids.

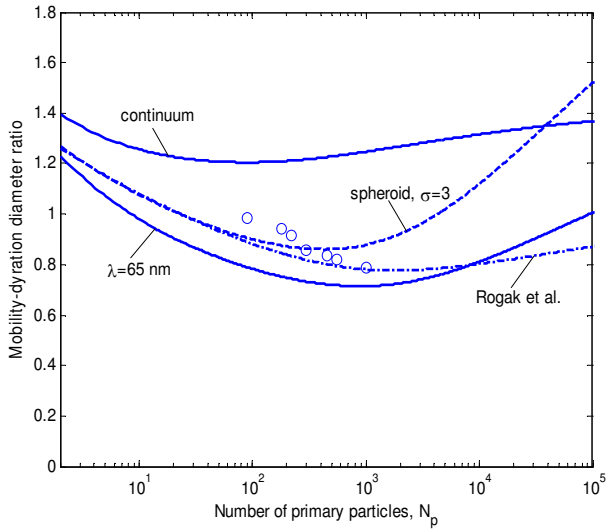

Figure 1. $D_f = 1.8$, $d_p = 10$ nm, $k_f = 1.0$. The solid lines correspond to the spherical model; dashed line to the prolate spheroid with aspect ratio $\sigma = 3$; dashdot line shows the ratio calculated using Rogak et al. (1993). Circles – experimental data of Katzel et al. (2008).

Nonlinear oscillations and deposition of aerosol in tubes

D.A. Gubaidullin, R.G. Zaripov, A.L. Tukmakov and L.A. Tkachenko

Institute of Mechanics and Engineering, Kazan Science Center, Russian Academy of Sciences, Kazan, 2/31, Lobachevsky str., 420111, Russia

Keywords: aerosol, coagulation, deposition, particles, oscillations.

Presenting author email: damirgubaidullin@gmail.com

In the present work, longitudinal oscillations of an aerosol of different initial number concentration and dynamics of particles is considered in tubes of different length with various geometry on the end near to resonant frequencies.

Experimental investigations oscillations of an aerosol were carried out for different length of tubes in a shock-wave and no shock-wave modes near to subharmonic and natural resonances. Di-ethyl-hexyl-sebacate $C_{26}H_{50}O_4$ was used as the working fluid to generate aerosol. The majority of droplets have the geometric diameter 0.863 μm. Number concentration of drops for all experiments monotonously decreases with time and with growth of the excitation frequency. In the case of a closed tube, this process is defined by the coagulation of aerosol and deposition of droplets on the tube walls. In an open tube, the discharge of aerosol to the environment is observed in addition to the coagulation of aerosol and deposition of droplets on the tube walls. The dependence of the time of coagulation of aerosol on the excitation frequency likewise exhibits a nonmonotonic pattern with a maximum and a minimum when passing the resonance. It is established, that presence of a flange slows down process of a coagulation of an aerosol. Reduction of internal diameter of a flange results in increase in the time of coagulation. In so doing, the time of coagulation of aerosol in the case of an open tube is reduced by a factor of two and more compared to the time of coagulation in a closed tube. Nonlinear dependence of the time of coagulation of droplets is established at nonlinear oscillations of an aerosol in a tube from initial number concentration of an aerosol. It has been found that a decrease in the tube length and increase oscillation intensity results in a decrease in the time of coagulation of aerosol. It is shown, that with increase of intensity of the oscillations, the caused increase of amplitude, time of coagulation and deposition of an aerosol decreases. Time of a coagulation and deposition of drops of an aerosol in no shock-wave mode in 2-4 times is lower, than at a natural deposition. Ordered space-time structures of different densities have been revealed in the visible region in the vicinity of the middle of a closed tube.

The numerical modeling of a drift of the solid spherical particles were in a suspension in a nonlinear wave field of the closed tube and open flat channel at excitation of oscillations of a gas column on three first fundamental frequencies is executed. These researches have been carried out about use of model of a single particle and with application of model of interpenetrating continuums. It is obtained, that easy particles drift under an operation of acoustical current, and heavy are displaced under an action of wave pressure. In result easy and heavy particles concentrate in different areas of the resonator: easy are displaced to antinodes of a standing wave of velocity, heavy – to nodes. Depending on a steepness of a wave front of compression, the same particles can behave as easy at small nonlinearity, or as heavy at steep enough fast-head wave front. Drift of heavy particles in the open channel proceeds in two stages. The first quickly proceeding stage is connected to the mechanism of drift due to asymmetry of a wave, and the second with drift under action of developed acoustic stream. Influence of radius of particles on distribution of temperature and average density of a disperse phase along an axis of the channel is revealed.

Dynamics of a single particle with various physical and geometrical parameters is experimentally investigated at the longitudinal oscillations gas in tubes. Along an axis of a tube the particle moves from the closed (open) end to the piston, near to a wall – to the return side, making longitudinal oscillations with increase in the oscillations swing that is caused by acoustic streaming. In a radial direction, the oscillating particle moves from an axis to a wall of the tube up to a boundary point. Outside of a tube, the particle moves from the open end to an exterior wave field practically without oscillations with nonlinear increase of coordinate from time. It is revealed, that the increase in lengths of a tube and excitation frequency of gas in up to - resonant modes gives in growth of an oscillations swing of a particle and increase of its average velocity. Nonmonotonic character for dependence of oscillations swing and average velocity of a spherical particle from excitation frequency of gas is detected. At approach to a resonance oscillations swing and average velocity are incremented, attain the maximum value on a resonance frequency and decrease behind a resonance. Effect of a weight and diameter of a particle on its oscillations swing and average velocity is investigated. Shift of a curve maximum for dependence of a particle average velocity from oscillation frequency aside magnifications of frequency is shown at increase of a weight or diameter of a particle.

Size measurement of dry ice particles in a jet flow using laser diffraction method

Yi-Hung Liu[1], Graham Calvert[2], Colin Hare[2],
Mojtaba Ghadiri[2], Shuji Matsusaka[1]

[1]Department of Chemical Engineering, Kyoto University, Nishikyo-ku, Kyoto 615-8510, Japan
[2]Institute of Particle Science and Engineering, University of Leeds LS2 9JT, UK
Keywords: dry ice, jet flow, size distribution, agglomeration.
Presenting author email: liu@cheme.kyoto-u.ac.jp

Dry ice blasting has been utilized as a dry cleaning method, which can be applied in many industrial fields, such as semiconductor, plastics, food, and pharmaceuticals, etc. The properties of dry ice particles, including size, shape, density, and hardness are thought to be important factors affecting the cleaning process (Spur *et al*., 1999). The agglomeration process of dry ice particles in the jet flow has been investigated (Liu *et al.*, 2010). It was shown that a chamber was effective for the generation of agglomerated dry ice particles. However, a precise measurement of the size of dry ice particles in the jet flow proved to be difficult due to the sublimation process. In the present study, the state of dry ice particles in the jet flow has been analyzed by an on-line laser diffraction method.

Dry ice particles were produced by rapid expansion of liquid carbon dioxide, based on Joule-Thomson effect. In this process, the temperature rapidly decreased by adiabatic expansion from the pressure of 5.5 ± 0.1 MPa to atmospheric pressure. The inner diameters of the nozzles used for expansion were 0.1, 0.2, and 0.5 mm. As an agglomeration chamber, ABS tubes, 50 mm in length and 2, 4, 6 mm in inner diameter, were attached to the nozzle outlet. The size of dry ice particles ejected from the nozzle or the ABS tube were measured by an aerosol analyzer (Spray-Tech, Malvern Instruments Inc.) based on the technique of laser diffraction. The laser beam and dry ice jet were both horizontal and oriented perpendicular to each other.

Figure 1 shows an example of the cumulative size distribution of dry ice particles in a steady state. For the distance from the nozzle $d \leq 40$ mm the median diameter was in the range from 1 to 2 μm and increased with the distance. As for $d = 50$ mm, the dry ice particles shrank to submicron size. A normal-like distribution can be ascertained at a short distance, i.e. $d \leq 40$ mm, while the distribution deviated as the distance increased ($d = 50$ mm). In the size distribution, two size regions were observed, i.e. a smaller diameter region of submicron and a larger diameter region around ten microns. It is found that the primary dry ice particles ejected from the nozzle still grew up and/or agglomerated up to a certain distance. When the distance was sufficiently large, two opposite phenomena, i.e. sublimation and agglomeration occurred. As a result, a bimodal distribution was obtained.

Figure 2 shows the cumulative size distribution of dry ice particles exhausted from the tube in a steady state. Comparing with Fig. 1, the particle size is remarkably larger, indicating that dry ice particles exhausted from the nozzle have already agglomerated in the tube. In addition, the median diameter decreased with increasing nozzle diameter.

Nucleation, condensation, agglomeration and sublimation processes all compete to yield the size distribution as measured. Among them, agglomeration is the most important in the tube (Liu *et al.*, 2010); i.e. dry ice particles of several micrometers are deposited on the tube wall and form a deposition layer; then, agglomerates are reentrained from the layer into the jet flow. The size of the reentrained agglomerates decreases with increasing flow velocity. In these experiments, the flow velocity increases with the nozzle diameter. This is considered as a reason for the trend of the results observed here.

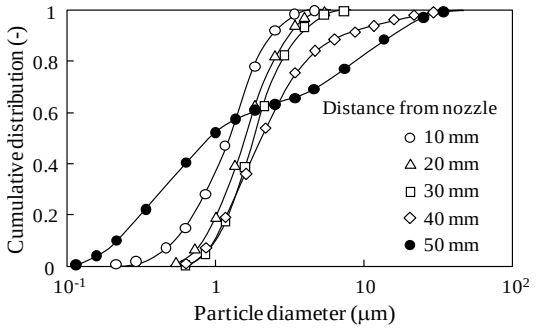

Figure 1. Cumulative size distribution of dry ice particles exhausted from nozzle (nozzle diameter = 0.2 mm).

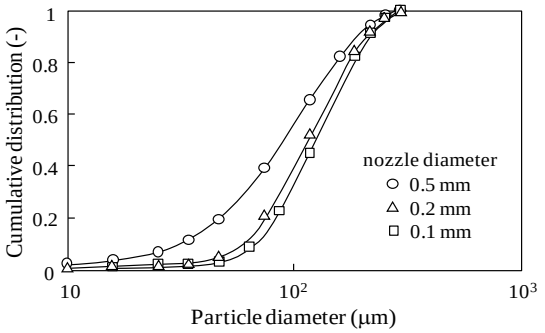

Figure 2. Cumulative size distribution of dry ice particles exhausted from tube (tube diameter = 6 mm, distance from the tube = 40 mm).

Dynamic structure of two-phase polydisperse spray in wake of a shattering drop

A.G. Girin[1]

[1] Odessa National Maritime University, Odessa, 65029, Ukraine
Keywords: spray, evaporation, generation of combustion aerosol, aerosol dynamics.
Presenting author email: club21@ukr.net

Mathematical model for dynamic processes in wake of a drop, shattering in uniform gas stream, is elaborated. It allows to describe quantitatively evaporation and acceleration of stripped mass of daughter droplets and thereby – formation of liquid-phase jet and vapor cloud in a wake. Parent drop is regarded as a source of daughter droplets with distribution function $f_{\rm n}(r,\tau)$ and in turn, each daughter droplet is regarded as moving point source of vapor; their totality forms the distribution of vapor mass. Evolution of distribution function $f_{\rm n}(r,x,\tau)$ in space and time is governed by equation of dispersed fuel (Williams, 1964), which must be added to equations of motion of daughter droplets and of vapor influx. The dependencies of droplet's drag coefficient on velocities and variable sizes as well as intensification of their evaporation due to streamlining were taken into account. The distribution function was taken for the case $h=1$ of equality of rates of torn mass efflux and of relaxational decreasing of relative velocity of gas flow and parent drop (Girin, 2011).

Formulated non-stationary two-dimensional problem for system of differential equations of dynamics of two-phase polydisperse spray was solved numerically with a help of Lax – Vendroff finite-difference scheme for kerosene drop in air stream. Calculations showed, that times of living of finest and largest droplets are the characteristics of liquid jet formation in a spray. Soon after time moment $\tau_{\min}$ of vanishing (entire evaporation) of droplets of minimum in spray radius $r_{\min}$, that were stripped at $\tau=0$, evaporation mass rate $\dot{M}_{\rm v}$ and current value of liquid-phase mass M_l in spray exceed their maximum values because of beginning of droplets vanishing. After moment $\tau_{\max}$ of vanishing of droplets of maximum radius $r_{\max}$ the vanishing of droplets of new radii doesn't occur, and this is the necessary condition for stabilization of length of liquid-phase jet in considered case $h=1$, which is confirmed by analysis of dispersive parameters.

For conditions behind shock waves and in rocket engines the intensification of evaporation by streamlining flow is substantial, so, the fuel is presented in spray generally in vapor phase.

In considering non-stationary process the proposed model allows to calculate all mean diameters d_{ij} of liquid-phase jet and to analyze evolution of its dispersive properties in space and time. Parameters of two kinds were considered: $\Omega_{ij}(x)=d_{ij}(x,\tau_{\rm c})$ are defined at every cross section x of jet and characterize its spatial structure at fixed moment $\tau_{\rm c}$, while $D_{ij}(\tau)=\int d_{ij}(x,\tau)dx$ are calculated at any τ for whole set of droplets and describe temporal changing of dispersity of jet in total. At the beginning the bunch of curves $\Omega_{ij}(x)$ is narrow, that testifies to weak polydispersity of jet, but after droplets vanishing starts, the polydispersity increases. Each curve and bunch as a whole tend to their limit positions at $\tau\to\tau_{\max}$. The stabilization proceeds gradually along jet from astern part to the tip. Soon after $\tau_{\max}$ all the parts of $\Omega_{ij}(x)$ are stabilized and remain still. The dependencies $D_{ij}(\tau)$ confirm the conclusions. In final state jet polydispersity is much greater than that produced by source.

The process of vapor cloud formation was studied. At the beginning of shattering the capacity of source is highest, therefore the intensification of evaporation due to rapid growth of surface of liquid is so large, that vapor wave appears which has sharp front similar to blast wave. After losing contact with liquid jet this wave has convectional drift, keeping its form invariable. Gradual weakening of capacity of source of daughter droplets leads to generating of rarefied wave in distribution of vapor mass, so at distances $x_{\rm f}>100R_0$ from wave front to source distribution tends to "triangle" form, which is also characteristic of blast waves.

Evaluations show that fuel – air mixture in a wake of shattering drop is substantially overreached in average, as vapor density several times exceeds the stoichiometric value, except of regions near spray borders. Vapor oversaturation leads to overcooling of the combustible mixture. Equation of heat balance for process of vapor – air mixing for considered conditions yields the temperature dropping in about 300°K, which means that delay of combustible mixture ignition may jump several orders high.

The elaborated model, which is grounded on obtained earlier distribution function, permits to obtain all the main characteristics of developing two-phase polydispersed spray in a wake of shattering drop and to investigate its internal structure. Development of the model will allow to reflect correctly the kinetics of further processes of mixing, heat transfer and chemical reactions of fuel burning.

Equations of kinetic of drop shattering in a speedy uniform flow

A.G. Girin[1]

[1] Odessa National Maritime University, Odessa, 65029, Ukraine
Keywords: dispersion, size distribution, aerosol dynamics, modelling.
Presenting author email: club21@ukr.net

An investigation of local surface instability with due regard to changing of velocity profile across the boundary layers, as well as to changing of boundary layers thickness and velocity along drop surface (Aslanov, Girin, 1981) revealed for weak-viscosity liquids a new type of hydrodynamic instability – "gradient instability". Mechanism of this type is caused by sufficiently large velocity gradient inside liquid boundary layer. The theory explains the "stripping" mode of breakup as quasi-continuous dispersing from unstable part of drop surface. At some simplifications it permits below to derive differential equations of drop mass efflux and of quantity of stripped droplets.

Using regularities of boundary layer theory and dependencies of wavenumber Δ_m and increment $\mathrm{Im}(z_m)$ of dominant unstable disturbance from "surface" Webber number (Girin, 1985), we obtain condition for gradient instability to exist on surface of shattering drop:

$$\frac{2.475\,\alpha}{(1+\alpha^{\xi})^2}\sqrt{R(\tau)\left(1-W(\tau)\right)^3}\,\sin^2\varphi\;\Psi(\varphi)\;\mathrm{GI} > 0.004\,, \quad (1)$$

where R, W are dimensionless radius and velocity of shattering drop, $\alpha=\rho_g/\rho_l$, $\mu=\mu_g/\mu_l$, $\xi=\log_{\alpha}(\alpha\mu)^{1/3}$ is parameter of mutual viscous engagement of media in boundary layers, $\mathrm{GI}=\mathrm{We_d}/\mathrm{Re_d^{0.5}}$ is criterion of gradient instability, $\Psi(\varphi)=((6\varphi-4\sin 2\varphi+0.5\sin 4\varphi)\sin^{-5}\varphi)^{0.5}$. Equality in (1) defines position of a critical point $\varphi_{cr}(\tau)$ on drop surface, which divides it on stable $\varphi<\varphi_{cr}$ and unstable $\varphi>\varphi_{cr}$ parts (φ is polar angle of ground on drop surface). At $\alpha\,\mathrm{GI}>(\alpha\,\mathrm{GI})_{cr}\approx 4\cdot 10^{-4}$ we have $\varphi_{cr}<\pi/2$, so, the part of drop surface, adjacent to edge, is unstable, providing a possibility of dispersing. Values of φ_{cr} are small enough in speedy flows: $\varphi_{cr}\ll\pi$, so, most part of drop surface generates a mist of droplets.

The quantity of unstable waves on any ground of surface equals to quantity of torus, that are torn from corresponding spherical belt. Assuming that radius of torn droplet is proportional to the length of dominant wave $r=k_r\lambda_m$, and relating volume of torus to volume of droplet, we obtain the equation for quantity Δn of droplets, torn from the ground, and their radius r:

$$\Delta n(\varphi,\tau)=B_2\sqrt{R(\tau)(1-W(\tau))^5}\,\Psi^{-3}(\varphi)\sin^2\varphi\,\Delta\varphi\,\Delta\tau\,, \quad (2)$$

$$r(\varphi,\tau)=B_1\left(R(\tau)/(1-W(\tau))\right)^{0.5}\Psi(\varphi)\,, \quad (3)$$

where $B_1=\dfrac{3.1\pi k_r\alpha^{1-2\xi}}{\Delta_m\,\mathrm{Re_d^{0.5}}}$, $B_2=\dfrac{0.3\Delta_m^2\,\mathrm{Im}(z_m)\,\mathrm{Re_d^{1.5}}}{\pi k_r k_t\alpha^{3.5-7\xi}(1+\alpha^{\xi})}$.

Relating now the stripped mass to the period $t_i=k_t\,\mathrm{Im}^{-1}(z_m)$ of its stripping, we obtain the rate of mass efflux from the ground, and by integrating along windward surface from φ_{cr} to $\pi/2$, obtain the differential equation for rate of mass efflux from drop:

$$\frac{dM}{d\tau}=-AR^2(\tau)(1-W(\tau))\left(1-\frac{2\varphi_{cr}(\tau)}{\pi}+\frac{\sin 2\varphi_{cr}(\tau)}{\pi}\right), \quad (4)$$

where $A=0.46(1+\alpha^{\xi})^{-1}(\mu^2/\alpha)^{1/6}$ is characteristic rate of mass efflux, $M=m/m_0$. It demands simultaneous solution of equation of drop motion in order to determine $W(\tau)$, and equation (1) to determine $\varphi_{cr}(\tau)$. For speedy flows, when $\mathrm{GI}>>\mathrm{GI_{cr}}\simeq 0.3$ and $\varphi_{cr}\ll\pi$, we obtain, assuming spherical shape of drop: $M(\tau)=$ $=\left(1-A\left(\tau-\alpha^{0.5}X_d(\tau)\right)/3\right)^3$, that indicates the direct influence of law of drop motion $X_d(\tau)$ on its ablation law. Using empirical data of Reinecke, Waldman (1975), we can write down law of drop motion in the form $\sqrt{\alpha}X_d(\tau)=\tau-(1-\exp(-H\tau))/H$, $H=2\sqrt{\alpha}$ whence

$$W=1-\exp(-H\tau)\,,\quad M=\left(1-h(1-\exp(-H\tau))\right)^3\,. \quad (5)$$

Parameter $h=A/3H$ is rate ratio of two governing factors of shattering: mass efflux ($\sim A$) and relaxational decreasing of relative velocity of gas and drop ($\sim H$). When $h>1$, the whole drop is dispersed to moment $\tau_b=H^{-1}\ln(h/(h-1))$. When $h<1$, dispersing terminates before the drop is shattered, because latter factor leads to quick reducing of main reason of dispersing – relative velocity $1-W$ (see (4)). Remnant may be shattered by another mechanism, for example, by Rayleigh – Taylor instability (Girin, 1985). Comparison of ablation law (5) with experimental data (Reinecke, Waldman, 1975) indicates their agreement.

System (2)–(4) allows mutual integration together with equation of drop motion without any empirical data. In both cases distribution of droplets by sizes is obtained.

Multi-Particle Sintering Dynamics: From Fractal-like Aggregates to Compact Structures

M.L. Eggersdorfer[1], D. Kadau[2], H.J. Herrmann[2] and S.E. Pratsinis[1]

Presenting author email: meggers@ptl.mavt.ethz.ch

Multi-particle sintering of fractal-like aggregates occurs in systems where initially coagulation dominates and aggregates are formed before sintering becomes significant. This is controlled by the temperature profile and particles residence time. Multi-particle sintering is typically encountered in many natural and industrial applications like aerosol production of nanoparticles (SiO_2) in flame, hot-wall and spray pyrolysis reactors (Tsantilis & Pratsinis, 2004). Detailed aerosol reactor models were developed combining particle and fluid dynamics (Johannessen et al., 2000) including particle sintering rates with the theoretically predicted fractal dimension D_f = 1.8 of diffusion limited cluster-cluster aggregation (DLCA). Sintering rates are commonly based on two-particle models and do not consider a change in aggregate structure. On account of this, limited information of particle morphology is available. The challenge lies in understanding the change in aggregate morphology and properties during sintering.

Now it is reasonably well understood that such aggregates form by gas and surface reaction, coagulation and partial coalescence (or sintering). As chemical reactions in high temperature aerosol processes are completed much faster than particle dynamics, the detailed structure of these aggregates is largely determined by the interplay of particle collision and coalescence. In the absence of such sintering between primary particles, agglomerates (rather than aggregates) are formed by collision and mere cohesion with well-defined structure and fractal-dimension, D_f, depending only on the particle collision mechanism. Once coalescence or sintering starts between constituent primary particles, sinter necks are formed between them converting the agglomerates to aggregates. During sintering, the latter progressively densify until complete compact (e.g. D_f = 3) structures are formed at sufficiently long process times at high temperatures. This has been experimentally demonstrated during silica formation in hot-wall (Seto et al., 1997)

Several models have been proposed for viscous sintering of mainly equally sized pairs of particles (Frenkel, 1945; Koch & Friedlander, 1990). Particles produced in flame reactors have typically a size distribution and complex morphology. In this work a simple model is introduced, which can describe the sintering of differently sized pairs of particles and multi-particle sintering. The sintering of amorphous spherical particles like fumed silica (SiO_2) is investigated with a new geometric sintering model, based on the conservation of volume and the energy balance proposed by Frenkel (1945). The change in surface energy equals the energy dissipated by the viscous flow. The advantage of the new model is its simple applicability and efficiency compared to more elaborate simulations (Kirchhof et al. 2009). Nevertheless the new model is able to reproduce the neck growth and evolution of surface area for equally and differently sized pairs of particles compared to the existing sintering models. Additionally it is applied for viscous sintering of irregular particle morphologies to study the evolution of surface area, radius of gyration and effective fractal dimension (Fig. 1).

SOA formation from campholenic aldehyde ozonolysis

Y. Iinuma, A. Kahnt, A. Mutzel, O. Böge and H. Herrmann

[1]Leibniz-Institut für Troposphärenforschung, Leipzig, 04318, Germany
Keywords: BVOC, LC/MS, Aerosol Chemistry
Presenting author email: yoshi@tropos.de

Atmospheric degradation of biogenic terpenes has a significant impact on the tropospheric ozone and SOA formation. Among various naturally occurring terpenes, the oxidation of monoterpenes such as α-pinene and β-pinene has been intensively investigated due to their relatively high emissions and SOA formation potentials. Although these studies have improved our knowledge about SOA formation from monoterpenes, little is known about SOA formation from other classes of terpenes such as oxygenated monoterpenes. Campholenic aldehyde ($C_{10}H_{16}O$) is an oxygenated monoterpene that can be readily formed in the oxidation of α-pinene (Jaoui and Kamens, 2003) or from α-pinene oxide in the presence of Lewis acid (Iinuma *et al.*, 2009). Jaoui and Kamens (2003) suggested that the formation and oxidation of campholenic aldehyde may explain some of SOA compounds in the α-pinene oxidation systems though the exact products and the SOA formation from campholenic aldehyde oxidation remain unclear. In the present study, a series of aerosol chamber experiments were conducted to provide information on the SOA products and yields for the reaction of campholenic aldehyde with ozone. The resulting SOA products were analysed using ultra-performance liquid chromatography coupled to electrospray ionisation ion mobility spectrometer quadrupole time of flight mass spectrometer (UPLC/ESI-IMS-QTOFMS).

Table 1 summarises the experimental conditions used in this study. The experiments were performed in the presence and absence of an OH scavenger to investigate its influence on SOA yields and products.

Table 1. Experimental conditions

Campholenic aldehyde (ppb)	RH (%)	Ozone (ppb)	CO (ppm)	Seed particle $(NH_4)_2SO_4/H_2SO_4$
100	50	60	-	pH 2
100	50	60	105	pH 2

Figure 1 shows time dependent SOA yield curves as a function of the mass concentration of formed SOA. SOA yields were very high for both sets of experiments, reaching plateau around 0.75 to 0.8. These values are much higher than SOA yields typically observed from the ozonolysis of non-oxygenated monoterpenes such as α-pinene, β-pinene and limonene (e.g. Hoffmann et al., 1997), suggesting that the formation and subsequent oxidation of campholenic aldehyde is important in the SOA formation of α-pinene oxidation.

Figure 2 shows typical chromatograms obtained from the analysis of campholenic aldehyde SOA samples. The SOA samples contained a number of highly oxygenated compounds such as detected at *m/z* 215 ($C_{10}H_{15}O_5^-$) and *m/z* 229 ($C_{10}H_{13}O_6^-$), indicating low volatile nature of campholenic aldehyde oxidation products.

In summary, highly oxygenated nature of campholenic aldehyde SOA compounds is consistent with very high SOA yields and the oxidation of oxygenated monoterpenes may be an important source of atmospheric SOA.

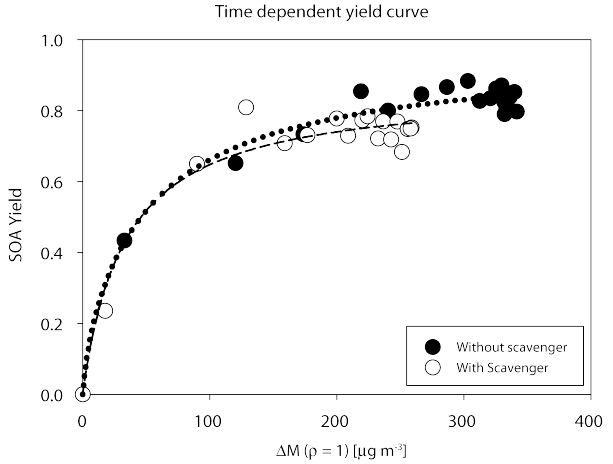

Figure 1. Time dependent SOA yields as a function of the mass concentration of formed SOA.

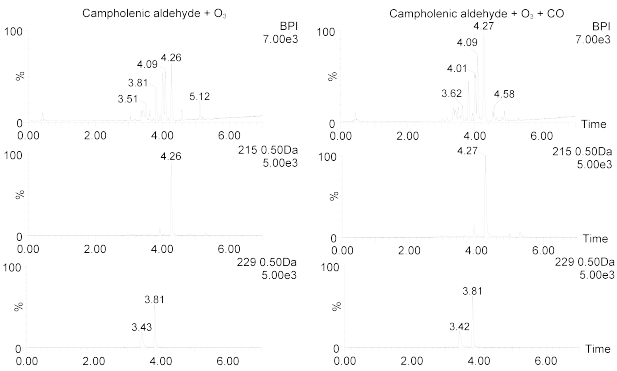

Figure 2. Base Peak Chromatograms (BPC) and extracted ion chromatograms (EIC) obtained from UPLC/(-)ESI-IMS-QTOFMS analysis of campholenic aldehyde SOA samples.

Atmospheric degradation of β-caryophyllene: laboratory and field studies

A. van Eijck[1], Taraborrelli, D.[2], Sander, R.[2], T. Hoffmann[1]

[1]Institute for Inorganic and Analytical Chemistry, Johannes Gutenberg-University, Duesbergweg 10-14, 55128 Mainz, Germany
[2]Atmospheric Chemistry Department, Max Planck Institute for Chemistry, P.O. Box 3060, 55020 Mainz, Germany
Keywords: Aerosol component composition, Degradation, Field measurements, GC-MS, HPLC-MS, Organic tracer, Reaction chamber, SOA
Presenting author email: van.Eijck@uni-mainz.de

Secondary organic aerosol (SOA) has a huge impact on air quality and climate change. It influences the Earth radiative budget through absorbing, scattering and reflecting radiation as well as the formation of clouds because the particulates can act as cloud condensation nuclei (CCN). Furthermore, it plays an important role for human health; through inhaling it can reach the alveoli and deposit. SOA is formed from gaseous precursors which get oxidized by ozone, OH- and NO_3-radicals in the atmosphere. Due to their low vapor pressure these degradation products can nucleate to form new particles or they can condense on existing aerosol particles. Despite the major progress in research during the last few years the actual chemical composition as well as the contribution of various volatile organic compounds (VOCs) to the formation of secondary organic aerosol is still partially unknown.

Recent studies indicate that sesquiterpenes play an important role in the formation of secondary organic aerosol because of the low volatility of their oxygenated products (Lee *et al*., 2006). Their emission is estimated to be about 14,8 Tg per year (Henze *et al*., 2008), however, these emission rates remain highly uncertain due to the lack of quantitative emission rate measurements. In addition, the knowledge about the actual atmospheric degradation mechanism and the main oxidation products of sesquiterpenes is quite limited. β-caryophyllene is found to be one of the most abundant sesquiterpenes in the atmosphere (Helmig *et al*., 2007). Because of its high reactivity and the low volatility of the oxygenated products it produces high aerosol yields in photooxidation chamber experiments (Lee *et al.*, 2006). Furthermore, the oxidation products of β-caryophyllene were found to play an important role in the formation of SOA over boreal forest (Parshintsev *et al*., 2008).

To determine the major oxygenated products of the atmospheric degradation of β-caryophyllene a new method was developed to synthesize the acidic compounds through ozonolysis in the liquid phase followed by further oxidation of specific eliminated products. The synthesized compounds were separated by preparative HPLC and identified by ^{1}H-NMR.

Atmospheric simulation experiments were performed in a 100 L reaction chamber to determine the influence of different ozone and OH-radical concentrations on the distribution of the β-caryophyllene oxidation products. To measure the time dependent formation of initial oxidation products, an APCI-IT-MS was directly connected to the reaction chamber. After 2 hours the APCI-IT-MS was replaced by a filter holder and the generated aerosol was collected for 5 hours. The results show that in the presence of OH-radical producers (e.g. 2,3-dimethyl-2-butene) the concentration of the acidic products which still contain double bonds decreases, whereas in the presence of OH-radical scavengers (e.g. cyclohexane) the concentration of these acids increases. In addition, the atmospheric chemistry box model CAABA/MECCA (Sander *et al*., 2011) was extended to calculate the influence of different ozone and OH-radical concentrations on the distribution of the different oxidation products of β-caryophyllene. The box model was adjusted to reaction chamber conditions. Reaction equations and rate coefficients of the oxidation reactions of β-caryophyllene with ozone and OH-radicals as well as the consecutive reactions were added to the model. The results of the atmospheric chemistry box model were compared with the results of the atmospheric simulation experiments.

Finally several atmospheric air samples taken during the HUMPPA campaign summer 2010 in Finland were analyzed for β-caryophyllene oxygenated products.

This abstract presents the results of an experimental investigation on the deposition of charged and neutral nanoparticles on wire screens by the combined mechanisms of diffusion and image force. Experiments were performed with particles having diameters below 10 nm and using four different flow rates and three kinds of wire screens.

As the experimental results have shown, the single fiber efficiencies for the mechanisms of image force, $\eta_{IM,}$ and diffusion, η_D, are of the same order of magnitude and, furthermore, they are both much smaller than one. Under these conditions, the total capture efficiency can be approximated as the sum of the efficiencies by diffusion and image force deposition, $\eta = \eta_D + \eta_{IM}$. The efficiency for the image force mechanism will be obtained from fitting of experimental results to an expression of the form $\eta_{IM} = AK_{IM}^B$, where

$$K_{IM} = \left(\frac{\varepsilon_f - 1}{\varepsilon_f + 2}\right)\frac{Cp^2e^2}{12\pi^2\mu\varepsilon_0 u d_p d_f^2} \qquad (1)$$

is the image forcé number (ε_f : dielectric constant of the fiber; ε_o: vacuum permittivity; C: slip correction factor; p: number of charges per particle, e: elementary charge; μ: air viscosity; u: air flow velocity; d_p:: particle diameter; d_f: fiber diameter).

For the experiments, an evaporation-condensation NaCl aerosol was charged in a ^{241}Am neutralizer. Positively charged particles of known size were withdrawn from a differential mobility analiyzer (DMA, TSI short column, L=11.11 cm) operated at an aerosol-to-sheath flow rate ratio of 2/20. Since our study has been restricted to particle size below 10 nm, all the particles classified by DMA were singly charged. These positively singly-charged monodisperse particles can follow two alternative routes: one, containing a ^{241}Am neutralizer and an electrostatic precipitator, and the second one, a bypass route to transport the +1 particles into the filter unit.

The filtration unit consists essentially in a grounded cylinder made of brass having a length of 186 mm and inner diameter of 8 mm. A series of five rings, 4 mm in width and made of brass, were placed inside the main cylinder. The wire screens were placed in between any two consecutive rings, so that the screen fibers are in contact with the grounded cylinder.

Three types of screen were used in the experiments; their characteristics are listed in Table 1. The “sandwich” wire screen consisted of a gold wire screen between a pair of aluminum wire screens; it has been experimentally assessed and its characteristics are also showed in Table 1**.** Penetrations were determined for varying values of: (i) aerosol flow rate through the filter; (ii) particle size; and (iii) number of charges on the particles (0, +1).

Material	Aluminium	Stainless steel	Sandwich
Fibre diameter, d_f (μm)	100	66	55
Opening (μm)	110	103	
Thickness (μm)	260	120	524
Density (g cm^{-3})	2.70	7.96	
Surface density (g cm^{-2})	0.02	0.03	
Open area fraction (-)	0.27	0.37	
Solid volume fraction (-)	0.30	0.32	0.32
Screen parameter , S	1.44	1.08	5.77

Table 1. Characteristics of the wire screens employed

From the experimental results, the following correlation has been obtained:

$$\eta_{IM} = 36.06K_{IM}^{0.55} \qquad (2)$$

The total penetration can then be calculated as

$$P = \exp\left[-nS\left(2.7Pe^{-2/3} + 36.06K_{IM}^{0.55}\right)\right] \qquad (3)$$

where n is the number of screens, and is compared in Figure 1 with typical experimental results obtained in the course of this work.

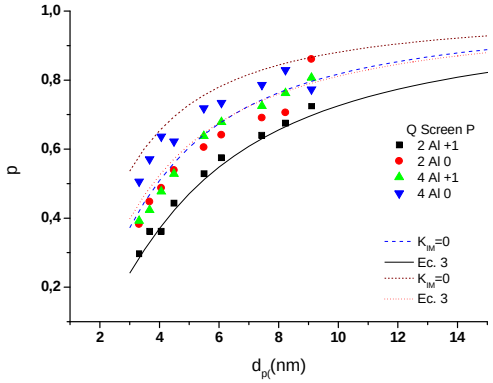

Figure 1. Comparison between experimental penetrations and those calculated with Ec. (3) for 2 and 4 aluminium screens and aerosol flow rates of 2 lmin^{-1} and 4 lmin^{-1}.

This work was supported by grants DPI2008-06199, CSIC 2009TW0017 and NSC 99-2923-E-264-001-MY2.

Depth filtration performance characteristics in accordance with the filter layer structure

Introduction

Until recently the cartridges used for the gas turbine intake air filtration were made mainly of surface filter media which are periodically cleaned using air pulsing. Some of these systems have been modified by installing the depth filter media cartridges instead of conventional surface media cartridge filters. Depth filter media are usually composed by a number layers which build the filter media sheet. During the development process, the aim is to reach the optimum of the main filtration parameters which are: filter pressure drop (DP), dust holding capacity (DHC) and the particle collection efficiency (PCE). Depth filter media layers should be arranged so that the gross particles are collected by the first upstream layer. The fine particles are captured by the final layer made of meltblown fibres. The arrangement of layers in a depth filter media should form a gradient as explained in Purchas and Sutherland (2002). The effect is noticeable in the patterns of the pressure drop as function of dust loading where is possible to spot the clogging of depth filter media as shown in Brown (1993).

The aim of this study is to analyse the effect of various layer structure on the filtration performance of the depth filter media samples.

Experimental method and material

All the sample cartridges are made of the depth filter media with the pleat count 90 and the filtration area of 5.5 m^2. Dimensions of the cartridges are: Outer diameter (OD) 328 mm, inner diameter (ID) 210 mm and the height (H) 660 mm. In the Table 1 there are some of the specifications of the flat sheet depth filter media samples which were tested using standard testing units. The testing procedures are explained in detail in our previous work Park et al (2009).

Table 1. Depth filter media sample specifications.

Specification	***A***	***B***	***C***	***D***
Thickness, mm	1.55	1.95	1.5	1.95
Permeability, cfm	140	130	165	220
NaCl PCE, %	91.5	93.7	81.5	83.1
Initial DP, mmH_2O	1.3	1.4	0.9	0.7
Spec. weight, g/m^2	204	254	190	240

The loading particles are of standard test dust A2 Fine (ISO Standard 12130-1). The inlet concentration was set 500 mg/m^3. The particle concentration is measured at the inlet and outlet sampling ports. The particle size analysis and size distribution is measured using the Portable Aerosol Spectrometer (GRIMM, model 1.108). The cartridge samples were tested using the gas turbine filter test unit with the nominal flow rate of 1000 m^3/min. Pressure drop tests are conducted by varying the flow rate. The dust holding capacity resulted from gravimetric measurements of the cartridges before and after the loading test. Overall and fractional collection efficiency is evaluated by comparing the mass particle concentration at the inlet and the outlet duct.

Results and Discussion

The patterns of the DP are different according to the difference in the upstream layer which is 0.4 mm thicker than the other two samples A and C are clearly visible. The meltblown layer of the sample C and D has a lower DP and lower PCE than the other two A and B samples as shown in the Table 1. Accordingly the particle collection efficiency is lower for sample cartridges C and D (97.69% and 97.38% respectively) than that of the samples A and B (99.67% and 99.65% respectively) at the initial stage of the dust loading. Right below the Dp = 80 mmH_2O all four samples exhibit an overall collection efficiency of over 99.9%.

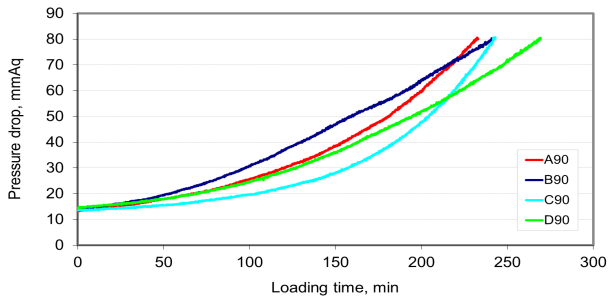

Figure 1. Pressure drop increase vs. loading time for samples A,B,C and D

Nanofibril filters for environmental nanoparticles

F.Belosi[1], G.Santachiara[1], F. Prodi[1] and K. Syverud [2]

[1]ISAC-CNR, Clouds and Precipitations Group, Bologna, 40129 - Italy
[2]PFI Paper and Fibre Research Institute, Trondheim, 7491-Norway
Keywords: Nanofibre, filtration efficiency, nanoparticles.
Presenting author email: f.belosi@isac.cnr.it

The development of nanofibrillar cellulose filters are very promising to enhance aerosol filtration at the most penetrating aerosol particles and could help in the prevention of nanoparticles connected pathologies (nanopathologies). Cellulose nanofibrils are the building blocks of the fibres, just like the fibers are the building blocks of the trees. The raw material for production of cellulose nanofibrils is cellulose fibres, produced from wood by chemical pulping. The fibrils are composed of bundles of cellulose molecules, arranged in crystalline and amorphous areas, giving a tread-like material with fibril diameters of typically 20 nm and with high aspect ratio and high specific surface area. The material retains many of the advantageous properties of cellulose fibers, such as the high strength and the ability to adhere to each other and make strong inter-fibril bonds. In addition, the small dimensions and the large specific surface area open up for applications that may not yet be foreseen (Syverud and Stenius, 2009).

Filtration tests have been carried out on filter samples made of glass fibers mixed with nanofibrills produced from pinus radiata using five passes through a homogenizer at 1000 bar pressure. Solvent was used to blend the various components before the filter was formed in a cylindrical arrangement.

The challenge particles for the filter transmission assessment was NaCl obtained through a Collison nebulization (1 bar pressure) of a water solution. The filter face velocity was set at 5.5 cms^{-1}. Particle number concentration upstream and downstream the filter was measured by means of an SMPS+C system (CPC model 5.4 with DMA model 5.5, Grimm GmbH). Pressure drop across the filter was measured using an electronic manometer (Testo mod. 511 AG, Germany). The filter Figure Of Merit (FOM), given by the ratio between the logarithim of the particle penetration and the pressure drop, was measured. Table 1 shows the integrated filter efficiency (Eninger et al., 2008) between 20 nm and 500 nm and between 100 nm and 500 nm for two different samples (A and B).

Table 1. Integrated filter efficiency for two filters.

Size interval (nm)	Filter A (%)	Filter B (%)
20 -500	72 ± 2	67 ± 4
100-500	62 ± 1	52 ± 6

Figure 1 and 2 show respectively the filter efficiencies and the FOM for both filters.

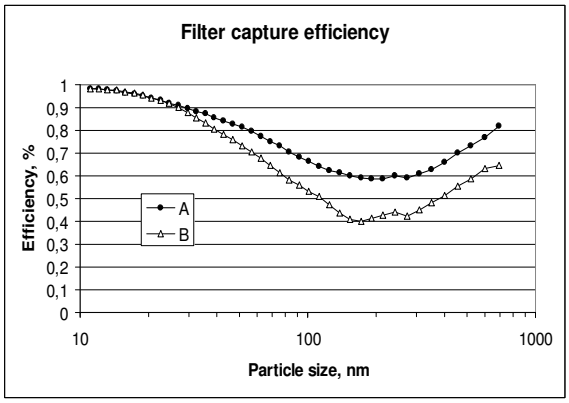

Figure 1. Filter capture efficiency for filters A and B.

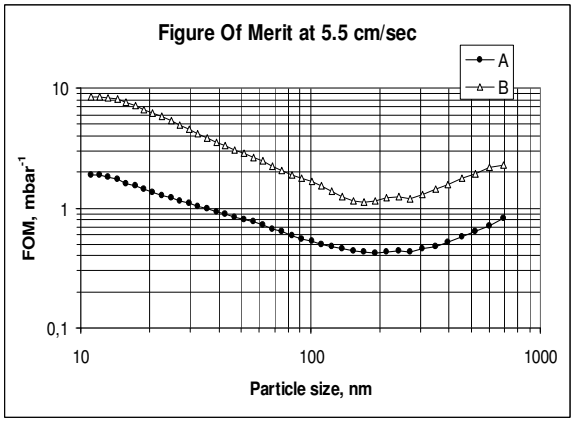

Figure 2. FOM for filters A and B.

Results show that filter A, 5% nanofibrills with a debonding agent containing a quaternary ammonium salt (berocell) has the better capture efficiency respect to the filter B (0% nanofibrills). However nanofibrills increase the pressure drop through the filter as shown in Figure 2. Pressure drop for filter A is 0.8 mbar while for filter B is 0.2 mbar at 5.5 cm s^{-1} face velocity.

Development of a fine particle filter for domestic wood-fired heaters

Dipl.-Ing. Sascha Schiller[1], Prof. Dr.-Ing. Hans-Joachim Schmid[1]

[1]Department of Mechanical and Environmental Process Engineering, University of Paderborn, Paderborn, 33098, Germany
Keywords: fine dust, baghouse filter, wood-fired heaters
Presenting author email: Sascha.Schiller@upb.de

In the recent decades wood combustion has become increasingly popular for private households. In our atmosphere the concentration of fine particles emitted by private wood-fired heaters has exceeded the emission concentration of the total road traffic. To control and reduce these emissions the German government decided in 2010 to renew emission regulations (1st BImSchV). The new limit contained therein was fixed in order to reduce the concentration of fine particles in the atmosphere. To comply with legal requirements a fine particle filter has to be developed, which combines good separation efficiency with convenience in operation for wood-fired heaters (e.g. pellet heaters or woodchip heaters).
For the first time a prototype of a baghouse filter (Fig. 1) has been designed with the aim to reduce the fine dust emissions to values substantially smaller compared to legislative limits. A special engineered test rig allows for analysis and optimization of the prototype and the required filter materials. CFD simulations are used to optimize temperature distribution and fluid flows through the filter.

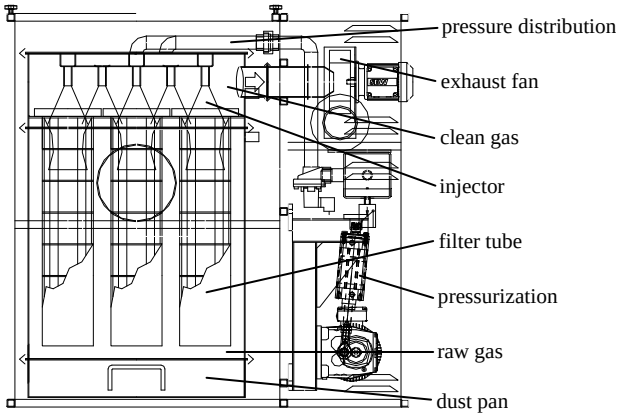

Figure 1. Prototype of the baghouse filter.

The development of a competitive filter system for private households makes it necessary to keep down acquisition costs and operating costs (electricity costs for the de-dusting process, costs for precoat material and costs for maintenance and repair). What are also inalienable are the process reliability (e.g. only annual checkup by the chimney sweeper) and the safety of the whole working process (flying sparks or kickback while de-dusting).

Results

First gravimetric analysis of the baghouse filter coupled with a pellet heater shows a mean fine dust concentration below 1 mg/m³ behind the filter, so the collection efficiency (compared to the fine dust concentration in front of the filter) amounts over 99.5%.
In order to prevent clogging of the filter cloth by sticky small particles, it is necessary to use a precoat. For this purpose different precoat materials were analysed (e.g. lime powder). In a test run that took over 48 hours the pressure drop of the filter has been determinated (Fig. 2) under real conditions.

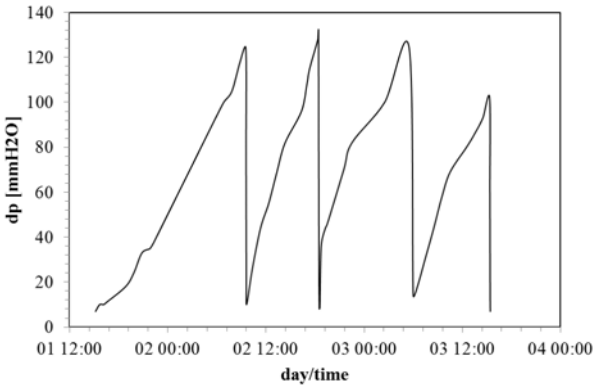

Figure 2. Pressure curve of a 48 h test run.

The pressure curve in Fig. 2 shows a nearly constant increase in pressure and a low level of remanent pressure drop after de-dusting (about 8 mmH2O). It is comparable to a typical pressure curve of a stable operated and online regenerated filter.
Some fluctuations are caused by variations of raw gas emissions due to internal ash removal cycles of the pellet heater.

These results are based upon a co-operation with the PEK GmbH in Konstanz, Germany. The project is supported by the AIF Berlin, Germany (support code: KF 2363802OH9).

Development of the Electro-physical Method of Aero-ion Cleaning of Gaseous Atmosphere

Presenting author email: grishin.andrew@gmail.com

Cleaning of gas-air flows in different branches of industry remains one of the most important directions in the field of technologies of environmental protection from aerosols of the different origin, including radioactive and toxic ones.

High-efficient aerosol filters being used today at NPP are the source of large volumes of radioactive waste subject to burial. They have a limited lifetime, and their fabrication and operation are costly.

The situation arisen with gas cleaning from radioactive and toxic aerosol particles at NPP requires, on the one hand, updating of traditional approaches and, on the other hand, development of fundamentally new methods and aids of air cleaning, namely, the principle of combined cleaning based on the fact that particles take up specific properties in ionized gas and then are to be caught on filters.

The problems of experimental investigation of the effect of intensive aeronization on catching of aerosol particles from the air flow using combined filtering systems is the subject of this paper.

Filtration of oil mists and dust - machining and grinding operations

T. Jankowski
Department of Chemical and Aerosol Hazards, Central Institute for Labour Protection – National Research Institute, 00-701 Warsaw, Poland
Keywords: nonwovens, oil mist, dust, filtration efficiency, machining

Air pollution in industrial workplaces in the form of liquid aerosols (mineral oil mist) and solid (dust) is the dispersed phase side effects of the processes with the use of coolant oil. The actual conditions of industrial processes, particularly with the use of coolant oil, the primary goal is to provide users with the work premises protection against the risks associated with simultaneous exposure to solid and liquid aerosols.

Numerous scientific studies conducted around the world, mainly focused on the mechanisms of dust filtration. We have conducted several studies on the harmful effects of aerosol particles of liquid in man. The available information suggests that the mechanism of aerosol filtration with a liquid phase is distributed differently from dust filtration mechanism. Hence it is important to conduct research leading to the knowledge of relationships and phenomena occurring during the simultaneous emission and deposition of aerosol particles from the liquid and solid dispersed phase.

To protect against the risks associated with exposure to dust and liquid aerosols particles are used in various purification systems, the basic structural element is nonwoven filter. Nonwovens are characterized by extensive spatial structure, so that dust and liquid aerosol particles can deposit inside the structure of the individual fibers.

The CIOP-PIB conducted the study are unknown filtering process for protecting workers from harmful solid and liquid aerosols by using filtration systems. The test method is to study the efficiency of filtration through systems consisting of nonwovens made of synthetic fibers of different morphology, which are used in ventilation, capture and separation systems during machining and grinding using oil coolant. Investigations are performed synthetic dust (ASHRAE 52/76) and aerosol ester bis (2-ethylhexyl) sebacic acid (DEHS) test using an optical particle counter OPC and scanning mobility particle sizer SMPS.

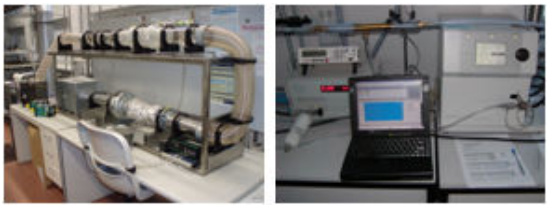

Figure 1. Experimental set-up.

Figure 1 illustrates the experimental set-up involving units generating, sampling and counting of dust and liquid aerosol particles.

Total and fractional filtration efficiency and inlet particle size distributions of solid and liquid aerosol for different values of aerosol velocity are presented in Figure 2, 3 and 4.

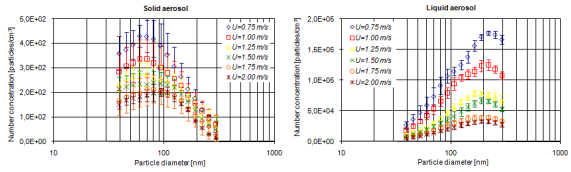

Figure 2. Inlet particle size distributions of solid and liquid aerosol.

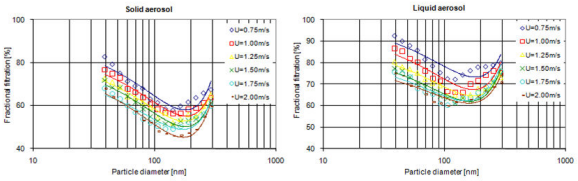

Figure 3. Fractional efficiency of solid and liquid aerosol at different aerosol velocities.

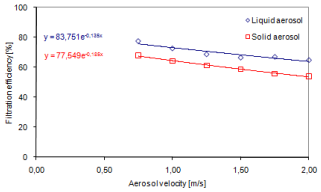

Figure 4. Total filtration efficiency of solid and liquid aerosol.

Based on the studies will be possible to define rules for assessing the efficiency of filtration systems for reducing or eliminating the risks associated with simultaneous exposure to aerosol particles of liquids and solids. This will allow the establishment of guidelines supporting their use to predict the deposition of solid and liquid aerosol particles, while maintaining the most favorable conditions for filtration.

This paper has been prepared on the basis of the results of research task carried out within the National Programme “Improvement of safety and working conditions” partly supported in 2011-2013 within the scope of research and development by the Ministry of Science and Higher Education. CIOP-PIB has been the Programme main coordinator.

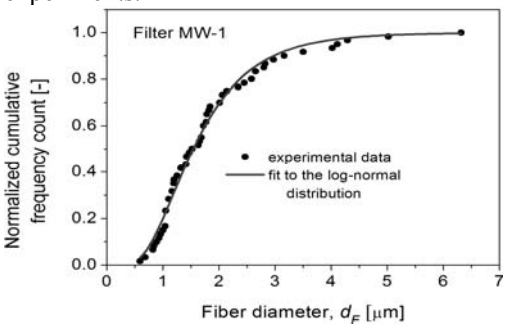
[†]recently deceased

Keywords: aerosol filtration, electret filter, fibrous filter, nanoparticles
Presenting author email: nikolaus.koch@univie.ac.at

In this study the penetration of neutral and singly charged particles in the sub 30 nm size range through polydisperse fibrous filter media has been investigated. The particles used for these measurements are proteins and silica particles. All particles are aerosolized from appropriate suspensions using a commercial electrospray aerosol generator (EAG Mod. 3480, TSI, Inc.).

To analyze and classify generated aerosol a home-made parallel DMA (PDMA) that uses two identical Vienna type nano-DMAs (nDMA1 and nDMA2) in parallel (Allmaier et al., 2008) is used. The first DMA scans for size distribution over the entire size range and the second one is used to classify the peak of the size distribution to generate highly monodisperse aerosol particles for filtration experiments.



Filter symbol	D_{fg} [μm]	ε [%]	L [mm]	Q_s [kg/m2]	σ [-]
○	1.54	97.50	2.05	0.039	1.67
Δ	1.45	97.40	1.94	0.041	1.72

Fig. 1. Fiber size distribution and filter characteristics

To determine the penetration through filter media two identical branches are used. Both consist of a steel Millipore™ filter holder and a 2-way valve to select between the two branches. In the first branch the filter holder is empty and used to determine upstream concentration and correct for particle losses. In the second branch the filter to investigate is placed inside. As a detection instrument a TSI CPC (CPC Mod. 3025, TSI, Inc.) is used in high flow mode (1.5 lpm) which leads to a face velocity of 8.8cm/s.

The melt-blown polypropylene filters consist of polydisperse filter fiber diameters. Their structural characteristics (porosity, ε, thickness, L, basis weight, q_S, geometric mean fiber diameter, d_{Fg}, and the geometric standard deviation, σ) are shown in the table within Fig. 1.

As shown in Fig. 2. measured penetration values indicate that the classical filtration theory, using a fiber mean diameter, significantly underestimates the penetration through polydisperse fibrous filters.

In addition it can be seen that for neutral particles there is no significant difference of penetration through electrical neutral or electret filter media. This indicates that the electrostatic effects such as polarization effects play a minor role in the investigated nm size range.

A theoretical approach to determine penetration of charged particles through mechanical filter media has been developed. The so called Partially Segregated Flow Model (PSFM) for fibrous filters uses a log-normal distribution (shown in Fig.1) of fiber diameters for calculations of penetration through the filter material. This theoretical approach has been experimentally, successfully validated (Podgórski et al., 2010).

Keywords: Axial-flow cyclone, Air handling unit(AHU), subway
Presenting author email: syspace@krri.re.kr

In Korea, particulate matter (PM) is one of the major indoor air pollutants especially in the subway. In order to remove PM in the subway station, several kinds of PM removal system such as medium filter, auto suction filter, auto washing filter and electrostatic precipitator are used in the air handling unit (AHU) of subway stations. However, those systems are prone to operation and maintenance problems since the filter-regeneration unit consisting of electrical or water jet parts might malfunction due to the high load of particulates unless the filter medium is periodically replaced. In this study, we suggested axial-flow cyclone system with minimized maintenance requirement comparing to above mentioned method.

Cyclone is widely used for dust or droplet removing from the main flow. This device has some advantages such as, constant pressure drop, high throughput with moderate efficiency and low maintenance cost (Slack *et al*., 2000). The axial-flow cyclone was developed based on previous numerical study (Kim et al., 2009). The mock-up system was evaluated by particle collection efficiency and pressure drop experimentally. The results obtained from particle number concentration showed that the collection efficiency of 41.2 ~ 85.9% for the particles of 1.5 ~ 5.8 μm with the pressure drop of less than 20 mmH_2O (fig. 2). The collection efficiency estimated by total mass collection also showed 65.7% which was higher than that of current filter system by 2 times.

Experimental Study on Transition from Bismuth Saturated Vapors to Liquid Nuclei

S. di Stasio[1], A.A. Onischuk[2] , A.M. Baklanov[2], V.V. Karasev[2]

[1]Istituto Motori CNR-IM Aerosol and Nanostructures Lab, Via Marconi 8, Napoli, 80125, Italy
[2]Institute of Chemical Kinetics and Combustion RAS, Institutskaya, 3, Novosibirsk, Russia
Keywords: Metal nanoparticles, Nanoparticles generation, Nucleation, Vapour Pressure
Presenting author email: stefano.distasio1600@gmail.com

Bismuth is a very interesting material. In the bulk state it is a metal with a very small overlap (38 meV at 0 K) between valence and conduction band but, if it is synthesized as nanomaterial below certain dimensions, it becomes semiconductor. Synthesis of differently shaped Bi nanostructures has been proposed (Wang et al, 2006). Bismuth is also widely used as material for Hall effect -nanosensors (Koseva et al, 2010) and scanning Hall probe microscopy (Sandhu et al, 2004).

In this study we present the results of our experiments on the process of transition from Bi saturated vapors to liquid nuclei in a classical evaporation-condensation generator. We performed measurements by Authomatic Diffusion Batteries (ADB), TEM, SEM and HR-TEM. Thin filaments (about 1 mm diameter) of quartz have been used to probe Bi deposits occurring during the stages of nucleation at different abscissas/residence times. An example of nucleation process with evaporation temperature 600 °C is discussed in the following. The analysis at SEM (LEO 1430 VP) of filament portion inside the furnace shows a deposition of a uniform layer of saturated vapors formed by islands (Fig. 1a, 1b, X=-26 mm, X=0 outlet section of furnace). At larger abscissas in proximity of furnace outlet section (X>0), some pillars and elongated structures are observed to form, first sporadically and after organized in skein (Fig. 1c, X=+4 mm). Later on, the first nanoparticles which deposit on the underlying island substrate are observed on the sample (Fig. 1d, X=+19 mm). This latter stage correspond to the start of homogeneous nucleation.

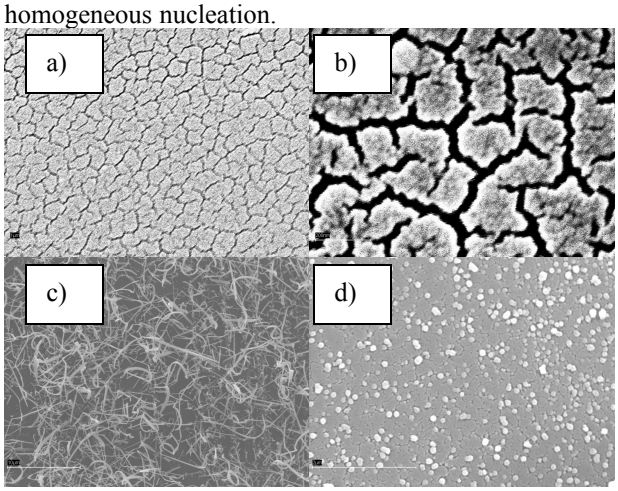

Fig. 1. SEM images of Bi deposit on quartz filament.

The measurements of Bi nanoparticles by ADB are reported in Fig. 2a, 2b. One inconvenient of the experiments is that at exit from furnace (X=0) the temperature is still above the melting point of Bismuth (T_{melt}=208.98 °C) and therefore liquid particles undergo a continuous coagulation and partial re-evaporation. In order to find out the placement of nucleation zone, we sample with metal grids (dia 8 mm, mesh ~ 0.7 mm) inside the reactor. At nucleation start a depletion of Bi vapor gas molecules does occur very quickly and the very small nuclei diffuse rapidly and deposit onto the grids. The fast growth of Bi nanoparticles produces soon a much smaller diffusion effect. Therefore with ADB we measure out of reactor a minimum of particle concentration just when the grid is positioned at the nucleation burst abscissa (Fig. 3).

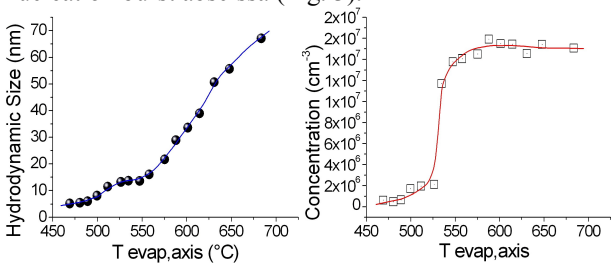

Fig. 2a, 2b. Size (left) and concentration (right) of Bi nanoparticles as measured by ADB.

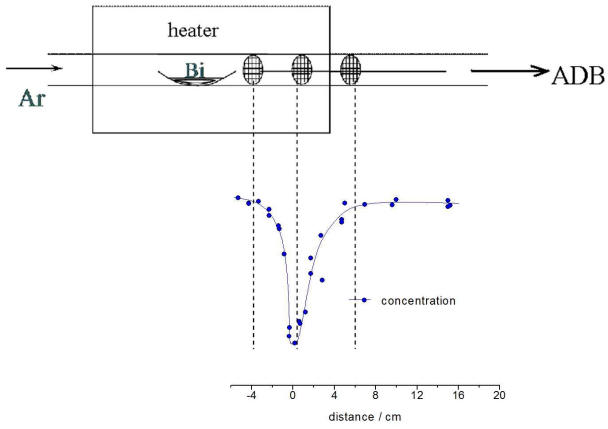

Fig. 3. Experimental determination of nucleation position inside the flow reactor.

Translation-Rotation Correction Factor in the Theory of Homogeneous Nucleation

S. V. Vosel, A. A. Onischuk, P. A. Purtov

Institute of Chemical Kinetics and Combustion, Novosibirsk 630090, Russia
Keywords: translation-rotation correction factor, homogeneous nucleation.
Presenting author email: onischuk@kinetics.nsc.ru

In the theory of nucleation from the vapor phase the contribution to the free energy of the critical nucleus from the translational and rotational degrees of freedom should be accounted. Due to this contribution the so-called free energy correction factor arises in the formula for the nucleation rate. Lothe and Pound [1] have estimated (within the framework of the Gibbs imaginary process of drop formation) the correction factor for water of about 10^{17}. Reiss and co-workers [2] have argued that the Lothe and Pound correction factor was exaggerated too much due to the neglect of the fluctuation of the center of mass of the nucleus and a new correction was proposed to be a factor of 10^3 - 10^6. Recently Kusaka [3] has derived a rigorous formula for the correction factor within the framework of the Gibbs process of drop formation and calculated numerically this factor for the Lennard-Jones system which was 10^9 to 10^{13}. The formula of Kusaka is applicable only for numerical calculations. However, the calculations of this kind are only possible for simple systems and, therefore, an analytical expression for the correction factor applicable to a wide range of real systems is necessary. In this work we give the derivation of the analytical formula for the translation-rotation correction factor. This formula is based on the Reiss approach considering the contribution from the clusters translational degrees of freedom, the Frenkel's kinetic theory of liquids, and Kusaka theory.

Accordung to the Lothe-Pound and Kusaka theory the free energy correction factor K can be determined within the framework of the Gibbs imaginary process of the drop extrusion from the homogeneous macroscopic liquid phase (reference phase) having the same chemical potential as the critical nucleus: $K = \frac{Q_{tr}Q_{rot}}{q_{rep}}$, where Q_{tr} and Q_{rot} are the partition functions for free translations and free rotations of the critical drops, respectively, $q_{rep} = Q_{tr}^{l}Q_{rot}^{l}$, is the partition function for the six degrees of freedom of the drop embedded into the reference phase (Q_{tr}^{l} and Q_{rot}^{l} are the translational and rotational partition functions, respectively) which are to be deactivated in the Gibbs extrusion process. We have shown that Q_{tr}^{l} and Q_{rot}^{l} can be determined as the partition functions for translational fluctuations of the center of mass of embedded drop and rotational vibrations of the embedded drop, respectively. The resulted analytical formula for the correction factor is:

$$K = \frac{\pi^{7/2}}{Sn_1^{sat}\sigma^3} \times \left(\frac{32R_S^5\rho k_B T}{15h^2}\right)^{3/2} \exp\left(\frac{3h\nu_{\max}}{2k_B T}\right)\left\{1 - \exp\left(-\frac{h\nu_{\max}}{k_B T}\right)\right\}^3 \quad (1)$$

where k_B is the Boltzmann constant, T is the absolute temperature, S is the supersaturation ratio, n_1^{sat} is the saturated vapor number density, R_S is the radius of the surface of tension of the critical nucleus, ρ is the density of the reference bulk liquid, h is Planck's constant, $\nu_{\max}$ is the Debye frequency for the reference phase $\sigma \approx \frac{0.2}{(4\pi/3)^{1/6}}\left(\frac{m}{\rho R_S}\right)^{1/2}$ is the standard deviation in any of the three Cartesian coordinates for the fluctuations of the center of mass of the embedded drop [2], m is the molecule mass. Fig. 1 compares the correction factor estimated analytically vis Eq. (1) and that calculated numerically by Kusaka [3]. One can see that these two factors are in a good agreement with each other. The temperature dependences are in an excellent agreement.

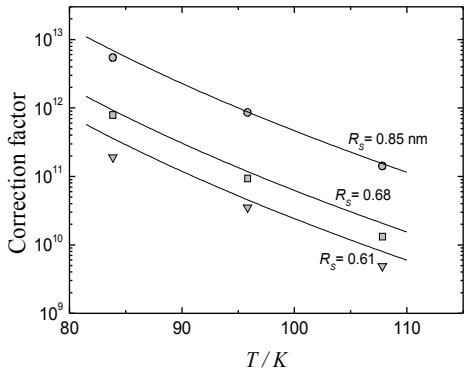

Fig. 1. Translation-rotation correction factor as estimated for Ar analytically via Eq. (1) (lines) and numerically [3] (symbols).

Sulphate aerosols play an important role in atmospheric chemistry. They have indispensable impact on climate, radiation balance, and human health. In the atmosphere sulphate aerosols are formed due to secondary particle production (gas to particle conversion) from sulphuric acid and water, and probable participation of other trace specie like ammonia or amines. The sulphuric acid diffusion coefficient data has wide application in atmospheric and aerosol mass transfer models.

The diffusion coefficient was estimated from the first-order rate coefficients for the wall loss of H_2SO_4. The wall loses were measured as a function of relative humidity (RH) in the range from 2 to 70 % in a laminar flow tube. The chemical ionization mass spectrometer (CIMS) was used to detect the H_2SO_4 concentration (Petäjä et al. 2009).

The H_2SO_4 loss measurements were carried out at three temperatures 5, 15 and 25°C and atmospheric pressure in a vertically positioned thermostated cylindrical tube with I.D.= 6 cm and length of 200 cm. The sulphuric acid vapour was generated by passing purified dry particle free air through a temperature controlled saturator filled with 95-97 % pure H_2SO_4 and subsequently mixed with humidified air in a mixer. The vapour gas mixture was then introduced to a laminar flow tube made of stainless steel where the H_2SO_4 concentration was measured with CIMS at six different positions along the reactor. The wall losses were determined from the slopes of the fits to experimental data in the plot H_2SO_4 concentration as a function of position in the tube. To ensure the independence of wall losses on H_2SO_4 concentration, the measurements were carried out at different H_2SO_4 concentrations (~10^5-10^8 molecules cm^{-3}) and different total flow rates (8-11 l/min).

Figure 1 shows the measured diffusion coefficients of H_2SO_4 in air as a function of RH and at three temperatures 5, 15 and 25 °C. The measured points are accompanied with the fit to H_2SO_4-N_2 data published by Hanson and Eisele, 2000. The diffusion coefficient values decreased as the RH was increased. The diffusion coefficient dependency on RH flattens in the range of RH = 20-50 %, where the difference is less than 5%. These results show lower wall losses and slower diffusion to the wall due to strong hydration of H_2SO_4 molecules (Jaecker-Voirol and Mirabel, 1988).

The temperature dependency was found to be the power of 6 to measured diffusion coefficient when data for the whole range of RH are considered. This discrepancy is possibly due to higher order losses of H_2SO_4 to bigger clusters at lower temperatures.

The calculated value of diffusion coefficient of H_2SO_4 in dry air using the Fuller method (Reid et al, 1987) is 0.11 cm^2s^{-1}, which is in close agreement with measured data at 25 °C.

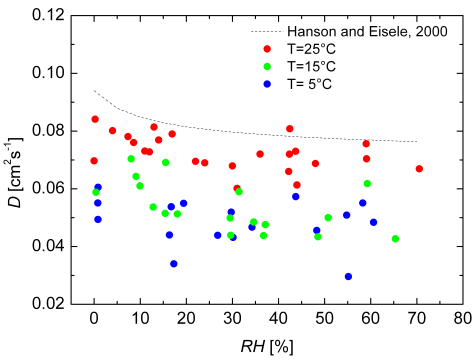

Figure 1. Diffusion coefficient data of H_2SO_4 in air as a function of relative humidity (RH) at three temperatures 5, 15 and 25 °C compared to fit to H_2SO_4-N_2 data of Hanson and Eisele, 2000.

Size effect in homogeneous nucleation in nanoscale particles

V.V. Levdansky[1], J. Smolik[2], V. Zdimal[2] and P. Moravec[2]

[1]Heat and Mass Transfer Institute NASB, 15 P. Brovka Str., Minsk 220072, Belarus
[2]Institute of Chemical Process Fundamentals AS CR, v.v.i., Rozvojova 135, 165 02 Prague, Czech Republic
Keywords: nanoparticles, nucleation, size effect.
Presenting author email: vlev5@yahoo.com

The nucleation process in nanoscale particles is of interest both for the new technology and atmospheric physics. It is known that many physicochemical processes in the systems with nanoscale objects are characterized by some specific features. In particular, the physicochemical processes in the aerosol systems with nanoscale particles and in aerosol particles themselves can depend on the particle size. Some questions related to the influence of the size effect on the critical size of aerosol particles and on homogeneous gas-phase nucleation were considered in (Levdansky *et al*., 2010). Here we study the influence of the size effect on homogeneous nucleation inside nanoparticles.

Let us consider the situation when supersaturation of one component in the two-component nanoparticle takes place that can lead to nucleation of this component. The rate of nucleation J_n by analogy with (Ring, 2001) can be written as

$$J_n = k_Z k_r n N_c = k_Z k_r n^2 \exp\left(-\frac{\Delta G_c}{kT}\right), \qquad (1)$$

where k is the Boltzmann constant, T is the temperature, k_r is the effective rate constant for the attachment of monomers (molecules or atoms) to the critical cluster allowing for both diffusion of monomers to the critical cluster and their incorporation into the cluster, k_Z is the Zeldovich factor, n is the number concentration of monomers, N_c is the number concentration of the critical clusters, ΔG_c is the free energy of critical cluster formation.

The value of k_r in the case under consideration can be estimated as

$$k_r = \frac{2\pi d_c v a^2 \exp\left(-\frac{Q_p}{kT}\right)}{1+\frac{2a}{d_c}\exp\left(\frac{Q_c - Q_p}{kT}\right)}, \qquad (2)$$

where d_c is the diameter of the critical cluster, Q_c is the activation energy for the incorporation of monomers into the critical cluster, Q_p is the activation energy for the diffusion of monomers in the particle, v and a are respectively the values characterizing the vibration frequency and the jump length of monomers.

Taking into account (Vanithakumari and Nanda, 2008; Rekhviashvili and Kishtikova, 2006), the values of Q_c and Q_p can be written as

$$Q_c = Q_{c\infty}\exp\left(-\frac{4}{1+d_{c0}}\right), \qquad (3)$$

$$Q_p = Q_{p\infty}\exp\left(-\frac{4}{1+d_{p0}}\right), \qquad (4)$$

where $d_{c0} = d_c/\delta_c$, $d_{p0} = d_p/\delta_p$, d_p is the particle diameter, δ_c is the Tolman length for the critical cluster, δ_p is the Tolman length for the particle, $Q_{c\infty}$ and $Q_{p\infty}$ are the values of Q_c and Q_p without considering the size effect.

From the foregoing it follows that the size dependence of the activation energies Q_c and Q_p can affect the nucleation rate in nanoscale particles. Let us consider for simplicity the case when the second term in the denominator of Eq. 2 is much more than unity. Figure 1 shows for this case the dependence of $k_{r0} = k_r/k_{r\infty}$, where $k_{r\infty}$ is the value of k_r for $Q_c = Q_{c\infty}$, on d_{c0}. It is seen that k_{r0} increases with a decrease in d_{c0}.

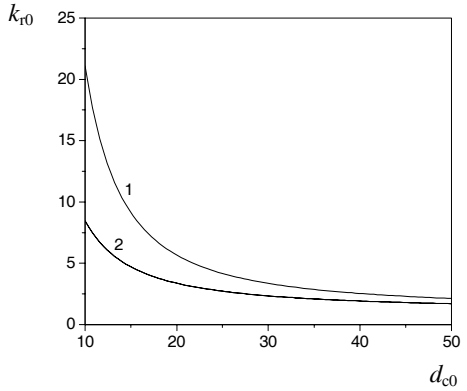

Figure 1. Dependence of k_{r0} on d_{c0}; 1: $Q_{c\infty}/kT = 10$, 2: $Q_{c\infty}/kT = 7$.

Contact angle, seed particle radius and the onset of heterogeneous nucleation

V. Loukonen[1] and H. Vehkamäki[1]
[1]Department of Physics, University of Helsinki, P.O. Box 64, FI-00014 Helsinki, Finland
Keywords: Heterogeneous nucleation, Classical nucleation theory
ville.loukonen@helsinki.fi

Perhaps the most common framework in both experimental and theoretical nucleation studies is the classical nucleation theory (CNT). Based on thermodynamics, it can be used as soon as a few macrosopic parameters are known, and as a computationally efficient method, it is the standard choice for large systems.

Regardless of its popularity, some details in CNT are still unclear. In the present work we study how the size of the condensation seed particle and the contact angle formed between the seed particle and the nucleating droplet affect the onset of heterogeneous nucleation.

Definitions

In one-component homogeneous nucleation, the onset is typically taken to be a nucleation rate of $J_{\mathrm{hom}} = 1/\mathrm{cm}^3\,\mathrm{s}$ or the corresponding value of saturation ratio S. In the heterogeneous case the existence of condensation seed particles introduces some complications, as now also the concentration and size distribution of the seed particles matters. To circumvent these problems, often an auxiliary quantity of nucleation probability is used. It is defined as

$$P \equiv 1 - \exp\left(-4\pi R^2 J_{\mathrm{het}}\tau\right),$$

where R is the radius of the condensation seed particle, J_{het} is the heterogeneous nucleation rate and τ is nucleation time interval. The onset of heterogeneous nucleation is often chosen to be the saturation ratio corresponding to the nucleation probability of $P = 1/2$.

Even though the both definitions of onset are somewhat arbitrary, they are frequently used in the literature. However, as it turns out, the definitions are inconsistent with each other.

Discrepancies

In Figure 1, heterogeneous onset curves for several contact angles are shown as a function of the condensation seed particle radius for water and non-soluble, electrically neutral seed particles at the temperature of 285 K.

It can be seen that with large enough contact angle, the saturation ratio required for the onset of heterogeneous nucleation is always larger than what is required for the onset of homogeneous nucleation. Although heterogeneous nucleation is energetically more favourable than homogeneous, it does not necessarily begin at the lower values of saturation ratio. The radius of the condensation seed particle and the contact angle have a strong effect on the onset of heterogeneous nucleation. From Figure 1 it is also evident that the homogeneous nucleation is not restored from the heterogeneous nucleation as the contact angle approaches the value of 180°, i.e. when the contact disappears.

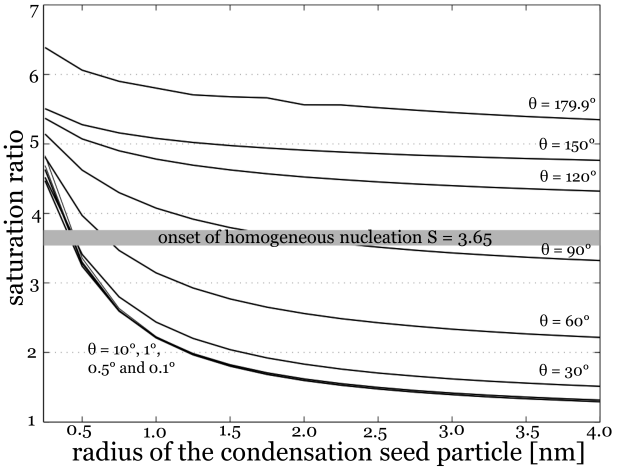

Figure 1: Heterogeneous onset curves for water at $T = 285$ K. Each point on the curves corresponds to a nucleation probability of $P = 1/2$ with an indicated contact angle in the (R,S)-plane. The onset of homogeneous nucleation, $S = 3.65$, is marked with a grey bar.

Furthermore, while interpreting experimental data, the seed particles are often assumed to be fully "wettable", that is, the contact angle is assumed to be zero. However, within CNT this assumption is geometrically possible only when the seed particle is smaller than the critical cluster. Close attention should be paid to the assumptions regarding the contact angle and radius of the condensation particle.

These issues bear some significance, as it is often important to know the conditions where nucleation begins. Thus consistent definitions for the onsets are called for, or perhaps altogether a novel way of comparing homogeneous and heterogeneous nucleation.

Heterogeneous nucleation of water vapor on nanoparticles and ions, and its temperature dependence

A. Kupc[1], A. Vrtala[1], P.E. Wagner[1], P. M. Winkler[2] and CLOUD Collaboration

[1]Faculty of Physics, University of Vienna, Vienna, A-1090, Austria
[2]Advanced Study Program, National Center for Atmospheric Research, Boulder, Colorado, 80305, USA

Keywords: heterogeneous nucleation, water vapour, aerosols
Presenting author email: agnieszka.kupc@univie.ac.at

Although particle formation processes have been the subject of investigation by many scientists, further research and detailed description of nucleation mechanisms are essential to better understand atmospheric aerosols, their interactions and influence on global climate.

In the present study we focus on the activation of molecular ions, as well as charged and neutral aerosol particles with diameters down to about 1nm in supersaturated water vapor. Seed particles of different composition (e.g. Ag, NaCl, WO_x) are investigated. The aim is to clarify the dependence of the heterogeneous nucleation of water vapor on seed particle size and charging state, with particular focus on nucleation behavior at different nucleation temperatures. Heterogeneous nucleation probabilities are determined using an expansion chamber, the Size Analyzing Nuclei Counter (SANC; Wagner et al., 2003), for measuring droplet number concentration. Besides the SANC, the experimental system consists mainly of aerosol-, and vapor generation units. Particles inducing heterogeneous nucleation in the SANC system at the vapor supersaturations considered, lead to the formation and growth of liquid droplets, which then are optically detected by means of the Constant-Angle Mie Scattering (CAMS, Wagner, 1985) method. Figure 1 presents an example of the growing droplets. Experimental findings on the activation of seed particles by heterogeneous nucleation of water vapour are compared with theoretical calculations (Kelvin and Fletcher theory, Fletcher, 1958), and other results from similar experiments for n-propanol, n-nonane vapour where inorganic insoluble seed aerosol (WO_x, Ag, $(NH_4)_2SO_4$), and soluble NaCl particles were used (Winkler et al. (2008a, b), Schobesberger S. et al., 2010). Currently, a mobile and more versatile version of the SANC is being developed and planned to be integrated in the experiments set up of the CLOUD (Cosmics Leaving Outdoor Droplets) project at CERN. At CLOUD various aspects of the interaction of cosmic rays with aerosols and clouds are investigated, bearing on the possibility of a 'solar indirect' influence on climate. The goal is to contribute to the understanding of mechanisms leading to new particle formation by studying ion induced and binary and ternary nucleation.

Experimental investigations on the activation of nanoparticles and ions by heterogeneous nucleation of water vapour at defined vapour saturation ratios and various temperatures will be presented.

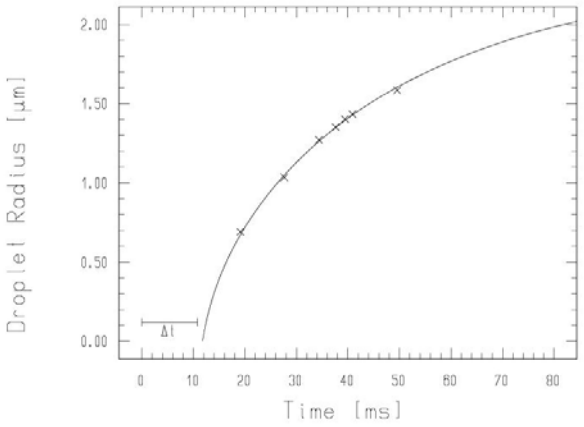

Figure 1. Radii of the growing water droplets measured versus time after expansion for one sample experiment. Oxidised Ag particles at 8nm size are used here. Markers present experimental values, while line presents theoretical calculations.

We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. Keywords: homogeneous nucleation, sulphuric acid, amine, flow tube.
kimmo.neitola@fmi.fi

Sulphuric acid is known to play a key role in atmospheric nucleation (gas to particle conversion). The attention has shifted lately towards a third nucleating species (ammonia, amines) in addition to sulphuric acid and water. This is due to recent quantum chemical calculations that suggest a third species to thermodynamically stabilize sulphuric acid-water molecular clusters.

Flow tube technique was used to study homogeneous nucleation of sulphuric acid and water with and without the presence of trimethylamine (TMA) in 2 different relative humidities (30% and 50%). Sulphuric acid was produced using a thermally controlled cylinder which is half filled with pure (97%) sulphuric acid. Dry, particle free compressed air is flown through the saturator with constant flow rate (0.1 lpm) to saturate the flow with sulphuric acid vapour. The concentration is controlled by the temperature of the saturator. The sulphuric acid concentration was measured with CIMS (Petäjä et al., 2009) or APi-TOF (Junninen et al., 2010).

The concentration of nucleated particles was monitored with Particle Size Magnifier (PSM, Vanhanen et al., 2009). The size of the particles was measured with DMPS system (HAUKE DMA, UCPC, TSI model 3025A) in the range of 3 to 200 nm.

Five different concentration levels of TMA was used (170, 480, 800, 1700 and 3600 ppt) with sulphuric acid concentration range between 10^5 and $5 \cdot 10^7$ mol./cm^3. The flow tube was operated is several hours in same conditions to ensure stable state. TMA concentration was changed only after a full cycle of saturator temperatures (0-45^{o}C) was done for both RH's separately.

Figure 1 shows DMPS size distribution (upper panel) and total count (lower panel) data without TMA for one saturator temperature cycle at RH 30%. Figure 2 shows data from DMPS (upper panel) and PSM (lower panel) for exactly similar conditions as in figure 1, except the addition of TMA. The sizes of the particles are similar in both figures before adding TMA. After the addition of TMA the size decreases out of the DMPS size range and concentration of particles decreases to 1/3 of the original concentration. Increasing the RH to 50% increases the concentration temporarily but after stable state is achieved concentration is decreased to about 800 cm^{-3}.

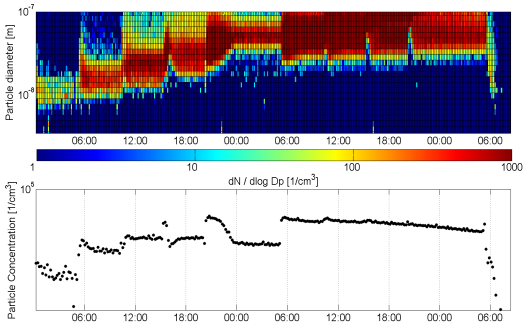

Figure 1. DMPS data for size distribution (upper panel) and total concentration (lower panel) for one saturator temperature cycle without TMA.

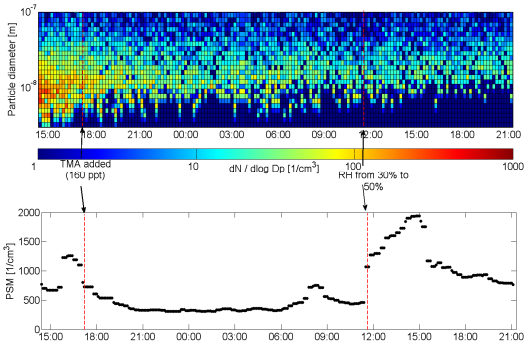

Figure 2. DMPS and PSM data over one cycle of saturator temperatures at RH 30% with lines when TMA (160ppt) was added and RH changed to 50%.

Results imply that TMA forms thermodynamically stable clusters with sulphuric acid with sizes below the detection limit of the PSM (~1.5 nm) suppressing the condensation of sulphuric acid to the surface of the particles and preventing the growth to detectable sizes. This was predicted by Anttila et al., (2005).

Coagulation scavenging of precritical clusters and the first nucleation theorem

Presenting author email: jussi.malila@uef.fi

During recent years, the first nucleation theorem has become a standard tool to estimate the number of constituents forming the critical cluster in nucleation kinetics, and consequently to compare to measurements, simulations and nucleation theories at molecular level. Although it is nowadays generally considered as a model-free result, it is typically used in form

$$\left(\frac{\partial \ln J}{\partial \ln S}\right)_T = g^* + 1 \qquad (1)$$

that can be obtained only if homogeneous nucleation of ideal vapour is taking place isothermally in particle-free, inert carrier gas, conditions that might be feasible in the laboratory, but rarely met in real world phenomena, such as combustion aerosol or atmospheric new particle formation. In Eq. (1), J is the nucleation rate, S the saturation ratio and g^* the (excess) number of particles in critical cluster. With the aforementioned assumptions, Eq. (1) can be derived directly from the kinetic Becker–Döring theory (Ford, 1997; McGraw and Wu, 2003).

The extended kinetic treatment for the effect of foreign aerosol in the nucleating vapour can be found from the literature (Friedlander, 1978; McGraw and Marlow, 1983). For continuously reinforced vapour and i-mer scavenging rate Q_i depending linearly on i-mer concentration, this extended Szilard model yields

$$\left(\frac{\partial \ln J}{\partial \ln S}\right)_{T,\{q_i\}} = \tilde{g} + 1 = \frac{J + \sum_{i=2}^{g^*} Q_i}{J} g^* + 1. \qquad (2)$$

Here J is now the rate of formation of new stable clusters of size $g^* + 1$ and q_i the i-mer scavenging coefficient.

Results of model calculations are given in Fig. 1, where the ratio of apparent and true excess numbers of molecules in the critical cluster, $\tilde{g}/g^*$, is given as a function of S. Model values presenting homogeneous nucleation of water vapour in nitrogen at 260 K and 1 atm with different background aerosol distributions are given. For simplicity, classical nucleation theory expressions and Fuchs' form for the coagulation kernel are used, but the results do not depend qualitatively on these choices. As obvious from Eq. (2), $\tilde{g} > g^*$ with $\tilde{g}/g^* \to 1$ at high S or low total scavenging rate $\sum_i Q_i$, and $\tilde{g}/g^* \to \infty$ as $J \to 0$: these results imply that application of Eq. (1) to nucleation measurements in presence of background aerosol overestimate g^*.

As coagulation scavenging is not restricted into precritical clusters, suitable transformation (*e.g.* Anttila *et al.*, 2010) should be applied on measured data before using Eq. (2). Furthermore, to calculate $\sum_i Q_i$ one has to resort on theoretical schemes like the one described above. On the other hand, if nucleation rate measurements on same system with and without background aerosol are available, these can be used to confirm different molecular schemes for coagulation scavenging of nanosized clusters. However, for most practical applications, extensions of Eq. (2) into multicomponent systems are required.

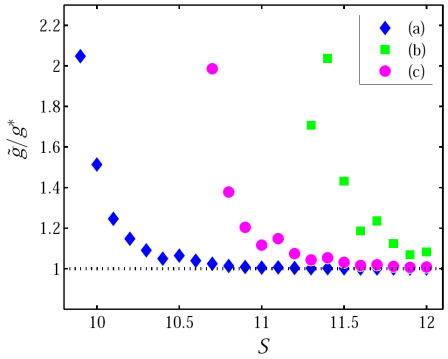

Figure 1: Ratio of apparent and true critical sizes for water at 260 K with three monodisperse background aerosol distributions: (a) diameter d_p = 100 nm and number concentration N = 10000 m^{-3}, (b) d_p = 10 μm and N = 10000 m^{-3}, and (c) d_p = 10 μm and N = 1000 m^{-3}.

Light-induced drift of aerosol particle

V.G. Chernyak

Department of Physics, Ural State University, Yekaterinburg, 620083
Keywords: particle, gas, molecule, optical radiation.
Presenting author email: vladimir.chernyak@usu.ru

In the present work we study the photophoresis of a particle that does not absorb light or absorbs it homogeneously. The particle is suspended in a binary gas mixture in which the molecules of the absorbing gas are excited selectively as to velocity by resonant optical radiation. We examine the dependence of the force and velocity of photophoresis on the detuning of the radiation frequency from the center of the absorption line and on the concentration and mass ratios of the molecules of absorbing and buffer gases.

Let the radiation is a traveling light wave whose frequency is close to that of an electronic or vibrational-rotational transition of molecules of a gas. In this case the light is absorbed by one of components of gaseous mixture. Because of the Doppler effect, the radiation is absorbed selectively as to molecular velocity. This gives rise to light-induced fluxes of matter and energy (Gel'mukhanov and Shalagin, 1979). The difference in the scattering of excited and unexcited molecules by the particle surface and the difference in the transport cross sections of their interaction lead to the emergence of a resonant photophoresis force on the particle. If the aerosol particle is suspended in a mixture of a light-absorbing gas and a buffer gas, the total momentum transferred to the aerosol particle also proves to be unbalanced because of the difference in the masses of the molecules.

We consider a spherical aerosol particle suspended in a binary gas mixture. We irradiate the system with a monochromatic traveling light wave. Let the radiation be absorbed by the molecules of one of the components in an electronic or vibrational-rotational transition from the ground state *n* to the first excited state *m*. Due to the Doppler effect, only the molecules whose velocity projection on the radiation direction lines within a certain velocity range can be excited.

The velocity distribution functions for the excited, unexcited and buffer gas molecules satisfy the linearized Boltzmann equations, considering the stimulated transitions and radiative decay of the excited level for absorbing molecules.

We analyze the Knudsen regime, in which the mean free path of molecules is much greater than the particle radius. We can then neglect the perturbation of the distribution functions for the molecules incident upon the particle due to collisions with emitted molecules.

In respect of the distribution functions for molecules emitted from the particle surface we assumed that the fraction ε_i of molecules of species *i* is reflected by the particle surface diffusely with a Maxwellian distribution, while the fraction $(1 - \varepsilon_i)$ is specularly reflected. The accommodation coefficients for excited ε_m and unexcited ε_n molecules are different. The unknown number densities of the molecules reflected from the surface of the aerosol particle are founded from the nonpercolation conditions.

The light-induced particle velocity is

$$U_f = \mu_\varepsilon \Delta\varepsilon + \mu_d \frac{\Delta d}{d_n},$$

$$\Delta\varepsilon = \varepsilon_n - \varepsilon_m, \quad \Delta d = d_n - d_m.$$

Here d_m and d_n are respectively effective diameters of excited and unexcited molecules of absorbing gas. The kinetic coefficient μ_S characterizes the surface mechanism of photophoresis, which is related to the difference in the accommodation coefficients for excited and unexcited molecules of the absorbing gas. The kinetic coefficient μ_d characterizes the contribution related to the differing effective diameters of excited and unexcited molecules.

The kinetic coefficients are proportional to the radiative intensity, and depend on the ratio of the rate of radiative decay of the excited level to the intermolecular collision rate, the detuning of the radiation frequency from the center of the absorption line of absorbing molecules, the component concentrations, and the molecular mass ratio.

The directions of the surface component of the force and velocity of photophoresis are determined by the signs of the difference of the accommodation coefficients $\Delta\varepsilon$ of the unexcited and excited molecules and the frequency detuning Ω. If $\Delta\varepsilon > 0$, the direction of the surface component coincides with the direction of light propagation when $\Omega < 0$, and is opposite the direction of light propagation when $\Omega > 0$.

The directions of the bulk component of the force and velocity of photophoresis are determined by the signs of the difference Δd of the effective diameters of the unexcited and excited molecules and the frequency detuning Ω. If $\Delta d > 0$, the direction of the bulk component coincides with the direction of light propagation when $\Omega < 0$ and is opposite that direction when $\Omega > 0$.

The numerical estimates give for an aluminum particle of radius 1μm suspended in a mixture of sodium vapor and argon, that the velocity of the particle is $U_f \approx 20\ \mathrm{m/s}$.

Particle activation via heterogeneous nucleation in *n*-butanol condensation particle counters

A. Mamakos and Y. Drossinos
European Commission, Joint Research Centre, 21027 Ispra (VA), Italy
Keywords: activation, heterogeneous nucleation, condensation particle counter (CPC), contact angle.
A. Mamakos: thanasis.mamakos@jrc.ec.europa.eu

Interest in particle activation in Condensation Particle Counters (CPCs) has recently resurged due to the introduction of Euro 5/6 legislation for particulate emissions from light-duty diesel vehicles. The legislation introduces a non-volatile particle number emission limit: the particle concentration is to be measured by a full-flow CPC.

We performed experimental and theoretical studies on the effect of particle chemical composition on particle activation in *n*-butanol CPCs. The detection efficiencies at various electical mobility diameters of graphite particles and Emery oil droplets (PAO, polyalpha olefin, is a component of synthetic oil) were measured by a TSI 3790 CPC. The CPC was operated at different saturator wall temperatures to study the effect of the bulk-to-wall temperature difference; the saturator inlet bulk temperature was kept constant at 38.3°C.

Particle activation at particle diameter d was studied theoretically via the activation probability $P_d(t)$, defined as the ratio of the concentration of activated particles to their saturator-inlet concentration. In terms of the activation rate constant per seed particle k the activation probability is

$$P_d(t) = 1 - \exp(-kt) \quad .$$

Particles are considered to be activated once their activation probability is greater or equal to 0.5. The activation rate constant was chosen to be the heterogeneous nucleation rate as is appropriate for activation of particles insoluble in *n*-butanol. The heterogeneous nucleation rate was calculated as described in Giechaskiel *et al.* (2011). In addition, we considered the effect of curvature on the surface tension of the heterogenous nucleating droplet via Tolman's length δ_T, namely $\gamma(R) = \gamma_\infty/(1+2\delta_T/R)$ with R the nucleating droplet radius and γ_∞ the planar surface tension. The effect of line tension was also investigated.

An essential ingredient of heterogeneous nucleation theories is the contact angle between the critical cluster and the curved particle surface. The contact angle determines a multiplicative geometric factor that lowers the free energy of formation of the critical cluster on the surface, and hence it enhances the nucleation rate (particle activation occurs at lower saturation ratios). The contact angle depends on the condensing species and on the chemical nature of the particle to be activated.

Calculated *n*-butanol contact angles as a function of CPC detection efficiencies for the two different species are shown in Figs. 1 (graphite particles) and 2 (PAO droplets). The curvature dependence of the surface tension was neglected, $\delta_T = 0$. Different colors correspond to different saturator-wall temperatures.

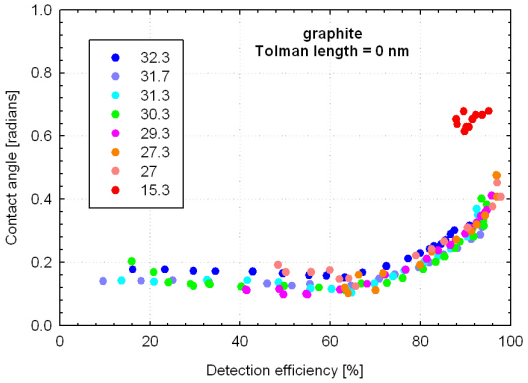

Figure 1: Calculated *n*-butanol contact angles on graphite particles.

Inspection of the Figures shows that for counting efficiencies less than approximately 70% a well defined contact angle, independent of the saturator-wall temperature, reproduces the experimental detection efficiencies. Furthermore, the contact angle depends on the chemical nature of the activated species: it is approximately zero for PAO and approximately 10° for graphite.

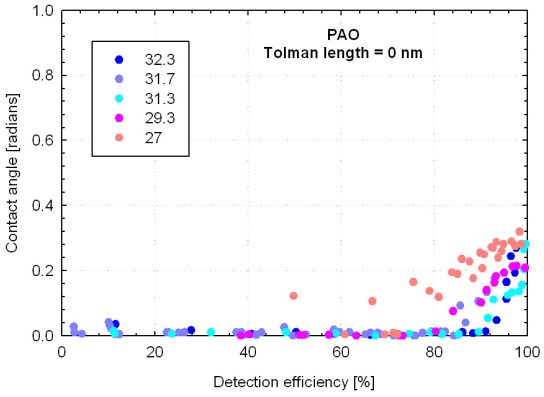

Figure 2: Caption as in Fig. 1, PAO droplets.

Thus, for a range of bulk-to-saturator wall temperature differences, a constant contact angles that depends on the chemical composition of the activated particle maybe identified to reproduce experimental CPC detection efficiencies (up to approximately 70%) .

Particle activation via heterogeneous nucleation in *n*-butanol condensation particle counters

A. Mamakos and Y. Drossinos
European Commission, Joint Research Centre, 21027 Ispra (VA), Italy
Keywords: activation, heterogeneous nucleation, condensation particle counter (CPC), contact angle.
A. Mamakos: thanasis.mamakos@jrc.ec.europa.eu

Interest in particle activation in Condensation Particle Counters (CPCs) has recently resurged due to the introduction of Euro 5/6 legislation for particulate emissions from light-duty diesel vehicles. The legislation introduces a non-volatile particle number emission limit: the particle concentration is to be measured by a full-flow CPC.

We performed experimental and theoretical studies on the effect of particle chemical composition on particle activation in *n*-butanol CPCs. The detection efficiencies at various electical mobility diameters of graphite particles and Emery oil droplets (PAO, polyalpha olefin, is a component of synthetic oil) were measured by a TSI 3790 CPC. The CPC was operated at different saturator wall temperatures to study the effect of the bulk-to-wall temperature difference; the saturator inlet bulk temperature was kept constant at 38.3°C.

Particle activation at particle diameter d was studied theoretically via the activation probability $P_d(t)$, defined as the ratio of the concentration of activated particles to their saturator-inlet concentration. In terms of the activation rate constant per seed particle k the activation probability is

$$P_d(t) = 1 - \exp(-kt) \quad .$$

Particles are considered to be activated once their activation probability is greater or equal to 0.5. The activation rate constant was chosen to be the heterogeneous nucleation rate as is appropriate for activation of particles insoluble in *n*-butanol. The heterogeneous nucleation rate was calculated as described in Giechaskiel *et al.* (2011). In addition, we considered the effect of curvature on the surface tension of the heterogenous nucleating droplet via Tolman's length δ_T, namely $\gamma(R) = \gamma_\infty/(1+2\delta_T/R)$ with R the nucleating droplet radius and γ_∞ the planar surface tension. The effect of line tension was also investigated.

An essential ingredient of heterogeneous nucleation theories is the contact angle between the critical cluster and the curved particle surface. The contact angle determines a multiplicative geometric factor that lowers the free energy of formation of the critical cluster on the surface, and hence it enhances the nucleation rate (particle activation occurs at lower saturation ratios). The contact angle depends on the condensing species and on the chemical nature of the particle to be activated.

Calculated *n*-butanol contact angles as a function of CPC detection efficiencies for the two different species are shown in Figs. 1 (graphite particles) and 2 (PAO droplets). The curvature dependence of the surface tension was neglected, $\delta_T = 0$. Different colors correspond to different saturator-wall temperatures.

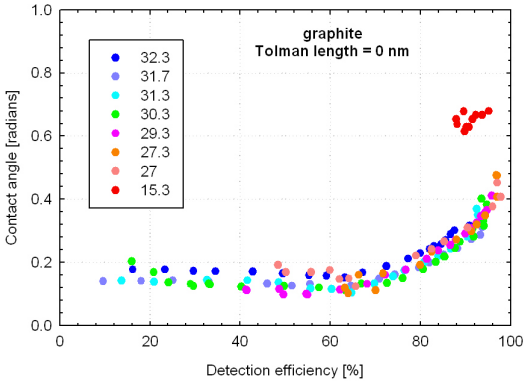

Figure 1: Calculated *n*-butanol contact angles on graphite particles.

Inspection of the Figures shows that for counting efficiencies less than approximately 70% a well defined contact angle, independent of the saturator-wall temperature, reproduces the experimental detection efficiencies. Furthermore, the contact angle depends on the chemical nature of the activated species: it is approximately zero for PAO and approximately 10° for graphite.

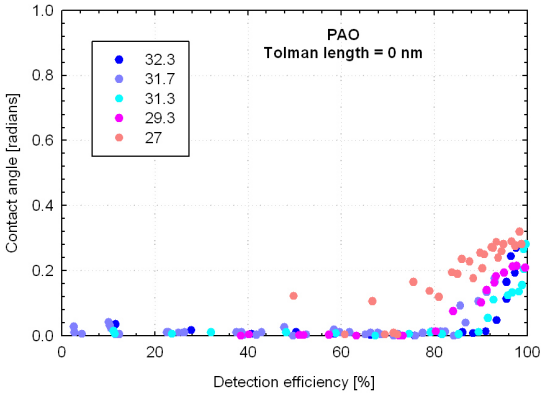

Figure 2: Caption as in Fig. 1, PAO droplets.

Thus, for a range of bulk-to-saturator wall temperature differences, a constant contact angles that depends on the chemical composition of the activated particle maybe identified to reproduce experimental CPC detection efficiencies (up to approximately 70%) .

Is Quantum Nuclear Dynamics significant in the study of the structure of sulphuric acid hydrates?

Sulphuric acid has been identified as an important molecule influencing the formation of aerosols in the atmosphere and as such is seen as a promising player in the field of geoengineering. The nucleation of clusters including this species has been studied using a variety of methods including Classical Nucleation Theory (CNT), Dynamical Nucleation Theory (DNT), Density Functional Theory (DFT), Quantum Monte Carlo (QMC), Quantum Chemistry (QC) and classical Force Field methods (FF). The various methods employed can address short and long timescale phenomena relevant to the nucleation event, and promise varying levels of accuracy, appropriate to the questions posed. Classical theory can be set aside since the small critical sizes relevant to atmospheric conditions makes the capillary approximation inadequate. Furthermore, typical atmospheric vapour supersaturations means that event time scales are difficult to achieve in brute-force simulation. Single molecular modelling schemes seem most appropriate, but those that neglect electronic detail make proton transfer events in hydrated clusters difficult to describe, and this is believed to affect the cohesion of such clusters. The most appropriate modelling method at present seems to be based on DFT.

B3LYP and PW91 are popular implementations of DFT but it has been some years since they were introduced in the DFT community and the field is highly active. Most noticeable is the progress made for non-covalent interactions such as hydrogen bonds (Burns *et al* (2011)). Interesting extensions that attempt to capture the quantum mechanics of nuclear motion have also been proposed. It is very plausible that such effects might influence the clustering, particularly where hydrogen bonding and proton transfer are important. Recent developments such as Centroid Molecular Dynamics (CMD) can accurately describe the quantum nuclear dynamics associated with proton transfer (Pavese *et al* (2000)). We have therefore undertaken a set of studies to determine whether the outcomes of this approach will differ significantly from treatments that neglect such quantum effects. An illustration of the difference in approach is provided in the images in Figure 1. Proton positional uncertainty is represented by replacing each atom by a collection of coupled beads, four in this case, and evolving the structure by classical molecular dynamics.

Centroid molecular dynamics promises to provide greater accuracy than standard DFT in determining structural properties of molecular clusters containing sulphuric acid. Our aim is to use such methods to parametrise a reactive force field (FF) that will be efficient for simulations at size and length scales where DFT is inappropriate. Such parametrisation will involve a force-fitting procedure applied to DFT-driven molecular dynamics of a few sulphuric acid and water molecules, and we aim to achieve a suitable compromise between accuracy and efficiency.

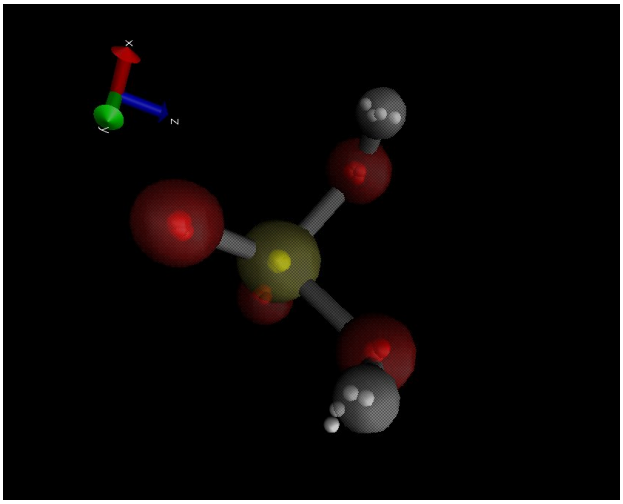

Figure 1: The image shows overlaid configurations of a single sulphuric acid molecule equilibrated at 300K using DFT with the PBE exchange-correlation functional. The centres of the large transparent spheres represent atomic positions determined with the neglect of quantum uncertainty. The four smaller beads are a representation of the quantum uncertainty in atomic position in the CMD model. The difference in sphere size is for clarity of image only. Quantum uncertainty is obviously larger for the hydrogens than for the heavier sulphur and oxygens.

Ideally the FF should be able to represent every event possible so as to fully capture the dynamics of the system. However it is quite apparent that accounting for bond breaking events is a particularly difficult task for classical FF. To this end ReaxFF (van Duin *et al* (2001)) has been developed, and is a candidate for our future work.

Presenting author email: jaehee@kist.re.kr

In the search for methods by which an ambient environment can be continuously monitored for potentially harmful biological aerosols, particle fluorescence methods have received considerable attention over the past decade. The aerosol fluorescence sensor (AFS; Biral, Bristol, UK) is a promising monitoring device for the continuous real-time detection of airborne microorganisms, which is based upon the principle of Ultra-violet light induced fluorescence (UV-LIF) targeting the intrinsic fluorescence response from common amino acids found in living matter. The sensor uses an UV optical excitation source of 280 (+20/-40) nm to illuminate an airstream flowing drawn continuously through the sensor detection volume. Fluorescence from all particles instantaneously present within a sensing volume is measured using two photomultiplier detectors optically filtered to detect radiation in the bands 305-385 nm (UV) and 415-550 nm (Vis), enabling a generic discrimination between different aerosol populations.

In this study, we demonstrate the fluorescence characteristics of bacterial bioaerosols using aerosol fluorescence sensor to distinguish between microorganism particles and environmental particles. Using AFS and aerodynamic particle sizer (APS), the aerosol and fluorescence characteristics of various particles, including bacterial (e.g., *Escherichia coli* and *Bacillus subtilis*) and non-bacterial aerosols (e.g., polystyrene latex) can be determined.

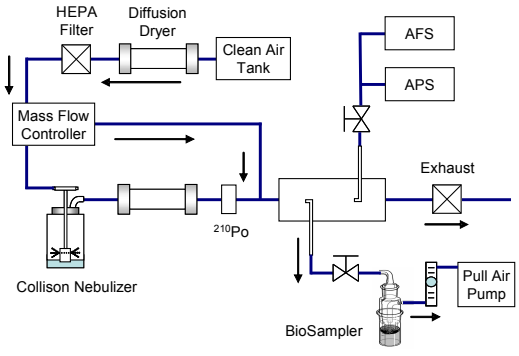

Figure 1. Experimental setup.

The experimental setup, illustrated schematically in Figure 1, included three major components: (i) a system for generating aerosols, (ii) AFS and APS aerosol measurement system, and (iii) a sampling system for culturability analyses of the bacterial bioaerosols.

In results, the UV-fluorescence intensity of both bacterial bioaerosols was higher than that of PSL at same total particle surface area concentration. In particular, the ratio of UV- to Vis-fluorescence intensity of bacterial bioaerosols showed sufficiently higher values than that of PSL particles, which is able to differentiate between bacterial bioaerosols and PSL particles. This minimum aerosol concentration to which AFS can respond were approximately 100 $\mu m^2/cm^3$ (c.f. 30 particles/cm^3) at UV fluorescence range and 330 $\mu m^2/cm^3$ (c.f. 200 particles/cm^3) at Vis fluorescence range in all test particles. In a view point of AFS operation, the variation in characteristics of fluorescence intensity was evaluated under various the sensor gain settings (Low and High) for the two fluorescence channels and the frequency (1-10 Hz) of the flash excitation light operation. The amplitude of the measured fluorescence offset and dynamic measurement range are dependent on the gain of the system. The coefficient of variance of reading values is increased with decreasing frequency of the flash light.

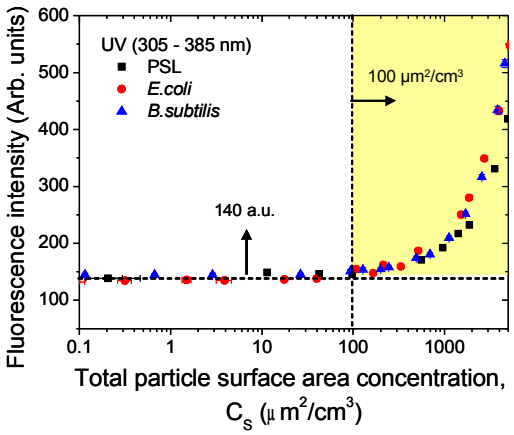

Figure 2. UV-fluorescence intensity (Arb. units) vs. particle concentration.

Mobile measurements of submicron particulate matter in Central Europe during wintertime inversions

R. Wolf, C. Mohr, M. Crippa, J. Slowik, A.S.H. Prévôt and U. Baltensperger
Laboratory of Atmospheric Chemistry, Paul Scherrer Institute, CH-5232, Villigen PSI, Switzerland
Keywords: Organic aerosols, Wood burning, Aerosol mass spectrometry, Source apportionment.
Presenting author email: robert.wolf@psi.ch

Wintertime inversions lead to an increase in concentrations of particulate matter. This phenomenon is of special interest because of the adverse effects of particles on health and visibility. During such episodes, aerosol mass concentrations are strongly influenced by local sources and topography. Recent studies (Weimer *et al.*, 2009, Alfarra *et al.*, 2007) indicate that both traffic and wood burning significantly contribute to particulate mass which accumulates in narrow Alpine valleys.

A mobile laboratory was deployed to determine the spatial distribution and the chemical composition of atmospheric aerosols during atmospheric inversion. The mobile unit contains a series of instruments including an Aerodyne quadrupole aerosol mass spectrometer (Q-AMS), a multi-angle absorption spectrometer (MAAP) and a fast mobility particle sizer (FMPS). The sampling was performed in both rural and urban areas along the Rhine Valley in Switzerland, Austria and Liechtenstein.

The main components of particulate matter and its sources were identified using Positive Matrix Factorization (PMF) (Paatero *et al.*, 1994). The organic fraction can be classified as primary (POA) or secondary organic aerosol (SOA). The primary organic aerosol classification includes contributions from wood burning and traffic. Local emissions of individual species were estimated by subtraction of SO_4-normalized background concentrations (Mohr *et al.*, 2011).

The results for the total mass concentration and the mean chemical composition are shown in Figure 1. It indicates a substantial difference in mass concentrations between the Austrian section (A) of the route ($\approx 53\ \mu g/m^3$) and the urban area of Chur in the southern Rhine Valley ($\approx 15\ \mu g/m^3$). According to Figure 2, the carbonaceous aerosol dominates the local contribution.

It can be concluded that the high amount of heavy-duty traffic and emissions from diesel powered cars in the Austrian part of the Rhine Valley lead to an increased concentration of organic aerosol and elevated emissions of black carbon (BC). In contrast, the local contribution of organic mass from wood burning, which can be attributed to domestic heating in this region, is lower (9 – 13 %).

We will present for this campaign and in addition the Mesolcina Valley with a higher ratio of wood burning the local and regional contributions to PM_1 and compare these with measurements in downtown Zurich.

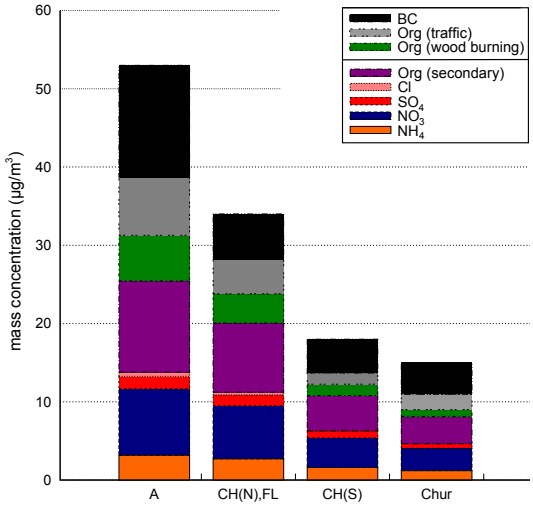

Figure 1: Mean chemical composition of PM_1 in the Rhine Valley at four different sections of the route (A Austria, CH(N) northern Switzerland, CH(S) southern Switzerland, FL Principality of Liechtenstein).

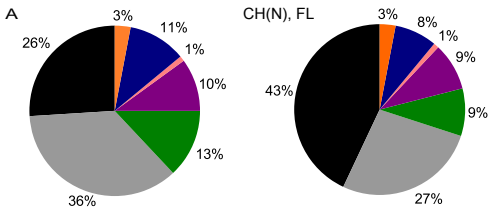

Figure 2: Relative local contributions after subtraction of the SO_4-normalized background concentrations of different species to PM_1 in the northern part of the Swiss Rhine Valley.

Atmospheric aerosol formation and aging are widely researched areas, however there are still many uncertainties related to both. Secondary organic aerosols (SOA) form through the oxidation of gaseous organic emissions; as SOA age their oxidation ratio increases. In a remote forest setting, urban aerosol are long-range transported and are thus more oxidized, often correlating with particulate sulphate. Markers of combustion come out in long-range transported air mass plumes and correlate with substances like black carbon, levoglucosan and CO_2.

This work focuses on characterizing organic sources in the clean northern boreal forest area using Positive Matrix Factorization (PMF) applied to Aerosol Mass Spectrometer measurements of particulate-phase organics (Paatero, 1994; Ulbrich 2009). PMF analysis was done for unit mass resolution (UMR) and time-of-flight mass spectrometer V-mode-based high resolution (HR) organics spectra. The factors found in the UMR and HR data sets were defined by correlation with trace gases, particle data, volatility, organic growth and meteorology. An example of PMF solution for 5 factors, their proportions of organics mass loading and organics average mass loadings are listed in Table 1.

The measurements were performed at the Station for Measuring Forest Ecosystem-Aerosol Relations (SMEARII) station, at Hyytiälä (61° 51'N, 24° 17'E, 180m ASL) between 10.5-13.6.2009. The study was performed during IS4FIRES (Integrated Monitoring and Modelling System for Wildland Fires) project and included measurements of aerosol chemical composition by Aerodyne High Resolution Time-Of-Flight Aerosol Mass Spectrometry and aerosol properties such as volatility by Volatility Tandem Differential Mobility Analyzer and organic growth by Ultra-Fine Organic Tandem Differential Analyzer (Vaattovaara, 2005). Other particle information (e.g., particle size distributions) and key trace gases such were measured during the study.

In Hyytiälä, organics consist mainly of LV- and SV-OOA (Low Volatile- and Semi Volatile-Oxidized Organics Aerosol respectively), whereas the mix of BBOA (Biomass Burning Organic Aerosol) and HOA (Hydrocarbon-like organic aerosol) cover roughly quarter of the organics mass loading. It was found that less oxidized, locally produced, organic aerosol constituents correspond to more volatile aerosol, whereas long-range transported SOA correspond to lower volatilities. The semi-volatile less oxidized organics aerosol, whose fraction increases during the daytime from new particle formation, correlate with the more organophilic aerosol fraction. In addition SV-OOA correlate with nitrate and normally increase during the night. The low volatile more oxidized organic aerosol was long-range transported, exhibited low volatility, correlated with sulphate, nitrate and ammonium and increased during the daytime. Hydrocarbon-like organic aerosol seem to be related to local traffic at the measurement site with correlation to black carbon, CO, NO_x and nitrate. Biomass burning came out in air mass plumes originated from urban areas and correlated with black carbon, CO, CO_2, NO_x and nitrate. HOA and BBOA showed distinct time trends, mainly low mass loadings and higher during the separate air mass plumes. BBOA correlated with masses of levoglucosan in HR PMF. The HOA factor was separated in HR PMF with unique time trend and the mass spectrum was characterized by hydrocarbon peaks.

Table 1. 5-factor-solution, factors proportions of organics and organics average mass loadings.

factor	*UMR (%)*	*HR(V)(%)*
LV-OOA	33.9 and 21.3	31.8 and 9.2
SV-OOA	21.1	29.3
BBOA	16.3 and 7.3	23.7
HOA		6.0
organics average mass (ug/m^3)	2.1	1.8

Comparison of PM10 source apportionment using PMF and PCA: an analysis of accuracy and robustness of results

D. Cesari [1], F. Amato [2], M. Pandolfi [2], D. Contini [1], A. Alastuey [2], X. Querol [2]

[1] Institute of Atmospheric Science and Climate (ISAC-CNR), 73100, Lecce, Italy
[2] Institute of Environmental Assessment and Water Research (IDÆA-CSIC), Barcelona 08034, Spain
Keywords: Source Apportionment, PCA, PMF, Apportionment Accuracy, PM10
Presenting author email: d.cesari@isac.cnr.it

A general overview of atmospheric aerosol Source Apportionment (SA) results shows a lack of uniformity in the analysis proposed in terms of "working variables", such as the number of samples present in the data-set and the number of chemical species included. Moreover, the comparison of different methods of SA, applied to the same data-set, shows that the number or the types of sources can be different (Amato et al., 2009). There are also difficulties in the characterization of sources with similar chemical profiles, if a sufficient number of specific markers are not analysed. This variability of SA output appears to be related to the specific characteristics of the measurement site and to the meteorological characteristics of the site analysis.

This work aims to analyze the performance of two SA models: EPA-PMF 3.0 and PCA through an inter-comparison of results obtained at three measurements sites: one Italian urban background site (Lecce, Contini et al., 2010), one Spanish urban background site (Barcelona, Amato et al., 2009) and one Spanish industrial site (Algeciras, Pandolfi et al., 2011). A second target of the analysis was to study the accuracy and robustness of the results proposed by the models and how these parameters are influenced by the typology of the measurement site and the chemical species available in the data-sets. For this purpose the data-sets were used with full inorganic chemical characterisation and Total Carbon of PM10 (complete data-sets), and with reduced data-sets, obtained from the complete ones removing specific chemical species (Total Carbon, Ti, P, Rb, Sr, As, Cd, Sn, Sb, Li, Se and La).

The results show that both techniques provide similar solutions in the identification of sources: "Crustal", "Traffic", "Industrial", "Marine", "Secondary Inorganic Aerosol (SIA)" and "Fossil Fuel Combustion" (this last one limited to the Spanish sites). However, the number of factors identified by PMF is different from the number of components of PCA. The differences are mainly related to SIA and marine contributions. In the Lecce site PCA finds an industrial contribution separated from SIA but PMF finds a single contribution that include both sources. In both Spanish sites the source "SIA" is disentangled by the PMF into two factors (secondary sulphate and secondary nitrate), while the PCA analysis identifies one unique SIA component. This trend, already observed in literature (Callen et al., 2009, Viana et al., 2008) is related, presumably, to the different operating method of the mathematical model and/or to the different role of measurements uncertainties in the two receptor models. Further, the source profiles, provide by PCA and PMF, are sometimes different. In the data-set of Algeciras, the PCA component "Marine" is loaded with nitrate, suggesting that this source identified is an "aged" marine aerosol, including a portion of sodium nitrate that the PMF model associate to secondary nitrate, identifying a "fresh" marine that does not include a significant contribution of nitrate.

The comparison of complete and reduced data-sets shows that the PCA solutions are more sensitive to changes in the chemical species available with respect to PMF that appears more stable. However, for both models, the elimination of the TC causes a difficulty in identifying the "Traffic" source, mainly characterised by TC, that could be confused with an industrial emission. In Figure 1 the "Traffic" PCA component derived from Barcelona site is reported for the complete and reduced data-set as an example. However, for PMF, the elimination of the TC does not influence relevantly the calculated contribution of the traffic source to PM10. Instead significant differences are observed with PCA.

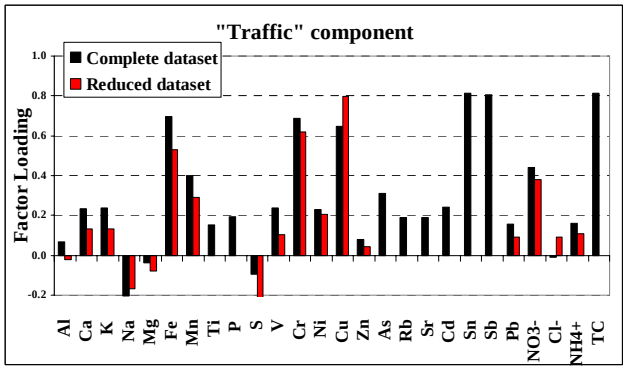

Figure 1. PCA loads for "Traffic" component in Barcelona. Complete dataset (black bar) and reduced dataset (red bar).

Presenting author email: milan.vana@chmi.cz

Aircraft measurement of PM vertical profile was implemented within the EMEP-EUSAAR-EUCAARI intensive monitoring campaign. The campaign was organized in the period from February 25th to March 26th 2009 (winter part). General aim of the campaign was to improve our knowledge about the behaviour of atmospheric aerosols in the CLRTAP region.

The measurement was carried out on March 21st 2009 by one-motor aircraft Cessna 172 Skyhawk. Fractions PM_{10}, $PM_{2,5}$ and PM_1 were measured according to the US EPA guidelines; automatic analyzer GRIMM Model 1.109 was used. The main task was to measure PM vertical profile above the Czech EMEP stations Košetice (49° 35' N; 15° 05' E; 534 m a.s.l.) and Svratouch (49° 73' N; 16° 03' E; 737 m a.s.l.). Moreover, the experiment was extended of measurement above the Ostrava region in the north-eastern part of the Czech Republic, which belongs to the most polluted areas by PM in Europe.

Meteorological situation in Central Europe was controlled by an anticyclone above north-western Europe and low pressure area above Baltic region in the period 18th-22nd March. Mean daily temperatures varied round freezing point, the majority of the territory was covered by snow. Meteorological conditions were favourable for long-range transport. According to the transport trajectories (NILU, 2011), air masses from far north areas came to the Central Europe on 21st March.

The aircraft ascended to the cloudiness level above Kosetice Observatory (1460 m a.s.l.). The vertical profile was characterized by homogeneous ratios between fine and course fractions; $PM_{2,5}$ / PM_{10} ratio was 85% in average and the PM_1 a $PM_{2,5}$ concentrations were almost identical during the ascend. Concentration levels ranged from 17 to 20 $\mu g.m^{-3}$ by PM_{10} and from 14,5 to 17 $\mu g.m^{-3}$ by $PM_{2,5}$ and PM_1.

The climb above Svratouch station reached the height 2038 m a.s.l. Concentrations were slightly higher than above Kosetice (5 $\mu g.m^{-3}$ averagely). The vertical profile and ratios between individual fractions below cloud layer showed similar patterns as above Kosetice. Concentrations of all fractions decreased very rapidly above cloudiness (1 600 m a.s.l.) to one third of those measured below the cloud layer. Ratios between fractions were not constant as below the level. Mean $PM_{2,5}/PM_{10}$ ratio above the cloud layer was 75% and dropped from 80% closely above the layer to 70% on the top of the flight. $PM_1/PM_{2,5}$ ratio declined from almost 100% to 94% on the top point.

After descend from Svratouch, the flight continued to the north-east. Concentrations above the north-eastern part of the Czech-Moravian Highland ranged between 17 - 20 $\mu g.m^{-3}$ by coarse fraction and 13 - 17 $\mu g.m^{-3}$ by fine fractions respectively. Approaching Ostrava, concentrations increased significantly to the limit value of 24-hour PM_{10} concentrations (50 $\mu g.m^{-3}$).

PM concentrations above main emission sources and locations with chronic target value exceedances of Ostrava-Karviná region were measured at the flight level 200-300 m above terrain. PM_{10} concentrations oscillated round the limit value of 24-hour PM_{10} level. The values were slightly higher than the target limit above industrial parts, while above urban background localities ranged between 40 – 50 $\mu g.m^{-3}$.

Aircraft measurement of PM vertical profile was the first attempt in this field in the Czech Republic. It is not possible to generalize the results of presented experiment. They represent the PM vertical profiles in the wintertime by specified meteorological conditions.

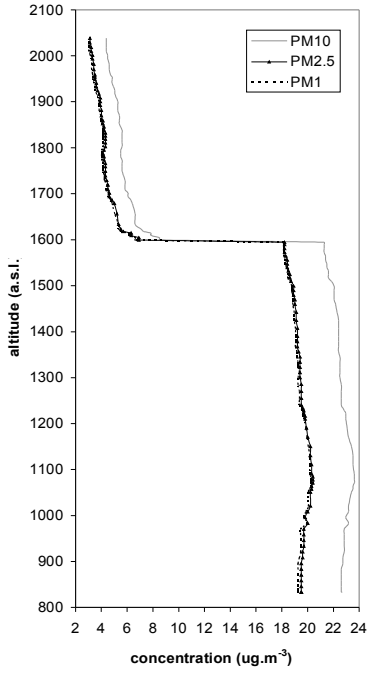

Figure1: Vertical profile of PM concentrations above Svratouch station.

PM_{10} suspension of road dust is depending on the road surface macro texture

G. Blomqvist, M. Gustafsson, C. Bennet, and T. Halldin

Swedish National Road and Transport Research Institute, SE-581 95 Linköping, Sweden
Keywords: road dust, resuspension, modelling, road surface texture.
Presenting author email: goran.blomqvist@vti.se

Emissions of road dust particles are influenced by both direct generation in the tyre/road interface and by suspension of particles deposited on the road surface. Suspension will be a result both from the action of the tires on the road surface and the turbulence occurring under passing vehicles. This abstract is aiming to find whether there is a relationship between the road surface characteristic 'macro texture' and the dust emission potential.

Road surface macro texture has been measured on five different asphalt surfaces (Table 1), all worn by studded tyres in a road simulator (Gustafsson *et al* 2009). The emission potential was established by measuring the PM_{10} (TSI, DustTrak) in a confined chamber placed on the road surface where 2 g filler material (crushed stone <200 µm) with 20% PM_{10} was distributed manually using a brush. Suspension of the particulate material was achieved by the method presented by Etyemezian *et al* (2007) at 1000 rpm. Each measurement was replicated five times.

Table 1. Pavement type, stone mineral and road surface macro texture on the tested pavement surfaces.

No	Pavement type	Stone mineral	Road surface texture (mm)
1	SMA 16	Porphyry	2.1
2	SMA 11	Quartzite	1.6
3	AC 11	Limestone	1.4
4	SMA 8	Porphyry	2.1
5	SMA 16	Quartzite	1.3

SMA = Stone Mastic Asphalt
AC = Asphalt Concrete
8, 11, 16 = maximum stone size (mm) in pavement

The PM10 concentration in the chamber during each test is described by an increase until a peak is reached and thereafter an exponential decrease (Figure 1). The mean peak value is used in this test as a measure of the dust emission potential for each pavement.

The results (Figure 2) show that there is a strong linear relationship (R^2=0.97) between the road surface texture and the emission potential of the five pavement surfaces. This implies that road surface texture is an important property for road dust emission through suspension and thus should be a parameter in emission modelling.

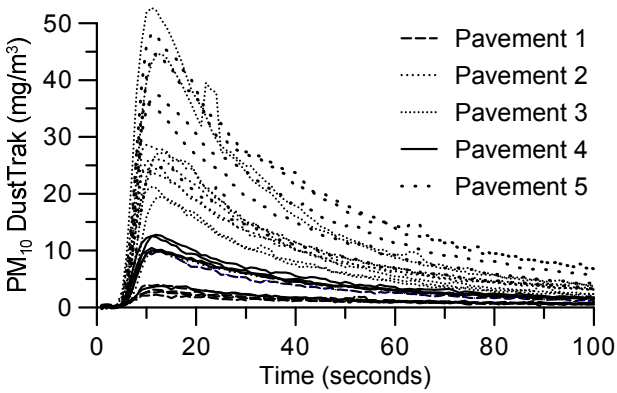

Figure 1. PM10 concentration in the measuring chamber during the test cycle.

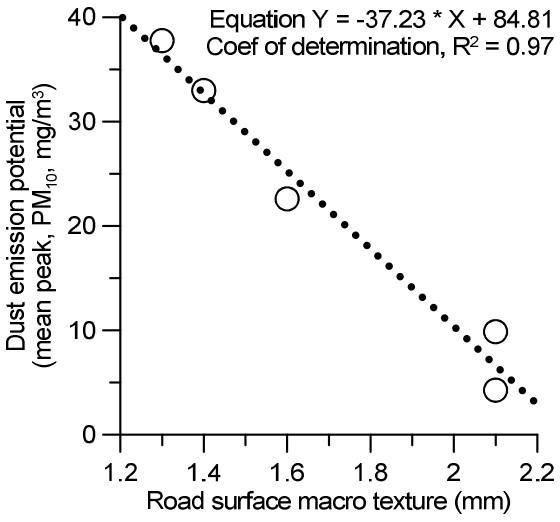

Figure 2. The relation between road surface macro texture and dust emission potential.

$PM_{2.5}$ and PM_{10} ambient concentration levels are still a major environmental problem in several urban areas in the E.U., while new evidence of its long term impacts on human health continues to emerge. The Commission of E.C. is moving towards the implementation of the thematic strategy on air Pollution and requirements of lower limit values for PM in air will come in effect. National Authorities will have to re-evaluate the present environmental policies and measures and develop new ones.

The Development of a Cost Efficient Policy Tool for reduction of Particulate Matter in Air (ACEPT-AIR) is an effort materializing through a dedicated LIFE+ project in order to enable Authorities (both at central regional and local level) to assess the reduction of key environmental pollutants, as well as their interdependencies, thus responding in a competent way to environmental issues, specific to particulate matter atmospheric concentrations.

The work is targeting, firstly, to unravel the relative contribution of the multiple anthropogenic and other sources to the observed PM air concentrations, Secondly it will document the relative contribution of secondary aerosol particles to those from primary emissions, by taking into account the atmospheric processes which contribute secondary and primary PM at any given receptor site. State of the art data and models will be incorporated in a versatile tool which will combine comparative analysis of source contributions calculated from air concentrations and emission inventories. The tool will create a historical record of control measures, changes in emissions, targeted or economy driven, and provide results in measured concentration reductions apportioned to changes in every accounted source. This can allow the policy makers to evaluate the effects of control measures applied on specific emission sources as well as plan new ones.

Three urban areas have been selected for study: Athens Metropolitan Area, Thessaloniki Metropolitan Area and Greater Volos Area. Historical data from previous studies including results on PM_{10} and $PM_{2.5}$ concentration levels at these three urban centres, covering a period of approximately two decades, as well as source apportionment results (identification of main PM sources and quantification of their relative contribution to the observed concentration levels will be reviewed. New data sets will be constructed by carrying out aerosol campaigns at the same sites that the previous samples were collected. Special attention will be given at three regions Athens Metropolitan Area (AMA), Thessaloniki Metropolitan Area (TMA) and Greater Volos Area (GVA). Aerosol samples PM_{10} and $PM_{2.5}$ at a daily basis will be collected at these 3 sites covering the warm and the cold period of the year. These sites (receptor sites for the source apportionment) will be selected as representatives of traffic-impacted and urban background areas, respectively. In addition, data collected at the "Demokritos" urban background station, which is already in operation, will be utilized.

Source apportionment techniques such as PMF (Karanasiou et al., 2009) and CMB modelling (Samara et al., 2003) will be employed for the sources contribution strength to be determined. The design of the policy tool requires at least two reference periods for performing calculations, trend analysis and construction of scenarios of the emission strength for the different sources. The historical and new databases will be used as the two reference periods. A comprehensive emission inventory will be constructed for the three areas of interest (AMA, TMA and the Greater Area of Volos). The operational platform will allow evaluation of both emission and source strength data. Historical trends and forecasted projections will be produced in order to associate emission sources and the respective air quality data and provide the optimum emission reductions and measures assisting with effective air pollution abatement and sustainability.

$PM_{2.5}$, PM_1 and $PM_{0.4}$ acidity during spring and summer at one Po Valley site.

G. Sangiorgi[1], L. Ferrero[1], M.G. Perrone[1] and E. Bolzacchini[1]

[1]POLARIS Research Centre, Department of Environmental Sciences, University of Milan - Bicocca, Milan, I-20126, Italy

Keywords: water soluble compounds, acidity, water content, PM2.5/PM1/PM0.4.

Presenting author email: giorgia.sangiorgi1@unimib.it

Nitrate, sulphate and ammonium are the three main important water-soluble inorganic ions of PM. Typically, they account for 30-60% of the total PM mass (Seinfled and Pandis, 2006; Lonati *et al*, 2005). In the Po Valley, they show a typical seasonal trend: during the summer sulphate is the dominant inorganic ion (13% of PM_1 and $PM_{2.5}$; Perrone *et al*, 2010) because of the strong atmospheric photochemistry, while during the winter nitrate becomes the most abundant inorganic ion (23-29% of PM_1 and $PM_{2.5}$; Perrone *et al*, 2010). This seasonal pattern affects the characteristics of aerosol acidity, because sulphuric and nitric acids are two of the most important aerosol precursors. Typically, ammonia is the main neutralizing species. The goal of this study is to expand the knowledge about aerosol acidity characteristics.

PM_x samples (Table 1) were collected at Sannazaro de' Burgondi (Pavia, Italy), a rural site located in the middle of the Po Valley (North of Italy). Three dimensional sizes of PM were sampled: $PM_{2.5}$ (4-h filters), PM_1 (8-h filters) and $PM_{0.4}$ (24-h filters). The sampling period was 24 March – 19 April (spring) and 10 June – 2 July 2010 (summer). All the collected filters were extracted in ultra-pure water and analyzed by IC to determine the concentration of water soluble inorganic ions (Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}; F^-, Cl^-, NO_3^-, PO_4^{3-}, SO_4^{2-}) and mono-/dicarboxylic acids (acetic, propionic, formic, glutarric, succinic, malonic, maleic, oxalic acids).

Table 1. Mean ± standard deviation of PM_x concentration ($\mu g/m^3$).

	$PM_{2.5}$	PM_1	$PM_{0.4}$	$PM_1/PM_{2.5}$	$PM_{0.4}/PM_1$
SPRING	21±14	12±8	3±1	0.61±0.12	0.23±0.05
SUMMER	13±8	12±7	5±1	0.64±0.13	0.35±0.08

While the ammonium concentration was at the same level during spring (e.g., PM_1=1.2±1.1 μg m^{-3}) and summer (e.g., PM_1=1.4±1.0 μg m^{-3}), nitrate and sulphate showed the typical seasonal pattern described above. For example in PM_1, NO_3^- was three times higher during spring (spring: 2.9±3.2 μg m^{-3}; summer: 0.8±1.0 μg m^{-3}); on the contrary, SO_4^{2-} was three times higher during summer (spring: 1.0±0.8 μg m^{-3}; summer: 2.9±2.3 μg m^{-3}).

All the samples (regardless of season, time of the day, and PM size) were ammonium-rich, i.d. $[NH_4^+]/[SO_4^{2-}]$ molar ratio was always >1.5. Moreover, it was clearly visible that the ammonium concentration increased at the increasing of the nitrate concentration, suggesting that nitrate formation was a consequence of the gas-phase reaction between ammonia and nitric acid.

However, the spring strong correlation between excess of NH_4^+ (excess $NH_4^+=[NH_4^+]-[SO_4^{2-}]$) and NO_3^- ($R^2 \geq 0.98$) was lost during the summer ($R^2 \geq 0.46$) (Figure 1), suggesting that the presence of ammonium in PM samples could not be attributed to this inorganic ion.

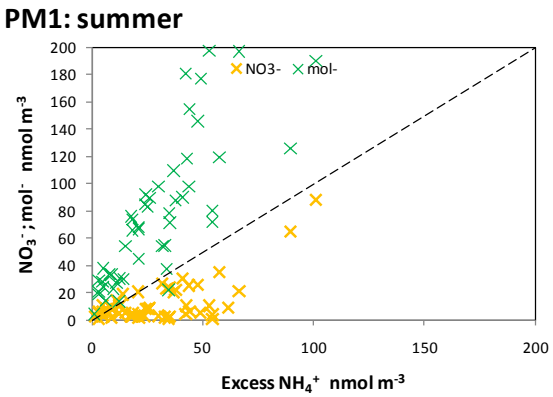

Figure 1. Relationship between excess of NH_4^+ and NO_3^- concentration.

The summer higher level of ammonium in PM_x could be explained by the increased concentration of mono- and dicarboxylic acids, due to stronger photochemical processes than in spring. In fact, the concentration of these acids was double in summer (e.g., PM_1=0.20±0.19 μg m^{-3}) than in spring (e.g., PM_1=.011±0.10 μg m^{-3}).

In addition to strong acidity (i.e., H^+ derived from strong acids in an aqueous extract of PM samples; Pathak *et al*, 2004), also free acidity (i.e., the actual concentration of free H^+; Pathak *et al*, 2004) is an important parameter to describe the aerosol acidity characteristics. Then, a thermodynamic model (*E-AIM*) will be used to determine free acidity for the collected samples.

perrone@le.infn.it

Epidemiological studies on particulate matter (PM) healt effects have highlighted a strong relationship between fine particles and increased cardio respiratory morbidity and mortality. These effects are stronger for particles with aerodynamic diameter d ≤ 2.5 μm, since they can penetrate deeper into the airways of the respiratory system and can reach the alveoli at the lung. It is therefore, important to investigate the dependence of concentration and composition on particle size and study the relationship between particle size and toxicity. 24-hour PM2.5 and PM1 samples have simultaneously been collected in a suburban site of south-east Italy (40.34° N, 18.01° E) from July 2008 to April 2009 to contribute to the characterization of fine fraction particle properties. The PM sampling has been carried out by means of a low-volume (2.3 m^3 h^{-1}) dual-sampler (HYDRA, FAI Instruments, Italy) located on the roof of the Physics Department building of University of Salento, at about 10 m from ground. Atmospheric particles have been collected on 47 cm-diameter pre-fired quartz-fiber filters. Mass concentrations of main water-soluble ions, metals and of organic carbon (OC) and elemental carbon (EC) have been measured in 29 randomly selected PM2.5 and PM1 samples, respectively, to characterize the particle composition. The ion chromatography (IC) technique has been used to determine the mass concentration of the major inorganic anions (Cl^-, F^-, NO_3^-, NO_2^-, SO_4^{2-}) and cations (Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}), and of methanesulfonate (MSA). Mass concentration of metals (Al, Cd, Cr, Cu, Fe, Pb, Mn, Ni, Ba, Mo, V, Zn) has been determined by the ICP-AES technique. OC and EC mass concentrations have been quantified by the thermal-optical transmission (TOT) method using the Sunset Labortatory Carbon Analyzer and the NIOSH 5040 protocol.

Mean mass concentrations (± 1SD) of the 29 PM2.5 and PM1 analyzed samples are 25±11 μg/m³ and 15±7 μg/m³, respectively. Hence, on average 60% of the PM2.5 mass is due to PM1 particles. Standard deviations provide a measure of the mass concentration variability. Non-sea-salt-sulfate (nss-SO_4^{2-}), ammonium (NH_4^+), nitrate (NO_3^-), OC and EC have been identified in both fractions as the main components of the particulate mass concentration, accounting on average for almost 50% of the total sampled mass. The mass concentration of tested ions accounts on average for 17% and 22% of the PM1 and PM2.5 sampled mass, respectively. The seasonal variation of ions concentrations is significant, with the highest concentrations observed in spring-summer and the lowest in autumn-winter. Figure 1 shows as an example, the MSA mass concentration evolution. Methanesulfonate is an oxidation product due to the marine biological activity. Hence, it is exclusively of biogenic origin (Mihalopoulos, 1997) and can significantly contribute to the Mediterranean PM. A clear seasonal trend is revealed by Fig. 1. MSA levels range from 0.003 to 0.06 μg/m³ in PM1 (full dots) and from 0.006 to 0.085 μg/m³ in PM2.5 (open boxes). MSA presents in both fractions significantly higher concentrations from May to September and a dramatic decrease from November to April. The observed seasonal trend of MSA reflects the higher phytoplankton activity during summer. Hence, MSA can be a good marker to evaluate the contribution of the biogenic source to the sulfur budget.

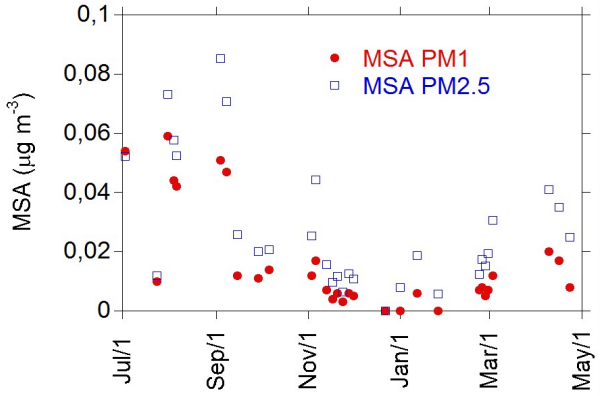

Figure 1. Seasonal evolution of MSA mass concentrations in PM1 and PM2.5 samples.

OC and EC mass concentrations also show a seasonal dependence: OC and EC mean levels are 7±4 μg/m³ and 3±2 μg/m³, respectively in PM2.5 samples and 4±2 μg/m³ and 2±1 μg/m³ in PM1 samples, respectively in autumn-winter. In spring-summer, OC and EC mean levels are 5±2 μg/m³ and 2±0.5 μg/m³, respectively in PM2.5 samples and 3.5±1 μg/m³ and 1.5±0.5 μg/m³ in PM1 samples, respectively. The higher concentrations of carbonaceous particles in autumn-winter are probably due to enhanced emissions coupled with unfavorable meteorological conditions. The mass concentration of tested TC accounts for 39% and 36% of the PM1 and PM2.5 sampled mass, respectively. These last results highlight the significant contribution of carbonaceous particles to PM1 and PM2.5 particles.

Atmospheric particulate matter contains significant portion of magnetite-like iron oxides with concentrations and properties depending upon the source and environmental stress at the deposition/collection site. In many cases, they may reflect such effects as differences between heating and non-heating season, source-specific information (e.g. in proximity to steel works), etc. In our contribution, we present concentration and grain-size dependent magnetic data of PM10, collected at industrial (close to steel works) and urban (city of Prague) sites, collected over period including heating and non-heating season. Magnetic phases were determined using thermomagnetic analyses. Further magnetic characteristics were determined using measurements of hysteresis loops and IRM acquisition and remagnetization curves. In addition, SEM observations and Mossbauer spectroscopy were employed to characterize the anthropogenic contribution to atmospheric dust. Concentration of iron oxides present in the samples is compared with the PM10 concentration. Interpretation of the data is based on comparison with meteorological data, namely wind direction and speed. Our data suggest that magnetic properties may be used for the assessment of source-specific PM. Moreover, in the case of industrial site, specific meteorological conditions – wind direction and speed – seem to affect significantly the contribution of the steel works to generally high air pollution by particulate matter at the nearby site.

Abstract

Due to the extreme steepness of the upstream of the rivers in Taiwan, the sediment yields in the downstream of the rivers are extremely huge. Furthermore, the dams obstruct most of the water thus leading to the formation of large areas of bare-soil downstream during the drought season. Dust emissions from the dry riverbed surface are an environmental concern in the west part of Taiwan (Kuo et al., 2010). These pollutants may pose adverse effects to human health and the environment.

In order to understand current status of the Jhuoshuei riverbed, dust sampling was conducted in this study. PM mass concentration and wind speed samplers from Jhuoshuei River bed near Hsin-Hsing Community, Yunlin, Taiwan were collected from 14 o'clock to 17 o'clock on November 25, 2010. $PM_{10\text{-}2.5}/PM_{2.5}$ mass concentrations were measured by Dichotomous Sampler on the upwind, riverbed, and downwind at the same time (Fig 1).

The result showed that the coarse particle ($PM_{10\text{-}2.5}$) of aeolian dust was about 4600 μg/m^3, and the fine particle ($PM_{2.5}$) was about 1200 μg/m^3 on the riverbed. However the PM mass concentrations of upwind and downwind were lower than 100 μg/m^3 (Fig 2). Moreover, the wind speed was above 12 m/s on the riverbed, and below 10 m/s on the upwind and downwind. The dominant wind direction was from North. Although very high PM concentration found on the riverbed (sampling at 1.5m high), however, not significant impact on the selected downwind site, It might be because of the sampling height (10m) and the relative location.

Figure 1.Sampling sites of Jhuoshuei River, Taiwan.

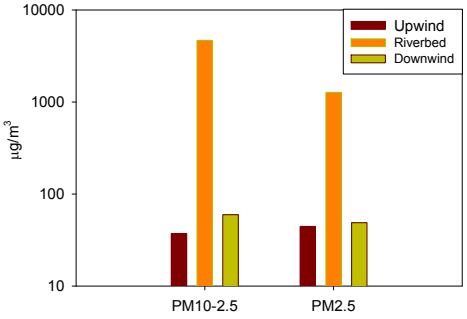

Figure 2.The $PM_{10\text{-}2.5}/PM_{2.5}$ mass concentrations were measured by Dichotomous Sampler on the upwind, riverbed, and downwind.

Keywords: chemical composition, organic tracers, source identification
Presenting author email: mpc@unife.it

This study reports a general assessment of the organic composition of the $PM_{2.5}$ samples collected in the city of Augsburg, Germany in a summer (August-September 2007) and a winter (February-March 2008) campaign of 36 and 30 days, respectively.

The collected PM filters were directly submitted to in situ derivatisation thermal desorption gas chromatography coupled with time of flight mass spectrometry (IDTD-GC-TOFMS) to simultaneously determine the concentrations of many classes of molecular markers: C_{20}-C_{35} n-alkanes, anteiso- and iso-C_{29}-C_{33} n-alkanes, 10 PAHs and 7 oxidized PAHs, and more polar compounds, including long chain n-alkanoic acids, levoglucosan and cholesterol.

The concentrations of the homologous series of n-alkanes were determined and the summer and winter concentrations were compared (Fig. 1). The summer profile is dominated by the heavier n-alkanes ($C \geq C_{27}$) mainly emitted from plant waxes, introduced into the atmosphere from plant abrasion or as products of incomplete biomass combustion: the C_{29}-C_{33} level is nearly 1.5 times higher in the warmer period. N-alkanes from these sources are characterized by a strong odd/even prevalence (CPI≥2) with maximum for the C_{29} and C_{31}terms.

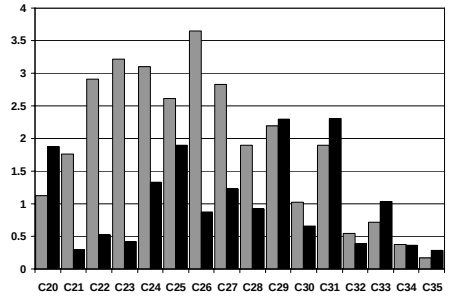

Figure 1: Winter (grey bars) and summer (black bars) distribution of C_{20}-C_{32} n-alkane concentrations

On average, the PAHs showed 8.8-fold higher mean values whereas the O-PAH mean concentrations increased 6.2-fold in the colder period. The higher winter abundance is mainly the result of increased emissions from primary sources, i.e. motor vehicle traffic and domestic heating, and the concomitant effect of atmospheric conditions, with consequent reduction of atmospheric transport and mixing. A comparison between winter and summer distribution of PAH and O-PAH concentrations (Fig. 2) shows an increased influence of non-traffic sources in the colder period characterized by an increased relative abundance of BaP, BaA, BbkF, CRY, IND, and BdA-O — related to domestic heating — vs. compounds prominent in emissions from gasoline and diesel vehicles, i.e., BeP, BghiP, COR, BaF-O.

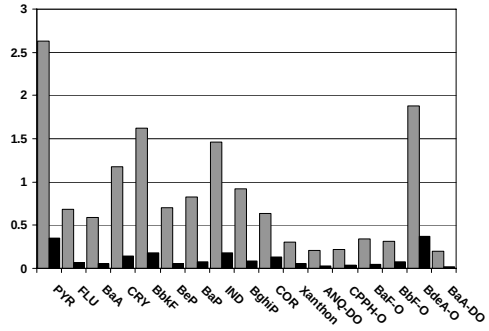

Figure 2: Winter (grey bars) and summer (black bars) distribution of PAH and O-PAH concentrations

Finally, some polar organic species were investigated as valuable markers in tracking the sources of atmospheric aerosols: in particular fatty acids, dehydroabietic acid, levoglucosan and cholesterol were quantified to estimate the contribution from specific biomass/biofuel burning and fossil fuel combustion.

The PCA analysis of the data identified the contributions of three emission sources, i.e., combustion sources, including fossil fuel emissions and biomass burning, vegetative detritus, and oxidized PAHs. These factors make it possible to discriminate PM samples according to seasonality. Winter is characterized by high emissions from petroleum/wood combustion while the contributions from higher plant waxes and atmospheric photochemical reactions are dominant in summer.

The results obtained confirm that IDTD–GC-MS is an effective technique applicable to atmosphere monitoring since it provides a large data set for simultaneous characterization of many chemical markers in particulate samples.

Keywords: Aerosol chemistry, size-segregator analysis, summer/winter concentrations

Presenting author email: alexandrecaseiro@ua.pt

The growing awareness of the impact of atmospheric particulate matter (PM) on climate, and the incompletely recognised but serious effects of anthropogenic aerosols on air quality and human health, have led to diverse studies involving almost exclusively the coarse or the fine PM fractions. However, these environmental effects, the PM formation processes and the source assignment depend greatly on the particle size distribution. The purpose of this work was to study the size-resolved particulate carbonaceous and ionic vehicular emissions in Madrid.

The Madrid Metropolitan Area is bordered to the north-northwest by a high mountain range 40 km from the city, and to the northeast and east by lower mountainous terrain. The metropolitan area has nearly 6 million inhabitants, involving a car fleet of almost 3 million vehicles with very intense traffic on weekdays on the two existing ring roads and the roads connecting Madrid with the surrounding towns, where more than 2.5 million residents live. Since its industrial activity consists essentially of light factories, the Madrid plume is typically urban, fed by traffic emissions.

Size-segregated (<0.5µm, 0.5-1µm, 1-2.5 µm, 2.5-10 µm) PM was collected with hi-vol samplers simultaneously at two sites (kerbside and urban-background) in the city of Madrid during two one-month long campaigns (winter and summer). After collection, the organic and elemental carbon fractions were determined by a thermo-optical method, while soluble ionic species were measured by ion chromatography.

Total PM_{10} mass was higher at the kerbside than at urban-background. The main species that contributed to this difference were organic and elemental carbon. Ionic species contribution to overall mass showed little spatial variations.

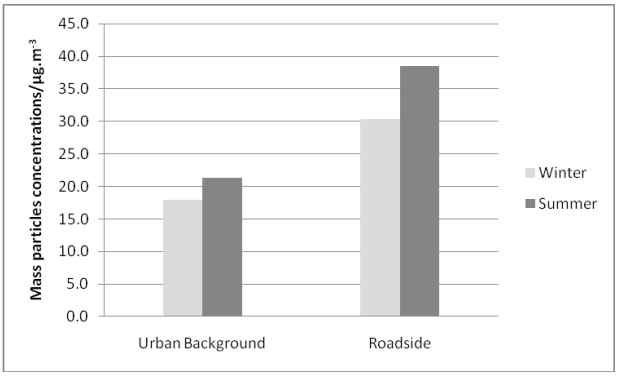

Figure 1. Total mass concentrations in PM_{10} at the urban background and roadside in both seasons.

Soluble calcium concentrations showed a significant spatial variation, mainly in the coarser modes and in winter, with higher concentrations at Roadside than at urban-background, due to the soil particles suspended by traffic.

In the coarser modes, organic carbonaceous species and nitrate were preponderant.

Elemental carbon and the secondary species gain importance towards the finer modes, but organic carbon generally remained the main contributor to the particulate mass.

The main seasonal differences were mainly found for sodium and chloride ions in the coarser modes, due to the use of thawing salt. On the other hand, potassium seasonal variations in the finer modes showed low amplitudes both at kerbside and urban-background, possibly indicating that residential wood burning is not a main source of PM in Madrid.

Table 1. Mean mass concentrations of measured ions at the urban background and roadside.

Characterization of Aerosol Particles around an Open pit coal mine in Germany by electronmicroscopic individual particle analysis

D. Müller-Ebert[1], M. Ebert[1] and S. Weinbruch[1]

[1]Environmental Mineralogy, Institute of Applied Geosciences, Technical University Darmstadt, 64287 Darmstadt, Germany
Keywords: individual particle analysis, carbonaceous aerosol, open pit coal mine, PM10.
Presenting author email: doe@geo.tu-darmstadt.de

PM_{10} around open pit coal mines in Germany frequently exceeds the 24 hours limit value of 50 µg/m^3. To comply with current EU regulations appropriate mitigation strategies have to be developed. For this goal accurate source apportionment is an indispensable prerequisite. In this study electronmicroscopic individual particle analysis was performed for the characterization of the dust immission around an open pit coal mine.

Particles were collected at two places in the direct vicinity of the open pit mine. One sampling site was chosen in the northeast and one in the southwest. At both sampling sites optical particle counters were operated for the determination of PM_1, $PM_{2.5}$ and PM_{10}. From March until August 2010 particle samples for electronmicroscopic analysis were collected with a two stage cascade impactor (aerodynamic particle diameter: 0.1 – 1 µm and 1 – 10 µm). In order to deduce the PM_{10} contribution of the open pit mine, sampling was only performed for situations with local winds coming from northeast (45 – 75°). During these situations a "luv/lee-situation" is received at the two sampling sites in respect to the open pit coal mine.

The size, shape, and chemical composition of more than 30,000 particles within twelve samples were determined by individual particle analysis performed by automated scanning electron microscopy (SEM) and energy-dispersive X-ray microanalysis (EDX).
The most abundant particle groups encountered are secondary aerosol particles, soot, silicates, silicate/coal mixtures, coal, calcium sulfates, carbonates, Fe-rich particles and (aged) sea salt.

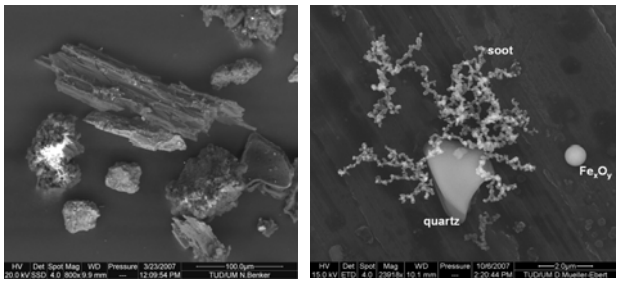

Figure 1. a) Backscatter electron image of a lignite particle; b) Secondary electron image of a soot, quartz and iron oxide particle.

Within the $PM_{10-2.5}$ fraction a high abundance of silicates and silicate/coal mixtures were observed, which can mainly be assigned to the open pit mine activity. Only a low number of pure coal particles were observed. In this way the main particle source from the open pit coal mine seems to be the excavated material and not the coal itself.
At two days also a high abundance of aged sea-salt was observed in this size-fraction.

In contrast the PM_1 fraction is completely dominated by a typical urban/rural background aerosol, characterized by a high abundance of soot and secondary aerosols (sulphate/nitrate/organics) and mixtures of these groups.

Following these results, significant reduction potentials for PM_{10} only exist for the contribution of the excavated material of the open pit mine (silicates and silicate/coal mixed particles) and for urban background aerosols (secondary aerosol particles and soot).
As the contribution of the open pit mine is mainly apparent in the $PM_{10-2.5}$ fraction, but adverse health effects are more likely associated to the PM_1 fraction (respectively particle number concentrations or surface area) a possible conflict of goals in the reduction strategies may arise depending if the focus is set at permissible value of PM_{10} or the relevance for adverse health effects.

Thermal behaviour of water and inorganic ions in particulate matter

S. Canepari[1], C. Perrino[2], S. Materazzi[1], E. Marconi[1], C. Farao[1], L. Tofful[1], S. De Angelis Curtis[1]

Keywords: water soluble compounds, chemical analysis, thermal desorption, salt aerosol.
Presenting author email: silvia.canepari@uniroma1.it

Thermal analysis have widely been used for the characterization of various materials, but only few studies concern its application to atmospheric particulate matter (Matuschek et al., 2004; Duarte and Duarte, 2008). All these studies are focused on the identification or quantification of desorbed organic species.

Among inorganics, the species that are expected to thermally desorb from PM are ammonium salts and water. Ammonium salts are subjected to solid/vapour equilibria that are responsible for one of the main artefacts in PM determination. The extent of these artefacts has been proved to be influenced by water vapour, which may be absorbed on particles. In the scientific literature, however, only a few and contrasting results have been reported about the analytical determination of water in PM samples, and they have been mostly obtained by the Karl Fischer method (Otha et al., 1998; Tsai and Kuo, 2005).

In this work, the thermal behaviour of water and ammonium salts has been examined under controlled conditions, with the purpose of exploring the potential of thermogravimetry and thermal desorbtion techniques with respect to both the analytical determination of water and the study of sampling artifacts mechanisms.

The themogravimetric curves of reference materials NIST 1648 and NIST 1649a (figure 1) show, as expected, different steps of mass loss. In the range from 25°C to 180°C a loss of ca. 6% (6.3% for NIST 1648 and 4.9 % for NIST 1649a) in two steps has been evidenced. These losses have been assigned, respectively, to weakly and strongly bounded water by using hyphenated TG-MS and TG-FTIR and by carrying out the chemical analysis of the residual obtained after heating at different temperatures. Although the method needs further validation, the thermo-gravimetric determination of PM water content seems to be a convenient alternative to the use of Karl Fischer method.

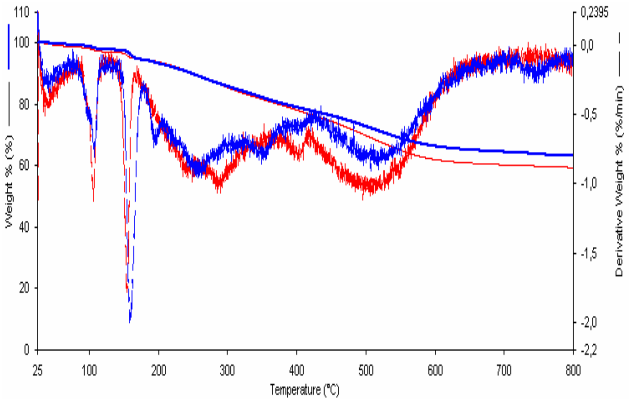

Figure 1. TG curve of NIST 1648 (blue) and NIST 1649a (red) in nitrogen, heating rate 10 °C/min.

Despite the evidence of ammonium salts evolution during the sampling at ambient temperature, the loss of ammonium salts from reference materials starts above 180°C and the residual concentrations of nitrate, chloride and ammonium become negligible at about 310°C. Mass loss registered by the TG analysis in the 180-310 °C range is 7.2% for NIST 1648 and 7.9 % for NIST 1649a. This loss is partially due to inorganic salts (i.e. for NIST 1648: ammonium 1.8%, nitrate ca. 1,1%, chloride 0.3% and sulfate, that partially decomposes to SO_2, ca. 1.1%) and partially to organic matter. The latter has been estimated to be about 2.5% by EC/OC thermoanalysis carried out in the same temperature range.

Similar results have been obtained also on real PM_{10} samples collected on Teflon membranes at an urban site in Rome, Italy. Even though the presence of the filter causes a worsening of signal to background ratio, also in this case water loss at T<120 °C may be measured with sufficient repeatability (about 10% on pairs of equivalent samples).

In the case of real PM samples, all the other release processes occur at lower temperatures than in the case of NIST (about 60°C less). The reasons for this behavior are not clear, but it is reasonable to hypothesize that the aging of dust plays a significant role. Anyway, no significant losses of inorganic ions and OC can be detected below 120°C, in contrast with the usual behaviour observed during the sampling phase (negative artifact due to the release of ammonium salts).

About 80% of the mass losses in the range 120-250°C were due to inorganic ions and OC. After heating up to 250°C ammonium concentration was always below 15% of the initial value, while nitrate and chloride residual amounts strongly depended on the nature of collected PM and were much higher in case of high contribution of natural dust (sea-salt and soil contributions). This residual nitrate and chloride concentrations remain constant also after further heating and are probably associated with sodium salts.

The aim of the present study is to characterize and identify possible PM sources in an industrial zone in southeastern Spain. This zone has an important presence of cement plants and ceramic industries. Unlike other studies already published in the same zone, in this one, the hourly evolution of the concentration of different elements is studied. In this way, it is possible to get a clearer identification of the sources responsible for the emission of these elements. To accomplish this objective, a 2-stage sequential streaker manufactured by PIXE International was used. This sampling device continuously collects the coarse (PM2.5-10) and fine (PM2.5) fractions separately along a circle. A pre-impactor stage is used to remove particles having aerodynamic diameters larger than 10 µm. The coarse fraction was collected on a Kapton foil and the fine fraction on a Nucleopore filter with 0.3 µm pore diameter. The elemental composition of the samples was determined by the particle induced X-ray emission (PIXE) analytical method. The measurements were carried out using the PIXE facility at the LABEC Lab. of the INFN in Florence, Italy. An SO_2 monitor was also used.

Element	Fine fraction (ng/m^3)	Coarse Fraction (ng/m^3)
S	427	343
Ca	418	2773
V	10.2	18.5
Fe	51.4	222
Ni	2.4	2.1
Cu	2.3	7.4
Zn	3.8	5.7
Pb	4.2	2.7

Table 1. Mean concentrations of some elements during the study period.

Although several campaigns were carried out during the entire year, one sampled week was selected in which there was neither the influence of long-range transport of particulate matter (African intrusions) nor a rain period that could interfere with the measurements of locally emitted contaminants. The sampling period was between 5 and 11 April 2006.

The average concentration of some elements during the measurement week is shown in table 1. High sulphate concentrations are found in both the coarse and fine fractions. Ca appears mainly in the coarse fraction with an average value close to 3 $\mu g/m^3$. Fe has a similar behaviour. V, Ni, Cu, Zn are distributed in both fractions although with higher concentrations in the coarse one.

Pb, an industrial source tracer, appears mainly in the fine fraction, although a significant amount is found in the coarse fraction.

A PMF study was performed in order to characterize the possible sources affecting the PM; in the coarse fraction, six sources were found: Aged sea salt, sea salt, traffic, industrial, and two crustal sources, one more characterized by Ca and the other for the other crustal elements (Al, Si, Ti and Fe). Several sources were found in the fine fraction: Traffic, aged sea salt, secondary sulphate, an industrial source characterized by K, Zn, and Pb, another characterized by V and Ni, and the two crustal sources found in the coarse fraction.

Temporal evolution of the sources related with industrial sources and traffic showed very marked concentration peaks. For instance, the source characterized by V displays peaks that reach values close to 90 ng/m^3 in both fractions. One of these peaks, shown in Figure 1, coincides with the SO_2 peak, pointing out that the plume coming from the cement plant chimney affects the sampling point. Both SO_2 and V could be a product of the petroleum coke combustion that takes place in the cement plant kiln. The traffic source displays different peaks that coincide with the traffic rush hours.

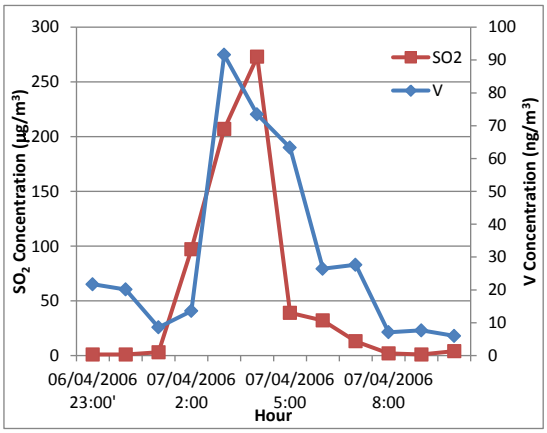

Figure 1. Coinciding evolution of the SO_2 and V concentrations

All these results are confirmed by means of CPF plots.

Determination of Cr(III) and Cr(VI) in atmospheric particulate samples

M. Catrambone [1], S.Canepari[2], C. Perrino[1]

[1]CNR Institute of Atmospheric Pollution Research, Monterotondo St. (Rome), 00015, Italy
[2]Department of Chemistry, Sapienza University of Rome, 00185, Italy
Keywords: aerosol sampling, filters, chemical analysis, soluble fraction.
Presenting author email: catrambone@iia.cnr.it

Chromium is released to the atmosphere in the form of particulate matter (PM) and may be originated by both natural sources (volcanic eruptions, erosion of soils and rocks) and industrial sources (metallurgic industries, refractory brick production, electroplating, fuel combustion) (Kotas and Stasicka, 2000). However, the relative impact of the several sources of chromium is still largely unknown and the source apportionment of this element requires further investigations.

As well known, the effect of chromium on human health may be influenced by its oxidation state: Cr(III) is essential for the metabolism of lipid, glucose and protein and is generally present as insoluble species, while Cr(VI) is carcinogenic, toxic for humans and animals, absent in nature and its species are characterized by higher solubility.

It is widely recognized that chemical speciation may be a valid instrument for improving studies on both emission sources identification and health and environmental impact. However, most of the studies about the distribution of Cr(III) and Cr(VI) forms in environmental matrices concern natural waters and soils and, to our knowledge, only a few research groups have attempted Cr speciation in airborne particulate matter (Domiınguez and Arcos, 2002; Grabarczyk, 2008).

This study addresses the optimization of an analytic method based on the ultrasound-assisted extraction of water soluble Cr from PM and the determination of Cr(III) and Cr(VI) by catalytic adsorptive stripping voltammetry (CAdSV) using diethylenetriammino pentaacetic acid (DTPA) as complex agent.

The influence of various filter materials and of extracting conditions has been evaluated. The method has been validated on both reference material and real PM_{10} samples and the accuracy of total extractable Cr determination was checked by parallel ICP-OES measurements.

In order to assess the relevance of the two soluble Cr species with respect to total Cr amount in atmospheric PM, the method has been applied to PM_{10} and size-segregated real PM samples. These samples were collected in the industrial areas of Ferrara (Italy) and Tunis, and at a peri-urban site near Rome (Italy).

At the peri-urban site, the total Cr concentrations in the analysed samples ranged from 2 to 5 ng/m^3, with a soluble fraction of 5-13% and Cr(VI) concentrations always below the detection limit (1 pg/m^3). In the industrial area of Ferrara, total Cr concentrations were between 4 and 8 ng/m^3, the soluble fraction was higher (10-12%) and detectable amounts of Cr(VI) were found, with a Cr(VI)/Cr(III) ratio ranging from 0.5 to 1. A further increase of Cr(VI) relevance was evidenced at the industrial site of Tunis, where Cr(VI)/Cr(III) ranged from 1.8 to 3.4 (see figure 1).

The results of the analysis of size-segregated samples, collected at the Ferrara site by a 10-stage cascade impactor, indicate a relevant fine fraction of Cr(VI), with Cr(III)/Cr(VI) ratios increasing with the decrease of particle size.

The proposed method will be in the next future applied to further intensive monitoring campaigns in order to verify the selectivity of Cr(VI) as source tracer. However, these preliminary results clearly indicate that Cr(VI) concentration in PM is strongly dependent on the presence of industrial emission in the area under study.

Airborne particulate matters (PM) have been studied intensively for their environmental effects on the public health, the reducing visibility and solar radiation balance (Yatkin and Bayram, 2008). The aim of this study is to characterize and compare the PM and their composition fractions at urban of central Taiwan and provide the input data for air quality model. The sampling site is located in National Chung Hsing University campus, influenced by local sources. Thirty-six of 24-hour daily samples were collected at Taichung from April to December 2009 using Dichotomous Sampler (Andersen Instruments, Model 241, USA). Water-soluble ions (Na^+, Mg^{2+}, K^+, Ca^{2+}, NH_4^+, Cl^-, NO_3^-, SO_4^{2-}) collected with quartz-fibers filters were determined using ion chromatography (DX-100, Dionex Ltd., USA). Total carbon (TC) and element carbon (EC) were measured using an element analyzer (W.C. Heraeus elemental analyzer CHN-O-Rapid, EA).

The mass concentrations and the fractions of $PM_{2.5}$ and $PM_{2.5-10}$ chemical compositions sampling in diurnal and night time are presented in Figure 1 and Table 1, respectively. The average concentration of diurnal $PM_{2.5}$ is 31.1μg m^{-3} including SO_4^{2-} (25.3%), Organics (13.8%), EC (10.9%), NH_4^+ (10.6%), NO_3^- (6.0%), Mg^{2+} (3.5 %) and sea salt (1.9%). The percentage of other compositions is 26.6%. In the other hand, the average concentration of diurnal $PM_{2.5-10}$ is 23.4μg m^{-3}. The percentage of other compositions in coarse particle is up to 47.1%. The major fractions of $PM_{2.5-10}$ compositions are EC (16.7%), Organics (12.4%), NO_3^- (10.3%) and then sea salt (4.8%) in daytime. The results of daytime particle composition in $PM_{2.5}$ and $PM_{2.5-10}$ are shown that the hygroscopic aerosols including sulphate, nitrate, Organics and EC mainly exist in the fine particle (Tsai and Chen, 2006; Pope et al., 2010).

The average concentration of nighttime $PM_{2.5}$ is 35.7μg m^{-3}. Like the main $PM_{2.5}$ compositions sequence in daytime, that of main $PM_{2.5}$ compositions in nighttime is SO_4^{2-} (23.4%), Organics (14.1%), EC (10.5%), NH_4^+ (9.8%), NO_3^- (7.4%), Mg^{2+} (3.6 %) and sea salt (1.3%). The average concentration of nighttime $PM_{2.5-10}$ is 20.8μg m^{-3}. The fraction of other compositions in fine and coarse particle at nighttime is 28.4% and 39.7%, respectively. The major fractions of $PM_{2.5-10}$ compositions in nighttime are EC (18.0%), NO_3^- (13.9%), Organics (13.8%) and then sea salt (5.5%). Comparing the particle compositions at night between the fine and coarse particulate matters, the hygroscopic particles grow up in $PM_{2.5}$ mainly in theory and can be observed from Figure 1. Basically, there is no obvious difference for the composition proportions among the $PM_{2.5}$ and $PM_{2.5-10}$ aerosols sampling in daytime and night time.

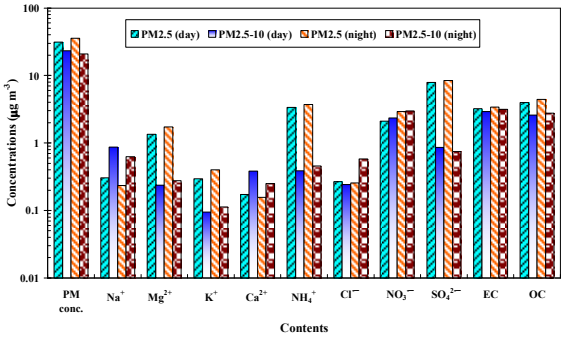

Figure 1. Mass concentrations of fine and coarse particulate matter compositions at Taichung, Taiwan in April – December 2009.

Table 1. Fractions of fine and coarse particulate matter at Taichung, Taiwan in April – December 2009.

Category	Fractions (%)										
	Na^+	Mg^{2+}	K^+	Ca^{2+}	NH_4^+	Cl^-	NO_3^-	SO_4^{2-}	EC	OC	others
$PM_{2.5}$ (day)	1.0	3.5	0.9	0.6	10.6	0.9	6.0	25.3	10.9	13.8	26.6
$PM_{2.5-10}$ (day)	3.6	0.9	0.4	1.8	.7	1.2	10.3	4.0	16.7	12.4	47.1
$PM_{2.5}$ (night)	0.6	3.6	1.0	0.5	9.8	0.6	7.4	23.4	10.5	14.1	28.4
$PM_{2.5-10}$ (night)	3.0	1.2	0.6	1.3	2.3	2.4	13.9	3.9	18.0	13.8	39.7

Fugitive Emissions

M. Amodio, E. Andriani, P. R. Dambruoso, G. de Gennaro, A. Di Gilio, M. Intini, J. Palmisani, M. Tutino

Department of Chemistry, University of Bari, Bari, Puglia, via Orabona, 4, 70126, Italy
Aerosol characterization, Industrial aerosols, metals, PAHs
alessia.digilio@uniba.it

Industrialization, urbanization, economic growth and the associated increase in energy demands have resulted in a profound deterioration of air quality. In particular, in recent years, the growing interest about particulate matter (PM) is due to its dangerous consequences on human health. The particles, in fact, may be the carriers of acidic or toxic species such as heavy metals, acids and carcinogenic organic compounds in the human.

Heavy metals and polycyclic aromatic hydrocarbons (PAHs) are important and well known pollutants that have been identified in several environmental matrices world-wide. In particular PAHs are carcinogenic with mutagenic potential and they are derived mainly from incomplete combustion processes. Metals and metalloids are potentially toxic, even at low exposure levels and they're mainly emitted by anthropogenic sources (Bosco et al., 2005). This pollutants locally emitted, undergo dilution with ambient air and various types of transformations during the transport process. The particles number concentration, the information about the vertical diffusive properties of the low layers of the atmosphere and the weather data could be a useful tool to identify the transport and dispersion of pollutants locally emitted. For this reason, plans to suggest right policy controls for human health protection have to taken into account the most relevant emission sources for the area under investigation and how PM concentrations at receptors can be influenced by transport, mixing and transformation processes. Fugitive emission campaign was performed from 15th April to 6th May 2010 in three different sites around the iron and steel pole of Taranto (Apulia Region, South of Italy). The main interest on Taranto is due to the presence of several activities of high impact as very wide industrial area close to the town and the numerous maritime and military activities in the harbor area (Amodio et al., 2008). The aim of the campaign was to triangulate in the neighbourhood of the examined site on the basis of the direction of the wind in order to determine the impact of the local emissive source on the surrounding areas. A prototype for the determination of the contributions of a single source ('fugitive emission') to the PM concentrations has been used: it consists of a Swam dual-channel sampler, an OPC Monitor, a sonic anemometer and a PBL Mixing monitor. The PM concentrations with the data on the advective trends of the air masses provided by the sonic anemometer, allowed to evaluate the pollutant concentrations according to the wind direction. Moreover, thanks to the PBL monitor, it was is possible to determine the dynamic and mixing characteristics of the low layers of the atmosphere and the pollutants dispersion. Finally, the chemical characterization of PM2.5 and PM10 samples was performed to determine PAHs and metals. The preliminary analysis of collected data for all three sites, showed that when the wind direction (reported as wind direction probability between 0 and 1, in Fig.1) allowed the transport from the plant to one of the considered receptor site, iron (Fe-Fg.1), manganese (Mn), zinc (Zn) and PAHs concentration greater than those observed in other two sites can be obtained. Moreover, in these days the Mn concentration exceeded the EPA threshold limit (50 ng m^{-3}), Benzo(a)Pyrene concentration exceeded the limit set by Directive 2008/50/EC (1 ng m^{-3}) and Arsenic concentration exceeded the limit set by Directive 2004/107/CE (6 ng m^{-3}). The statistical analysis, performed by Principal Component Analysis (PCA), was used for a detailed study of the impact of the local emissive source on the neighboring areas. The PCA analysis provided four components, in particular it allowed to identify the coke contribution (PC1), characterized by PAHs high loadings, and the mineral park component with Zn, Fe, Mn and As high loadings (PC2). PC3 was characterized by Si, Ti and Ca high loadings and it was identified as crustal contribution, while PC4 was characterized by high Vanadium loadings and it can be identified as traffic or harbour contribution.

Size distribution of atmospheric aerosols and associated ion species on the western Mediterranean

M. Varea, N. Galindo, J. Gil-Moltó, C. Chofre and E. Yubero

Department of Physics, Miguel Hernández University, Avda. de la Universidad s/n, 03202, Elche, Spain
Keywords: ambient PM, ions, size distribution, urban aerosols.
Presenting author email: eyubero@umh.es

Between October 2008 and June 2010 PM10, PM2.5 and PM1 samples were simultaneously collected by means of Derenda low volume samplers (2.3 m^3/h) at an urban background site located in Elche, approximately 12 km from the Spanish Mediterranean coast. Gravimetric and ion chromatography analyses were performed in order to determine PM and water-soluble ions mass concentrations.

Table 1 shows average concentrations of PM1, PM2.5, PM10, and associated ions during the whole study period. PM levels were considerably lower than those measured by Pérez *et al.* (2008) at Barcelona, a much more populated and industrialized city. The differences were more significant for PM2.5 and PM1 because these fractions are more influenced by anthropogenic emissions than PM10. If the levels of PM and ionic species shown in Table 1 are compared with those previously registered at the same city (Nicolás *et al.* 2009), a visible reduction can be observed. This could be partially attributed to meteorological conditions (Galindo *et al.* 2010) and to a decrease in pollutants emissions' caused by the economic crisis.

Table 1. Mean levels of PM and associated inorganic ions between October 2008 and June 2010.

	PM1 (μg/m^3)	PM2.5 (μg/m^3)	PM10 (μg/m^3)
PM	9.2	13.5	24.9
SO_4^{2-}	1.79	2.21	2.56
NO_3^-	0.76	1.34	2.80
Cl^-	0.22	0.29	0.65
NH_4^+	0.63	0.78	0.52
Na^+	0.28	0.38	0.84
Mg^{2+}	0.02	0.03	0.13
Ca^{2+}	0.32	0.35	1.51
K^+	0.20	0.22	0.25

Nitrate, sulfate and calcium were the most abundant ions in PM10, accounting for 11, 10 and 6% respectively, while in PM1 and PM2.5 secondary inorganic ions (SO_4^{2-}, NO_3^- and NH_4^+) were the major contributors, representing more than 40% of the PM mass. Although the percentage contribution of nitrate was very similar for the three size fractions, around 20% of the PM1 mass was made up of sulfate, which doubles SO_4^{2-} contribution in PM10. Ammonium concentration in PM10 was lower than in PM2.5 and PM1, indicating a substantial loss of NH_4Cl by reaction of NH_4NO_3 with NaCl in the PM10 filter (Nicolás *et al.* 2009). Ca^{2+} was reduced in PM2.5 and PM1 with respect to PM10 due to its crustal origin.

Figure 1 shows the distribution of PM and water-soluble ions between PM1, PM2.5–1 and PM10–2.5. For chloride, only the relative distribution between the fine (PM2.5) and coarse (PM10–2.5) fractions could be determined since a large number of PM1 samples were under the detection limit. Approximately 35% of PM10 particles were below 1 μm, indicating lower emission rates of fine anthropogenic particles compared with other urban areas in Europe. Crustal (Ca^{2+}) and marine (Na^+, Mg^{2+}, Cl^-) ions were mainly associated with particles larger than 1 μm. Almost 60% of K^+ was distributed in PM1, revealing the prevalence of anthropogenic over natural sources. Nitrate was almost evenly distributed between the fine and coarse fractions, although important seasonal variations in its size distribution were observed. Around 70% of SO_4^{2-} and NH_4^+ were associated with particles smaller than 1 μm.

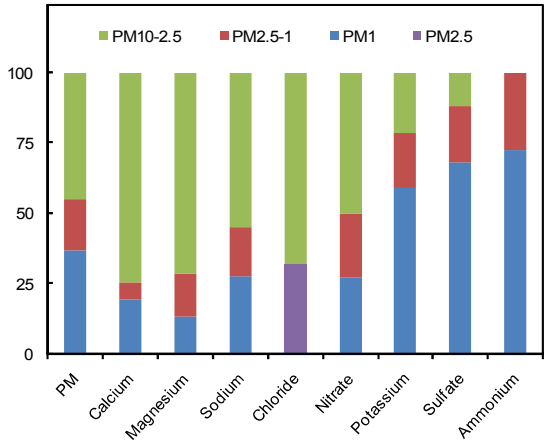

Figure 1. Relative distribution of PM and inorganic ions between different size fractions.

Routine monitoring of coronene in the Czech Republic

L. Hejkrlík, H. Plachá

Czech Hydrometeorological Institute, Branch office in Ústí nad Labem, Czech Republic
Keywords: PM, PAH(s), coronene
Presenting author email: hejkrlik@chmi.cz

Air pollution caused by suspended particles and by PAHs is a particular problem in industrial areas and at places with heavy traffic loads, but also in small communities.

In the Czech Republic exists an extensive programme for automated monitoring of the PM_{10} and $PM_{2.5}$ by radiometry - beta ray absorption, mainly for the sake of smog warning system, low volume sequential sampling of both fractions of PM in a manual network, providing the possibility of monitoring the heavy metals and also the non-sequential manual measurement of PAHs.

Monitoring of PAHs is based on notorious U.S. EPA TO-13A (1999) method of collection of chemicals from ambient air onto a quartz filter and a polyurethane foam (PUF) cartridge using a high volume sampler. The sampler is operated at a low flow rate of 38.5 l/min for up to 24 hours. The 19 target compounds are extracted and analyzed by gas chromatography-mass spectrometry (GC/MS). The GC/MS method is applicable to the determination of PAHs compounds involving three member rings or higher. Naphthalene, acenaphthylene, and acenaphthene have only ~35 percent recovery when using PUF as the sorbent; therefore, they are not included in this study. With optimization to reagent purity and analytical conditions, the detection limits for the GC/MS method range from 1 ng to 10 pg based on field experience.

The Branch office of Czech Hydrometeorological Institute (CHMI) in Ústí nad Labem is responsible for organizing the measuring system of PAHs in the Czech Republic. The laboratory was established in 2002, first measurements began in 2004 and since October 2008 there has been routine monitoring of PAHs at more than 20 stations over the whole Czech Republic.

One of the monitored substances is coronene that is recommended in literature (Leníček *et al*, 2011) as possible traffic pollution indicator. In Table 1. are given some examples of annual concentrations of coronene at various types of measuring stations in the network of CHMI.

Table 1. Select stations of ambient air pollution control measuring coronene in 2009

Station	Classification	Annual conc. ng/m^3
Sokolov	Suburban	0.2
O. Přívoz	Industrial	1.7
Zlín	Suburban	0.5
Košetice	Rural	0.2
H. Králové	Traffic	0.6

It is evident from Figures 1. and 2. that the concentrations of coronene (and also of benzo(a)pyrene and benzo(g,h,i)perylene) exhibit significant seasonality. It is known (Dvorska *et al*, 2009) that coronene as a marker for traffic should be used with care, so we plan to carefully evaluate by means of diagnostic ratios of various PAHs, similar to examples from Figures 1. and 2., the possibility to identify the sources of PAHs at a great number of localities at the end of the campaign of 2010.

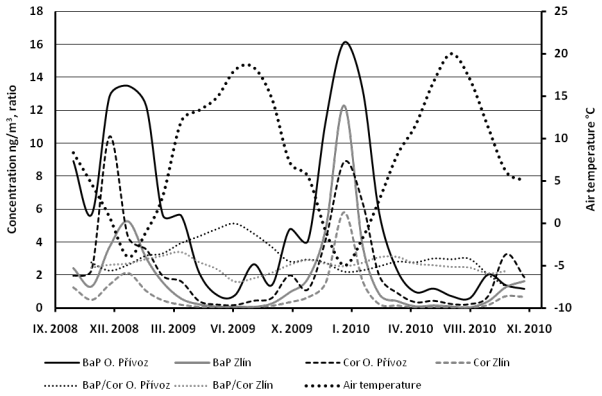

Figure 1. Monthly concentrations of benzo(a)pyrene, coronene and the ratio benzo(a)pyrene/coronene at O. Přívoz and Zlín

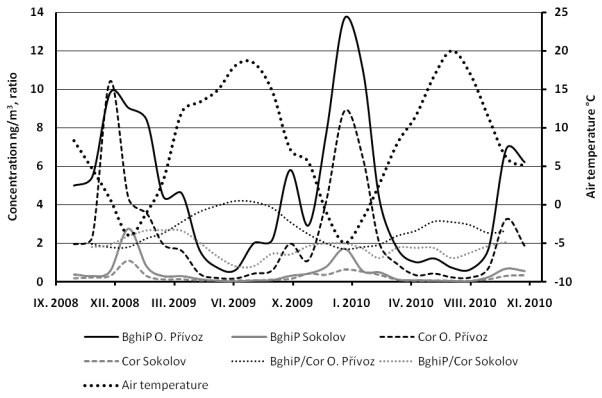

Figure 2. Monthly concentrations of benzo(g,h,i)perylene, coronene and the ratio benzo(g,h,i)perylene/coronene at O. Přívoz and Sokolov

Keywords: $PM_{2.5}$, Aerosol characterization, Inorganic Ions

Presenting author email: stefania.squizzato@unive.it

Pollution from fine particles is an important environmental risk factor for both human health and the possible effects on climate and ecosystems. In polluted urban environments, it affects human health and deteriorates visibility. On a global and regional scale aerosol particles and trace gases have the potential to change weather patterns and the hydrological cycle. Venice area is affected by several emission sources: (i) the medium size urban area of Mestre; (ii) the industrial zone of Porto Marghera; (iii) a crowded road-network; (iv) the artistic glass-making area of Murano; (v) the shipping traffic and (vi) the Marco Polo airport. To better and deeper understand air pollution in the study area, in particular $PM_{2.5}$ and the secondary inorganic aerosol fraction, a collaboration between Università Ca' Foscari Venezia and Ente della Zona Industriale di Porto Marghera started in 2008.

This study is focused on the detailed characterization of Water Soluble Inorganic Ions (WSII) and Secondary Inorganic Aerosol (SIA) on $PM_{2.5}$ in the Venice area. Three sampling sites in different environmental conditions were chosen to evaluate spatial variations: (i) Punta Sabbioni (PS, semi-rural-background costal site); (ii) Mestre-Via Lissa (VL, urban background site); (iii) Malcontenta (MC, industrial site) (fig. 1).

Twenty four hours samples were collected onto quartz fiber filters in all the sampling locations simultaneously, with a flow of 2.3 m^3 h^{-1} according to EN 14907. The experimental campaign has been developed in 2009 and then four periods have been selected to evaluate seasonal differences: (i) spring, 26th February - 3rd April; (ii) summer, 11th June - 16th July; (iii) autumn, 20th September -31st October; (iv) winter, 22nd December - 31st January.

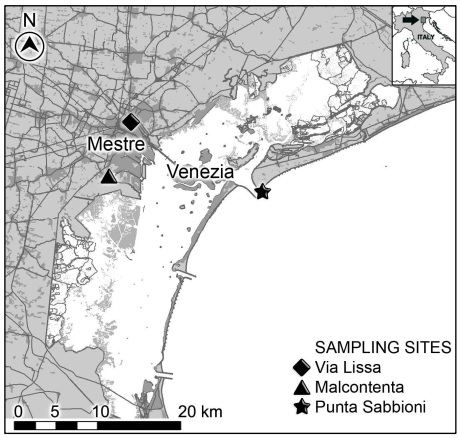

Figure 1. Sampling sites location.

Ultrasonic method was used to extract all filters for determination of inorganic ions by ion chromatography (Na^+, NH_4^+, K^+ Mg^{2+}, Ca^{2+}, F^-, Cl^-, NO_3^-, SO_4^{2-}).

Monthly average concentrations show a typical pattern with maximum values in cold season and minimum in warm season. Ammonium, nitrate and sulfate result to be major ions in $PM_{2.5}$ in all periods. Nitrate highest values have been detected in spring and winter. Sulfate presents maximum concentration in summer and autumn. On annual basis, results of the linear regression between NO_3^-+$nssSO_4^{2-}$ and NH_4^+ (expressed as neq m^{-3}) show a strong correlation (fig. 2). These results indicate that ammonium neutralizes almost completely sulfates and nitrates. Consequently, SIA fraction can be estimated as sum of NH_4^+, NO_3^- and $nssSO_4^{2-}$ masses. SIA mass shows similar values in the three sites but Punta Sabbioni presents the highest SIA% on $PM_{2.5}$ mass (36%).

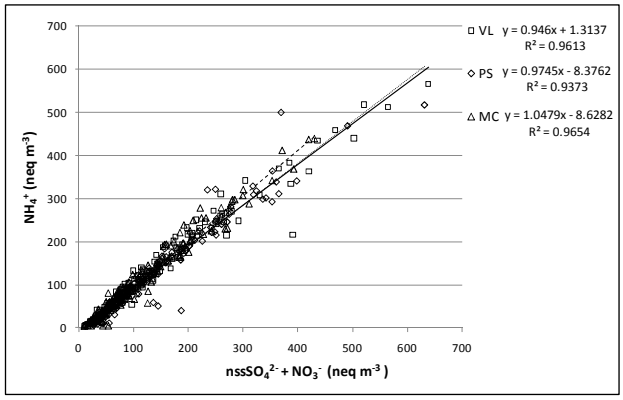

Figure 2. Regression between NO_3^-+$nssSO_4^{2-}$ and NH_4^+.

A Q-mode Hierarchical Cluster Analysis (qHCA, using Ward's method and the squared Euclidean distance measure) was performed to select groups of samples on the basis of their similar chemical composition. Then, each cluster has been interpreted according to local wind data. Preliminary results indicate that heavy pollution events were usually observed in days characterized by low wind speed and high % of wind calm hours.

Impacts of local atmospheric circulation on $PM_{2.5}$-bound Polycyclic Aromatic Hydrocarbons in three different emission scenarios in Venice-Mestre (Italy)

M. Masiol[1], A. Hofer[1], E. Centanni[1], F. Fiorotto[1], S. Squizzato[1], E. Pecorari[1], G. Rampazzo[1] and B. Pavoni[1]

[1]Dipartimento di Scienze Ambientali, Informatica e Statistica, Università Ca' Foscari Venezia, 30123, Venice, Italy

Keywords: GC-MS, Meteorology, PAH(s), PM2.5.

Presenting author email: masiol@unive.it

The occurrence of Polycyclic Aromatic Hydrocarbons (PAHs) in the urban atmosphere is demonstrated being a result of anthropogenic emissions from transportation, domestic heating, oil refining, waste incineration, industrial activities, asphalt production, burning of biomass, etc. Particulate-phase PAHs have recently received particular attention because of their diffused presence in the atmosphere and their potentially toxic, carcinogenic and mutagenic effects on humans (Ravindra *et al.*, 2008). Hence, most studies include these compounds in the analyses of priority pollutants for air quality management.

The whole Po Valley is recognized having the highest levels of airborne pollutants in Europe. Venice-Mestre is a large city located in the Eastern part of Po Valley with a population of more than 270,000 inhabitants. It hosts one of the most important industrial zones of Italy, including several chemical factories, waste incinerators and thermoelectric power plants.

This study presents some preliminary results of a one-year sampling campaign focused on the determination of 11 $PM_{2.5}$-bound PAHs collected in three different sites of Venice-Mestre area. These were selected to represent different emission scenarios and were categorized as urban background, industrial- and semi-rural-coastal site. The main aims of this study are: (i) to determine the level of selected congeners; (ii) highlight the most probable emission sources; (iii) investigate on the effects on PAHs levels of local meteorological conditions including air circulation; (iv) assess the human exposure to PAHs and the associated health risk.

About 180 daily samples were collected simultaneously at the sampling sites during Autumn (October, 2009) and Winter (December, 2009-January, 2010 according to EN 14907 standards. $PM_{2.5}$ masses were measured by gravimetric determination. 9 PAHs mainly associated to particle-phase, Benz(a)anthracene (BaA), Chrysene (Chr), Benzo(b)fluoranthene (BbF), Benzo(k)fluoranthene (BkF), Benzo(e)pyrene (BeP), Benzo(a)pyrene (BaP), Indeno(1,2,3-cd)pyrene (IP), Dibenzo(a,h)anthracene (DBahA), Benzo(ghi)perylene (BghiP), and 2 PAH congeners in particle-gas-phase, Fluoranthene (Fla), Pyrene (Pyr), were quantitatively determined using Gas Chromatography-Mass Spectroscopy after solvent extraction and clean-up on silica gel.

Results show for both $PM_{2.5}$ and PAHs significantly higher concentrations in the winter campaign. From PAHs profiles (percent contribution of each congener to $\sum_{11}$PAHs), it is evident that average molecular weight PAHs (Chr, BbF, BkF, BeP and BaP) largely prevail. Profiles for the Autumnal sampling campaign are presented in Figure 1.

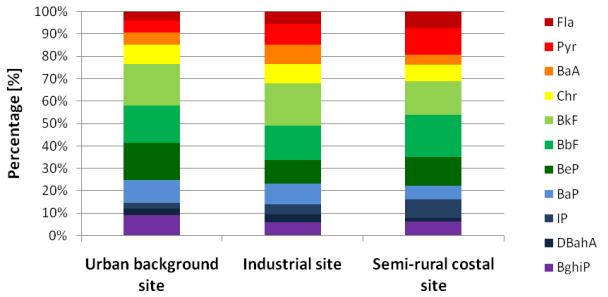

Figure 1. Representative PAHs profiles for each sampling site.

On the basis of diagnostic ratios and statistical analyses vehicular emission are the probable major source for PAHs. The analyses of seasonal variations and spatial distribution provide some interesting information on air quality in this highly polluted part of Southern Europe. A study of experimental data in combination with micro-meteorological conditions and atmospheric circulation patterns was conducted to evaluate the impact and the location of local sources. Results show that the levels of pollutants are strongly affected by local atmospheric circulation. In particular, the increasing of pollutants during winter is associated to air mass stagnation (low wind velocities) in the study area.

An estimation of BaP equivalent toxic and mutagenic factors highlighted a possible risk for humans due to PAH exposure. Results can also be useful to verify changes in air quality and probable source emissions in the Venetian region.

This work was supported by Ente della Zona Industriale di Porto Marghera. The authors also express thanks to Environmental Protection Agency of Veneto Region (ARPAV) for the valuable support and logistics.

Keywords: PM2.5, Source apportionment, Back trajectories.

Presenting author email: masiol@unive.it

The Po Valley expands over a great part of Northern Italy and is recognized as the most industrialized and populated region of Italy, hosting large cities, such as Turin, Milan, Verona, Boulogne and Venice-Mestre. Air quality is strongly affected by anthropogenic emissions and unfavourable weather conditions frequently trap pollutants. Air quality in Venice is influenced by local complex multi-emission sources, regional long-range transport of pollutants and a peculiar micro-meteorology due to the sea/land breezes (Masiol *et al.*, 2010). Target values for the fine particulate matter ($PM_{2.5}$) fixed by the directive 2008/50/CE are frequently exceeded. The urgent implementation of strategies to reduce the $PM_{2.5}$ levels is therefore mandatory. The identification of the various emission sources is one of the main goals of atmospheric research and plays a key role in formulating and applying $PM_{2.5}$ abatement strategies.

This study is a part of an extended project to characterize the $PM_{2.5}$ in the Venice area by coupling chemical analyses and modelling approaches. The main goal is to detect and quantify the contribution of local emission, aerosol generation processes and regional-scale transport episodes that may contribute to atmospheric pollution.

A one year-long sampling campaign was carried out in three sites characterized by different emission scenarios: urban background, industrial and semi-rural-coastal environments. This study presents the preliminary results for the Spring (March, 2009) and Summer (June-July, 2009) seasons. About 180 daily samples were collected simultaneously in all the sampling sites according to EN 14907 standards. $PM_{2.5}$ masses were measured by gravimetric determination. 9 inorganic ions (F^-, Cl^-, NO_3^-, SO_4^{2-}, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}), 18 elements (Al, Ca, Mg, Fe, K, Na, S, As, Ni, Cu, Cd, Pb, Mn, V, Zn, Ba, Ti, Sr) and 11 Polycyclic Aromatic Hydrocarbons (Fluoranthene, Pyrene, Benz(*a*)anthracene, Chrysene, Benzo(*b*)fluoranthene, Benzo(*k*)fluoranthene, Benzo(*e*)pyrene, Benzo(*a*)pyrene, Indeno(1,2,3-*cd*)pyrene, Dibenzo(*a*,*h*)anthracene and Benzo(*ghi*)perylene) were quantitatively determined using Ion Chromatography, ICP-OES, ICP-MS and GC-MS, respectively.

A preliminary source apportionment study was performed by using the principal component coupled with the multi-linear regression analyses, using absolute score factors as source tracers. Some independent $PM_{2.5}$ sources were identified and interpreted basing on the presence of tracers and the results of previous studies (Rampazzo *et al.*, 2008a;b; Masiol *et al.*, 2010): combustions, road dust resuspension, glass factories, secondary inorganic aerosol, marine aerosol. In a second step, the daily contribution of each source on the $PM_{2.5}$ mass was quantitatively assessed.

A cluster analysis on air mass backward trajectories was then performed to evaluate the influence of long-range transport on $PM_{2.5}$ mass and chemistry. Four main cluster of trajectories were extracted. Significant differences in air quality and air mass histories were found, showing that the levels of $PM_{2.5}$ increase when air masses move from Northern to Central and Northwestern Europe and a drop when the trajectories originate from the Mediterranean area. Heavy polluted episodes were found when air masses spend most time over the Po Valley.

Qualitative Source Identification of PAHs Using Diagnostic Compounds

E. Krugly[1], L. Kliucininkas[1], T. Prasauskas[1] and D. Martuzevicius[1]

[1]Department of Environmental Engineering, Kaunas University of Technology, Kaunas, LT-50254, Lithuania
Keywords: PM, PAHs, indoor, outdoor.
Presenting author email: edvinas.krugly@ktu.lt

Experiment

The sources of particulate-phase polycyclic aromatic hydrocarbons (PAHs) in ambient and indoor air in Kaunas, Lithuania were analyzed. The ambient and indoor particulate matter (PM) were sampled at two locations: Vydunas alley (Site 1, representing residential area) and Kestutis street (Site 2, representing city centre). Both sampling sites were located within 10 m from busy streets. PAH concentrations of outdoor (PM_4, $PM_{2.5}$, and PM_{10}) and indoor (PM_4) PM fractions were investigated during analysis period.

PM was collected on glass microfiber filters (GF/A, Whatman International Ltd., Maidstone, UK; diameter 25 mm, pore size 1.6 mm) over a sampling period of 8 hours. PM_4 fraction was sampled using a flow rate of 2.2 l min^{-1} (0.13 m^3 h^{-1}) by SKC Conductive Plastic Cyclones for respirable dust sampling with personal sampling pumps, as well as PM2.5 and PM10 cyclones (URG). PM mass concentrations (μg m^{-3}) were determined from the gravimetric analysis of samples, using a MXA5 microbalance (Radwag, Poland). Deposited particles were extracted from the filters by means of a Sonica ultrasonic extractor (Soltec Srl, Italy) in 3 mL of dichloromethane for 10 min. The extract solutions were filtered through Pasteur pipettes filled with Na_2SO_4, then concentrated by purging with ultra-pure nitrogen gas to 200–300 mL. The MS instrument (a 5973 model connected to a 6890N GC, both made by Agilent Technologies, Inc., Santa Clara, CA, USA) was operated in electron impact (EI) ionization, selected ion monitoring (SIM) mode. The GC column was a non-polar capillary column (60 m _ 0.32 mm id and 0.25 mm film thickness; J&W DB-5, Folsom, USA). 36 PAH compounds were determined.

Several methods for determining sources of PAHs by specific compounds have been published. In our study, diagnostic ratios method was used to analyze collected data on PAH concentrations on purpose to identify the sources of PAH formation (Ravindra et al, 2008). Diagnostic ratios of IdP/(IdP+BghiP) and Fla/(Fla+Pyr) demonstrates the prevailing sources of PAHs (Yunker et al, 2002). Retene has been suggested as an indicator of biomass burning and has a unique formation mechanism or environmental pathway (Li et al, 2009).

Results

The relationships of diagnostic ratios IdP/(IdP+BghiP) and Fla/(Fla+Pyr) are presented in Figure 1. Both sampling sites have revealed a clear urban transport-related source of PAHs emissions. This was actually expected, since both sampling locations were situated near busy streets. At the same time, in Site 1, which was situated in residential area with single family houses, the IdP/(IdP+BghiP) in $PM_{2.5}$ and PM_{10} fractions indicated PAH particles generated in individual heating boilers. This was also confirmed by peaking concentrations of Retene. Wood and coal are very commonly used fuels for heating individual houses in Kaunas. At the same time, in indoor environment, only petroleum-combustion compounds were identified.

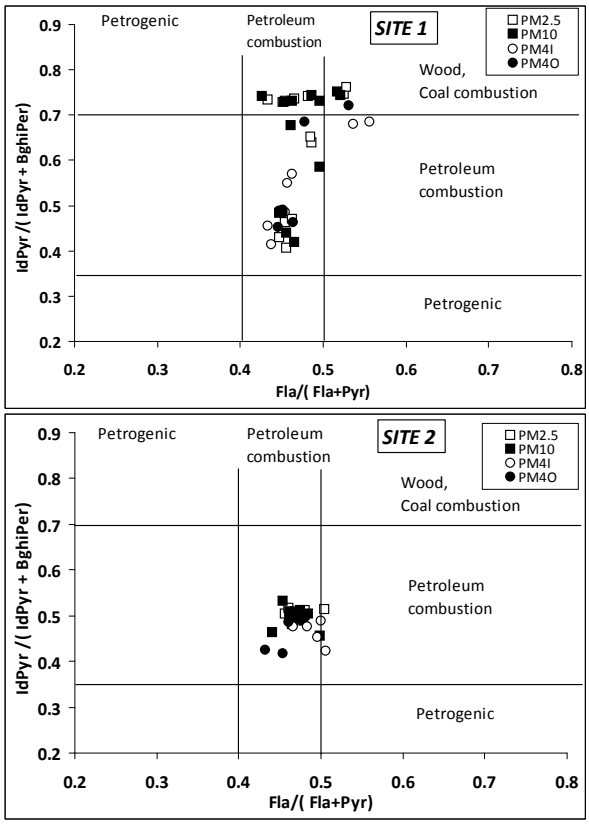

Figure 1. Interdependence of different phase praticles diagnostic ratios IdP/(IdP+BghiP) and Fla/(Fla+Pyr) in different sites .

Variability of PM10 concentrations at different types of locations in central Poland, 2007-2010

Janusz Jarosławski, Aleksander Pietruczuk and Izabela Pawlak

Institute of Geophysics Polish Academy of Sciences, ul. Księcia Janusza 64, 01-452, Warsaw, Poland

Keywords: PM10, air pollution.

Atmospheric PM10 is one of the air pollution components which concentration is difficult to control in respect of the fulfillment of air quality standards specified in the EU air quality Directives. This problem was noticed in Poland, where, after joining the EU, air pollution monitoring networks have been significantly expanded. This made possible to obtain more detailed information about the levels of main air pollutants such as PM10. After several years of measurements it was found, that air pollutants such as ozone, nitrogen oxides, carbon monoxide do not pose a risk from the standpoint of EU air quality standards. A different situation occurs in the case of particulate matter PM10. The concentration limits are exceeded for most analyzed stations especially in the winter season.

In this paper we present the results of measurements of concentrations of PM10 in the central region of Poland (Mazowieckie voivodship). The measurement data were collected in the period 2007-2010. Different types of stations (hot spot, urban, suburban, rural) appear in the analyzed area. Four of them are located in Warsaw, three in small or medium size cities up to 100 km from Warsaw and one is located in a rural area about 50 km southwest of Warsaw. All stations are equipped with TEOM ambient particulate monitor model 1400 expanded by FDMS module. Measurements were performed continuously. The daily means that are calculated from hourly means are used for data analysis.

Selected results of the measurements are shown in Tables 1 and 2 and Figure 1. Table 1 shows yearly means of PM10 concentrations for all stations in the analyzed area. It may be noted that similar levels of PM10 occur at all stations regardless of the type of station except one station with higher levels in Warsaw which is located on the road with heavy traffic (Wa2). The limit for annual average (40 μg/m3) is exceeded systematically at Wa2 station. Another air quality parameter which is not fulfilled, is the number of days with PM10 concentrations exceeding 50 μg/m3 per year (35). At all stations in the region, this limit is almost always exceeded (Table 2).

Figure 1 shows the monthly average concentrations of PM10 for the year 2009, which is typical when it comes to seasonal variations of PM10. One station (Wa2) has distinctly higher levels of PM10 due to position directly with a heavy traffic road, while for the other stations the concentrations of PM10 are very similar. This may indicate that PM10 concentrations are more the result of larger-scale phenomena such as the presence of long range transport than local sources of PM10.

Table 1. Annual mean concentrations of particulate matter PM10 in Mazowieckie voivodship (μg/m^3).

Source apportionment of trace metals in atmospheric aerosols in the United Kingdom

R. T. O'Donoghue[1], R.M. Harrison[1]

[1]Division of Environmental Health and Risk Management, University of Birmingham, B15 2TT, UK
Keywords: Source apportionment, PMF, long range transport.
Presenting author email: r.odonoghue@bham.ac.uk

Coarse ($PM_{2.5-10}$) and fine ($PM_{2.5}$) particulate matter (PM) was sampled and analysed for trace metals and SO_4^{2-} at an urban background site in Birmingham, United Kingdom. Daily 24 hour bulk samples were obtained and analysed for Al, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Cd, Sb, Ba and SO_4^{2-}. The sampling period ran for approximately 4 months, from 15/02/2010 to 10/05/2010. This time period coincided with the Eyjafjallajökull volcano eruption in Iceland.

To assess the data in relation to source apportionment, we applied positive matrix factorisation (PMF) using USEPA PMF 3.0. The uncertainty matrix applied to the PMF analysis was calculated based on literature guidelines (Tauler et al, 2009).

From the PMF analysis carried out on coarse PM, we identified 3 factors associated with dominant sources at the receptor site.

The first factor identified is associated with emissions from the nearby rail line. As the vast majority of traffic on this line is in the form of electric trains, any associated emissions are likely to be linked to steel and copper abrasion i.e. from tracks, wheels, brakes and the overhead traction line. Under such conditions the predominant emissions are Fe / Cu / Cr and Mn, all of which are present in considerable proportions in this factor.

The second factor determined in the coarse mode relates to road traffic non-exhaust emissions. The large contributions for Cu, Fe, Ba and Sb confirm this as the main source. These elements are typically associated with brake and tyre wear. To further corroborate that this factor is locally sourced and primarily associated with road traffic, we examined the plot of locally measured NOx against the daily factor contributions. From the results we deduced that the factor is indeed traffic related, the large scatter (R=0.46) observed is due to the emissions of NOx associated with hot exhaust compared to the brake and tyre wear emissions for the metals (in addition to re-suspension).

In relation to the third factor, it was determined that these concentrations are associated with regional transport of mainly naturally sourced species. The high concentrations of elements Mn, Fe, Al, Ti in this fraction seem to confirm the mainly crustal associations with this grouping. For the regional factor it is readily apparent from Figure 1, the increased relative contributions associated with the time period post 16/04/2010. The peaks observed in Figure 1 relate to the 16/04, 18/04, 21/04 and 22/04, a time associated with the volcano eruption of Eyjafjallajökull. Additional evidence was obtained associating this factor with the Eyjafjallajökull incident through the assessment of species ratios and correlations of daily factor contributions with regional wind directions. In addition, air mass backtrajectory analysis confirmed the air mass movements associated with the Icelandic volcano for these time periods. Finally, comparison between the regional factor concentrations and the Eyjafjallajökul plume composition suggested similar sources. From our analysis we estimated that if such an event occurred on a yearly basis, we could expect an approximate contribution of 2%, 4%, 4% and 3% to ambient coarse concentrations for the metals Al, Ti, Mn and Fe respectively.

Lastly, to compare behaviour across PM modes, we applied similar receptor modelling techniques to the fine PM fraction. The PMF analysis led us to positively identify 2 factors; a regional factor and a traffic and resuspension factor. The regional factor was associated with mainly SO_4^{2-} and primarily of anthropogenic origin. Most notably, compared to the coarse mode, we did not obtain any clear sources for the fine mode relating to the Eyjafjallajökul volcanic plume. This is perhaps not surprising bearing in mind the nature of the eruptive incident, which would likely emit any smaller particles higher into the atmosphere inhibiting their deposition over the UK due to the longer time period required for deposition.

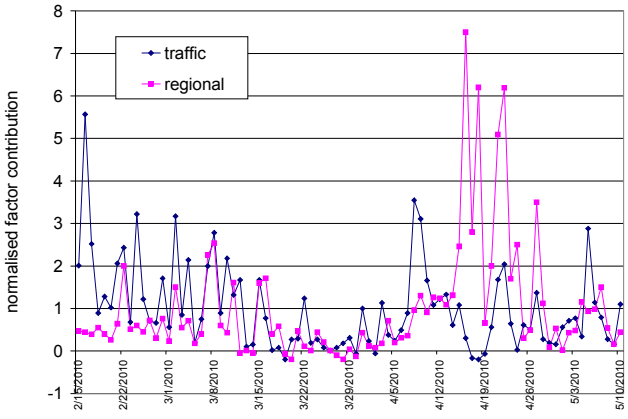

Figure 1. Normalised daily factor contributions for the traffic and regional coarse PM factors

Estimation of PM_{10} local sources contribution to background levels in an area of the Basque Country

Barrero M.A., Berasaluce A., Cantón L.

Department of Applied Chemistry, University of the Basque Country, 20018, San Sebastián, Spain

Keywords: PM10, spatial variation, major pollutants

Pollutant concentrations in a certain site are dependent mainly on the incidence of emission sources and meteorology and their relative strengths. Therefore, the evaluation of their concentrations simultaneously in several points in a region can yield relevant information about which are the main processes having influence on pollutant levels. This work focuses on the variations of PM_{10} and other major pollutants in six urban locations with different anthropogenic inputs placed in the surroundings of Donostia - San Sebastián, in the Basque Country.

A wintertime measurement campaign (from November to March) was carried out with mobile units of the Basque Government's Air Quality Monitoring Network that measured PM_{10} and major pollutants concentrations (CO, NO, NO_2, O_3, SO_2) and meteorological variables.

Time series of the daily PM_{10} concentrations were evaluated, showing a very similar evolution in the majority of sites. One of the sampling points exhibited high values of PM_{10} comparing with the other ones. Therefore, daily PM_{10} values showed significant, high correlations between sites (Fig.1), the lowest coefficients corresponding to that with high values of PM_{10} (about 0.80). This pointed to a common behaviour of PM_{10} concentrations which could be attributed to similar pollutant sources affecting the area and/or to the effect of meteorological phenomena, with little variations between sites.

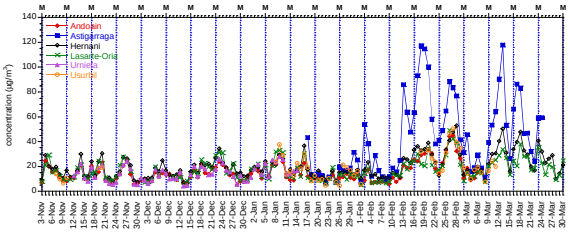

Figure 1. PM_{10} concentration time series in the different sampling locations. M = Monday.

An "area background" daily PM_{10} level was defined, and local contributions were identified using the concentrations of the other major pollutants as some of the "local" PM_{10} peaks were coincident with maxima of other primary pollutants such as carbon monoxide or nitric oxide.

The "area background" contribution to regional background PM_{10} concentration was 8.27, 5.77 and 2.89 $\mu g/m^3$ for working days, Saturdays and Sundays respectively.

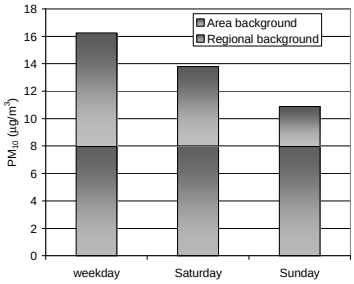

Figure 2. Average levels of PM_{10} regional and "area" background in the study area on weekdays and weekend days.

As well as the "area background" daily levels, the diurnal patterns of the pollutants clearly reflected the incidence of anthropogenic (weekdays-weekend differences).

Bioaerosols & air quality testing with an innovative microbial air sampler

Brossard-Desjonqueres Q

[1]Bertin technologies – CNIM Group, 10 avenue Ampère, Parc d'activité du Pas du Lac, 78180 Montigny le Bretonneux, France

Keywords: Air sampling, aerobiocontamination, cleanroom, indoor air quality, *Stachybotrys*, *Aspergillus*

Presenting author email: brossard@bertin.fr

In the context of indoor air quality and environmental bio-contamination control, Bertin Technologies (France) has developed a technology dedicated to the monitoring of airborne bio-particles. The goal is to propose a sampling method compatible with Rapid Microbiological Methods to get reliable and specific data about the airborne biocontamination (bacteria, molds, pollen, viruses, endotoxins…) in any environment. With this cyclonic technology, airborne particles are separated from the air and collected into a sterile liquid media which is compatible with Rapid Microbiological Methods (RMM) such as immunoassay, PCR assay, Cytometry. This tackles the drawbacks of the traditional impaction method by significantly reducing the time-to-result, providing more information than only cultivable flora (VNC, viruses, allergens…) and avoiding the saturation of the collection media.This sampler is validated according to ISO14698-1 (Health Protection Agency HPA, Porton Down, UK). With the Coriolis® technology, many studies have been carried out to detect bacteria, viruses, pollens, allergens or non-cultivable pathogens. Different applications using Coriolis can be presented.

In one study, an audit on the air quality at workplace was carried out following to employees' complaints headaches and respiratory troubles. Suspicious contamination of *Stachybotrys chartarum,* notorious producer of mycotoxin which is often associated with the "sick building syndrome" was found out to be the cause. Sampling with the Coriolis® revealed the presence of *Stachybotrys chartarum* which is hardly detected by traditional method.

As for air contamination control in pharmaceutical cleanrooms, RNSA Laboratory (France) carried out an investigation in which pollen were identified in the culture supernatant of a pharmaceutical laboratory. Yet these contaminants were not detected by traditional impaction methods. The implementation of an active air sampler and RMM methods were shown to be essential in this case to avoid contamination incidents.

Monitoring of bioaerosol emissions and related risk assessments are indispensable for waste treatment facilities where microorganisms are highly concentrated. Agar plates get quickly saturated and often results in the underestimation of the level of microorganisms. UK's National Physical Laboratory (NPL) developed a new method dedicated to the study of the presence of *Aspergillus* released from composting process. This method combines Coriolis® with subsequent qPCR determination, which produces reliable results within a few hours.

RMM and cyclonic air sampling open up a new horizon for bio-contamination control, and lead a way to a most efficient microbiological monitoring for the well-being of human and the safety of products.

[5] Department of Mineral Resources Engineering, Technical University of Crete, Chania, Greece

Keywords: PM_{10}, $PM_{2.5}$, mass concentration, Saharan dust events.

Particulate matter (PM) measurements were performed during the period 2003 – 2009 at the Akrotiri monitoring station on the island of Crete, Greece. The objective of the study was to determine the ambient mass levels of PM on continuous basis and their chemical composition at selected time intervals. Emphasis was given to the analysis of pollution events due to transportation of particulate matter form Northern Africa (Sahara dust events), since they have an influential impact on the atmospheric composition and dynamics on the Mediterranean area.

The measurements were performed at Akrotiri, a suburban area of the city of Chania, Crete (Lazaridis et al., 2008). It is a coastal site at an elevation of 137 m from sea level.

The PM mass concentration was continuously measured using an automatic beta radiation attenuation monitor. The head of the instrument was changed at selected time intervals and measurements of PM_{10} and $PM_{2.5}$ particles were performed. Meteorological data were collected on continuous basis as well. The path that the air masses travelled before arriving at the station was estimated using back trajectories provided by the HYSPLIT model. In addition, the PM mass size distribution of metals, ions and organic carbon / elemental carbon (OC/EC) was characterized using an 8-stages cascade impactor and a gravimetric sequential particulate sampler during two selected periods.

The mean PM_{10} mass concentration during the measuring period (01.01.2003 – 31.12.2009) was equal to 36.1 ± 9.5 μg/m^3, whereas the $PM_{2.5}$ mass concentration was equal to 23.6 ± 5.8 μg/m^3. Figure 1 shows the monthly averaged PM_{10} and $PM_{2.5}$ concentrations and the corresponding standard deviations. As it is depicted in Figure 1, throughout the winter period (mainly during the months January and December) both PM_{10} and $PM_{2.5}$ mass concentrations were lower than the corresponding mass concentrations in other seasons.

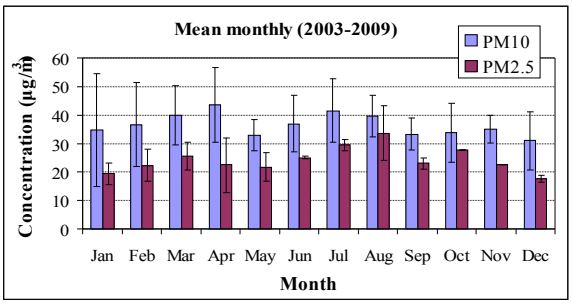

Figure 1: Mean monthly PM_{10} and $PM_{2.5}$ concentrations (in period 2003-2009).

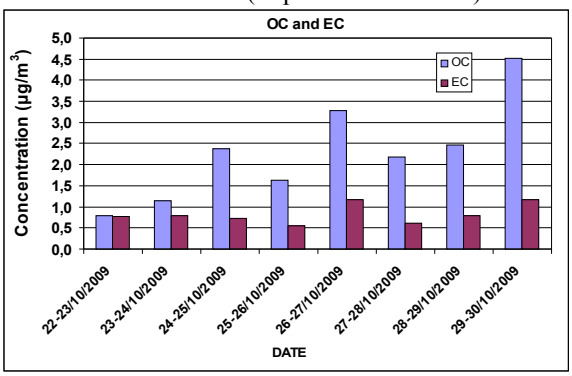

Figure 2: Mean PM_{10} concentrations for EC and OC.

An example of the chemical composition measurements is shown in Figure 2 which depicts the mean 24-h PM_{10} concentration for EC and OC for a selective measurement period (October 2009). During this measurement period (except at 22-23/10/2009), OC had a mean 3 times higher concentration than EC (OC/EC = 2.8 ± 1.0).

Furthermore, several major Saharan dust events were identified in the region of west Crete. The 24-h limit value of PM_{10} mass concentration (50 μg m^{-3}) was exceeded approximately by 14 % throughout the whole measurement period. On the other hand, the lowest daily PM concentrations were measured during intense storm events.

CHEMKAR PM10 'wood burning'
A year-long chemical characterization of PM_{10} in Flanders (Belgium) with a focus on the contribution of wood burning

J. Vercauteren[1], C. Matheeussen[1], E. Roekens[1], R. Vermeylen[2], W. Maenhaut[2] and M. Claeys[2]

[1] Flemish Environment Agency (VMM), Kronenburgstraat 45, 2000 Antwerpen, Belgium
[2]University of Antwerp (UA), Dept. of Pharmaceutical Sciences, Universiteitsplein 1, 2610 Antwerpen, Belgium

Keywords: PM_{10}, wood burning, levoglucosan, EC/OC

Presenting author email: j.vercauteren@vmm.be

From February 2010 to February 2011 the Flemish Environment Agency (VMM) carried out its third "*Chemkar PM10*" project. Just like the two previous projects this was a large scale chemical characterization project of PM_{10} in Flanders (Belgium). The focus of the current project was mostly on the contribution of wood burning. Although the two previous Chemkar projects[1] had shown that organic matter (OM) is the second most important fraction of PM_{10} (approx. 20%), little is known about the average contribution of wood burning to this fraction in Belgium.

Setup:

During one full year PM_{10} was sampled simultaneously on every 4th day at 7 monitoring sites with different characteristics resulting in **about 700 samples** (including field blanks). The sites are listed below with a short description:

- **Houtem** (rural background near coast)
- **Gent** (urban background)
- **Hamme** (rural background)
- **Borgerhout** (urban background)
- **Mechelen** (suburban background)
- **Lier** (rural background in horticulture area)
- **Retie** (rural background)

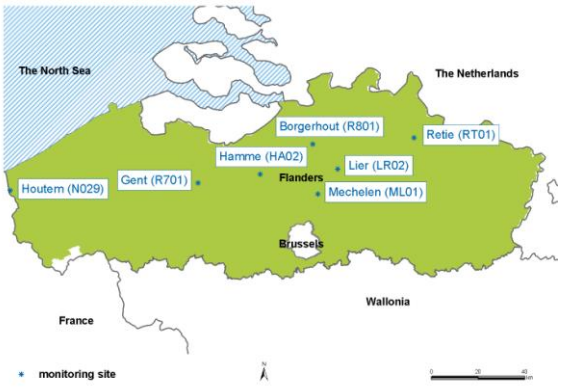

Fig 1: Location of the project sampling sites

Sampling was done for 24h with one Leckel SEQ 47/50 low volume sampler at 2.3 m^3/h on 47mm Pallflex® Tissuquartz™ 2500 QAT-UP filters. After sampling the PM_{10} mass concentration was determined by dual weighing of the filters according to the European reference method EN14907. Next, the filters were punched for chemical analysis and stored at -18°C until analysis. One punch (1.5 cm^2) was used for the determination of **elemental and organic carbon** (thermal/optical transmittance) with the NIOSH protocol. Another punch (1 cm^2) was used for determination of **levoglucosan** by means of GC/MS after derivatisation with *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) containing 1% trimethylchlorosilane (TMCS).

Preliminary results:

Results for the first four months of the project (Feb-May) show average levoglucosan concentrations between 0.08 en 0.30 µg/m^3 and daily maxima up to 1.6 µg/m^3.

[Wood burning OM] = [levoglucosan] x 7.35 x 1.4

The common conversion factors[2] above were used to calculate wood burning OC and OM. The **average 'wood burning OM'** concentrations were in the range of **0.8 - 3.0 µg/m^3** and maximum daily values for the various sites were between 4 and 16 µg/m^3. The highest concentrations were measured in Hamme, where there are some known sources of domestic wood burning.

Based on these preliminary results, estimates suggest that the average relative contribution of wood burning to total organic matter is in the range of 15-40%, and that the average contribution of wood burning to total PM_{10} is in the range of 3-8%. The latter value is comparable to the contribution of diesel soot in Flanders.

Results of the full project and additional analysis of the data will be presented at the conference.

A new integrated device for on-board particle measurements: Sampling system

T. Tzamkiozis[1], L. Ntziachristos[1], E. Lamminen[2], V. Niemelä[2] and Z. Samaras[1]

[1]Laboratory of Applied Thermodynamics, Aristotle University of Thessalonica, Greece
[2]Dekati Ltd., Tampere, Finland
Keywords: PEMS, PFSS, sampling, on-board, EPONIMOS.
Presenting author email: thtzam@auth.gr

The European Commission introduced the Particle Measurement Programme (PMP) to develop a rigorous sampling and measuring system that would be suitable to regulate the number of particles emitted by vehicles. In addition to type approval testing, advanced sampling and real-time measuring systems will also be employed in portable emission measurement systems (PEMS) for testing the in-use-compliance of heavy duty vehicles. Currently available aerosol instrumentation has not been developed to be exposed in the hostile, real-word environments of vehicle or engine testing. In addition, the constant-flow sampling systems, which are usually employed for this kind of applications, suffer from sensitivity in exhaust pressure fluctuations, being unable to retain a constant dilution ratio (DR).

This work presents a new, simple concept of an on-Board Sampling System (BOSS), which leads to constant DR sampling, independently of exhaust gas pressure and pressure variations. BOSS is consisted of two cascaded stages (primary and secondary), each involving a capillary and a stabilization chamber. The sample is drawn by the primary capillary, due to the under-pressure maintained in the stabilization chamber by means of a pump. Pressure difference between ambient and the primary stabilization chamber forces air to enter the latter. The dilution air has been purified before entering the chamber, while a throttling valve can be used for the regulation of its flow-rate. The capillary diameter is 550 um (prototype), hence, BOSS samples only a very small fraction of the exhaust gas (in the order of 1 lpm), according to Ntziachristos *et al* (2008).

Due to the very small exhaust gas quantity sampled, no tight fixation between the capillary and the exhaust line is required. The capillary is fully surrounded by the exhaust gas, which freely exhausts to ambient pressure, through an opening in the exhaust line. In this way, the capillary inlet is always exposed to exhaust gas of ambient pressure, regardless of the gas pressure inside the exhaust line. Since the inlet and outlet of the capillary are exposed to constant pressure conditions, the sample flow-rate and, therefore, the DR remain constant during the measurement.

The prototype BOSS has been tested regarding the stability and absolute level of the DR against a commonly used sampling system, i.e. an FPS-4000 (Dekati Ltd., Tampere, Finland) cascaded with an ejector diluter (ED) of the same company. To this aim, a turbocharged Euro 3 common rail unit of 2.2 l capacity was employed, also equipped with exhaust gas recirculation. The DR of both systems was determined by measuring the CO_2 concentration at raw exhaust and at their outlets. The engine operated at various steady-state modes.

Figure 1 shows that the DR of the BOSS remains quite constant (CV=1%) and unaffected by the pressure variations in the exhaust line. This characteristic combined with key features like low power consumption (less than 0.5 kW) and small size, make it the ideal candidate for PEMS.

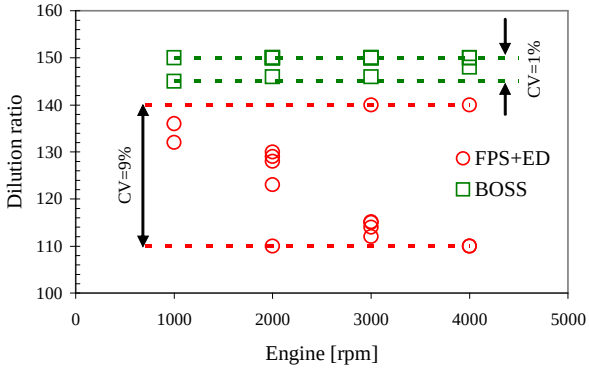

Figure 1. BOSS is compared to a commonly used sampling system, available in the market.

To this direction, the Laboratory of Applied Thermodynamics launched a co-operation with Dekati Ltd. in the framework of a Marie Curie action, in order to develop a PEMS candidate, employing this technique. The system is intended to be used for aerosol sampling on-board the vehicles. The results of this co-operation are demonstrated in Figure 2, where some initial designs of the parts, which will be used for the attachment of the BOSS to the exhaust line, are depicted.

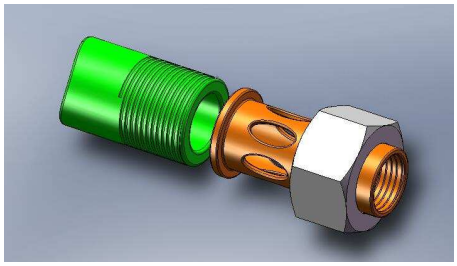

Figure 2. 3D depiction of BOSS parts

This work is supported by the Seventh Framework Programme under Grant Agreement no. 218149.

The twenty two inorganic elements such as iron, manganese, nickel, lead, carbon, nitrate, sulfate were determined from selected $PM_{1.0}$, $PM_{2.5}$ and PM_{10} samples collected at three monitoring sites near iron and steel complex of Pohang city during different seasons from March 2009 to February 2010. Pohang is the largest industrial city producing iron and steel in Korea and has distinguishing chemical composition in the airborne particular matter. The aim of this study is to detect the seasonal and diurnal variations of the size distribution and chemical compositions of PM related to iron and steel industry. The sample collections of daily $PM_{1.0}$, $PM_{2.5}$ and PM_{10} were carried out every fifteen days for each season.

Table 1. Summary of mean concentration at three monitoring sites in four seasons.

unit : ug/m3

Season	Site	$PM_{1.0}$	$PM_{2.5}$	PM_{10}
Spring (Apr.)	S1	25.1	41.3	67.5
	S2	22.6	35.2	52.2
	S3	27.3	39.4	55.6
	Mean	25.0	38.6	58.4
Summer (Jul.)	S1	23.7	36.7	58.9
	S2	17.9	25.6	40.1
	S3	22.4	34.7	45.4
	Mean	21.3	32.3	48.1
Fall (Oct.)	S1	21.8	38.5	60.6
	S2	20.4	30.9	47.2
	S3	26.7	37.1	51.1
	Mean	23.0	35.5	53.0
Winter (Jan.)	S1	27.9	43.2	62.9
	S2	19.4	27.6	48.4
	S3	22.2	34.7	50.7
	Mean	23.2	35.2	54.0
Annual mean	S1	24.6	39.7	62.5
	S2	20.1	29.8	47.0
	S3	24.7	36.5	50.7
	Mean	23.1	35.4	53.4

The average mass concentrations of $PM_{1.0}$, $PM_{2.5}$ and PM_{10} at three monitoring sites were 23.1 ug/m^3, 35.4 ug/m^3 and 53.4 ug/m^3, respectively. $PM_{2.5}$/ PM_{10} and $PM_{1.0}$/ PM_{10} of three monitoring sites ranged from 0.63 to 0.72 (average 0.66) and $PM_{1.0}$/ PM_{10} ranged from 0.39 to 0.49 (average 0.43). S1, S2 and S3 monitoring sites is located at industrial area, residential area and traffic area, respectively.

Table 2 shows the average concentration of major components in $PM_{1.0}$, $PM_{2.5}$ and PM_{10} at S1 monitoring site. The concentration of components such as arsenic, lead, cadmium, chromium, nickel and nitrate in $PM_{2.5}$ were above 70% of PM_{10}. In contrast, the concentration of aluminum, iron, sodium and calcium in $PM_{2.5}$ were below 30% of PM_{10}. The concentrations of most components in PM1.0 were above 70% of $PM_{2.5}$ except sodium, nitrate and sulfate.

Table 2. The average concentration of major components in PM at S1(industrial area) monitoring site.

unit : ng/m3

Chemical characterization of PM_{10} and trace gas measurements with the online-system MARGA at the research station Melpitz in Germany

B. Fahlbusch[1], G. Spindler[1], A. Grüner[1], M. Wallasch[2] and H. Herrmann[1]

[1]Leibniz-Institut für Troposphärenforschung e. V., Permoserstr. 15, 04318 Leipzig, Germany
[2]Umweltbundesamt, Wörlitzer Platz 1, 06844 Dessau-Roßlau, Germany

Keywords: PM_{10}, Instrumentation, Long-range transport, Tropospheric aerosols, Chemical composition

Presenting author email: fahlbusch@tropos.de

In this study the new sampling system MARGA (***M***onitor for **Aer**osols & **G**ases in ambient **A**ir, Applikon Analytical, NL, *ten Brink et al., 2007*) was connected to a PM_{10} inlet to measure the mass concentrations of the water-soluble ions Cl^-, NO_3^-, SO_4^{2-}, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+} and their corresponding trace gases HCl, HNO_2, SO_2, HNO_3 and NH_3 at a time resolution of one hour. Measurements were carried out for more than one year (October 2009 – January 2011) at the research station of the Leibniz Institute for Tropospheric Research in Melpitz, Germany (12°56'E, 51°32'N, 86 m a.s.l.). The station is located 50 km north-east of the city of Leipzig near the river Elbe in a flat terrain surrounded by agriculture land without wind obstacles. Melpitz is an urban background site in Europe. Two main wind directions are influencing the station: Wind from the south-west transports maritime air after crossing a large area of Germany. The second main wind direction is east with anthropogenic polluted air masses from eastern Europe (long-range transport, *Spindler et al., 2010*).

The hourly PM_{10} MARGA measurements were analyzed with consideration of the meteorological conditions (relative humidity, temperature and wind direction).

The data set obtained by the MARGA was compared with results of gas monitors (UV-fluorescence for SO_2 and cavity-ring-down spectroscopy for NH_3) and with daily filter samples (HV-DIGITEL DHA-80 sampler with a PM_{10}-inlet and quartz-fibre filter by Munktell, Sweden) to evaluate the new measuring system.

The SO_2 concentration of the MARGA and the gas monitor are in very good agreement. The comparison between the MARGA and a NH_3 gas monitor (Picarro G1103), however, shows significant differences due to a particle filter inside the Picarro system. The filter is needed to guard the measuring cell against particles. But NH_3 can evaporate from the particles collected on this filter due to the volatility of NH_4NO_3 and generate positive artefacts.

A good agreement was observed for the concentrations of NH_4^+ and SO_4^{2-} between filter and MARGA measurements. Discrepancies occurred during the summer month for the nitrate concentration. NO_3^- measured by the MARGA was on average two times higher than the concentration determined by the filter-based method in July 2010. Again this artefact of the filter measurements can be explained with the volatility of NH_4NO_3. During months with high mean temperatures the corresponding trace gases HNO_3 and NH_3 evaporate from the particle phase collected with the filter. During the winter this artefact is not detected (figure 1).

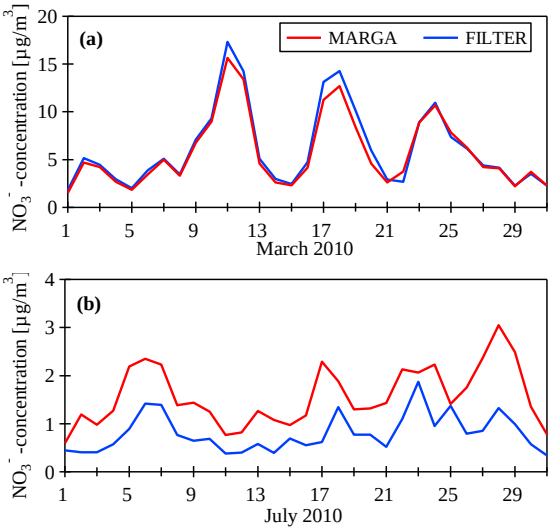

Figure 1. Nitrate measurements in PM_{10}. Comparison of daily High-Volume filter measurements (quartz-fibre filter, DIGITEL DHA-80, blue line) with MARGA measurements (red line) in (a) March 2010 and (b) July 2010.

Aerosol-based Nanotechnology

Oxidation of C_{60} aerosol by ozone

A. J. Tiwari[1] , E. D. Davis[2], Y. Zhang[2], J. R. Morris[2], and L. C. Marr[1]

[1]Department of Civil & Environmental Engineering, Virginia Tech, Blacksburg, Virginia, United States
[2]Department of Chemistry, Virginia Tech, Blacksburg, Virginia, United States
Keywords: nanoparticles-characterization, carbon oxidation, ultrafine aerosols, nano-DMA
Presenting author email: ajtiwari@vt.edu

In studies that have explored the potential environmental impacts of manufactured nanomaterials, the atmosphere has largely been viewed as an inert setting that acts merely as a route for inhalation exposure. Carbonaceous nanoparticles, such as C_{60} fullerenes, will enter the atmosphere during production, use, and disposal (Yeganeh *et al.*, 2008). Rather than simply being transported, they will be subject to physical and chemical transformations which could modify their cross-media transport from the atmosphere to terrestrial and aqueous ecosystems, as well as their fate, transport, bioavailability, and toxicity within those ecosystems. In one such transformation, it is likely that C_{60} fullerenes will become oxidized in the presence of ozone (O_3).

The objective of this research is to determine the products and rates of reaction of aerosolized C_{60} with atmospherically relevant concentrations of ozone. Batch reactions are carried out in a $6m^3$ Teflon chamber using ozone concentrations from 40 – 120 ppb. C_{60} aerosol is introduced into the chamber through atomization of an aqueous suspension prepared by stirring C_{60} in water without surfactants or transfer solvents, a method that is believed to produce more environmentally relevant form of C_{60}. Aerosol samples are collected from the chamber onto filters, gold slides, and TEM grids for offline analyses.

Analytical techniques employed include infrared spectroscopy (RAIRS), liquid chromatography (HPLC), UV-Visible absorbance spectroscopy (UV-Vis), and transmission electron microscopy (TEM). Additionally, online techniques include a scanning mobility particle sizer (SMPS) to monitor the evolution of the particle size distribution and an ozone analyzer to monitor ozone consumption during the reaction.

Results

X-ray photoelectron spectroscopy (XPS) analysis indicates that the aqueous C_{60} suspension resulting from stirring in water contains less than 10% oxygen, as shown in Table 1. This oxygen is primarily attributable to hydroxyl groups on the surface of C_{60} aggregates, affording them enough hydrophilicity to exist stably in aqueous suspension (Labille *et al.*, 2009).

Figure 1 shows an infrared spectra of C_{60} aerosols exposed to ozone. In addition to two of C_{60}'s characteristics peaks (1182 cm^{-1} and 1429 cm^{-1}), the formation of the $C_{60}O$ epoxide and various carbonyl groups is suggested by peaks at 1461 cm^{-1} and in the 1700 cm^{-1} range (Cataldo 2008).

Table 1. Oxygen content of C_{60} sample before and after preparation of aqueous suspension.

C_{60} Processing Stage	% C	% O
As received	94	6
After stirring	91	9

Results from complementary analytical methods are expected to verify the identities of epoxides and carbonyls, to allow calculation of reaction rates, and to describe C_{60} aerosol size and morphology before and after ozonation.

Keywords: Nanoparticles, Occupational exposures.
virgomez@unizar.es

There is a growing interest in the impact of engineered nanoparticles (ENPs) on the human health and environment. Because of their reduced size (less than 100 nm), ENPs pose hazards that cannot be tackled with the conventional industrial safety and hygiene methods without further considerations [1].

Among the most common ENPs used for technological applications, the TiO_2 ENPs were chosen as test nanoparticles. This increases the interest on discriminating the TiO_2 ENPs from the naturally occurring TiO_2 in the environment. An effective way to distinguish this contribution to the total concentration of nanoparticles in air streams is labeling the TiO_2 ENPs with trace amounts of lanthanides that could be easily identified using online and offline analysis techniques.

Microwave radiation has been applied to synthesize different nanomaterials. The synthesis procedure of Ce-TiO_2 ENPs combines a sol-gel processing followed by microwave treatment. This procedure leads to anatase ENPs avoiding the aggregation due to high temperature treatments. Monodisperse Ce-doped anatase ENPs were prepared from titanium tetraisopropoxide. Several Ce(III) amounts were added using $Ce(NO_3)_3$ as precursor up to 0,5, 1, 3, 6 and 9% Ce/Ti atomic ratio. The synthesized Ce-TiO_2 ENPs were analyzed by XRD, TEM, SEM, EDX, N_2 adsorption, UV-VIS and DLS. XRD patterns show the characteristic anatase diffraction peaks. Regardless the amount of Ce doping, no signals of Ce (III) or Ce(IV) oxide were observed. The morphology of Ce-TiO_2 samples can be seen in the TEM images of Figure 1, which show homogenous particle shapes together with an average particle size about 15 nm. Ce 4d XPS spectra of nanoparticles with 0.5, 1 and 3 % Ce/Ti atomic ratio are also shown in Figure 1.

In a set of experiments, a certain mass of 3% Ce TiO_2 ENPs powder is added for ten consecutive portions of similar mass with a spatula to a glass flask. During the experiment, the nanoparticle aerosol formation is alternatively monitored with a Condensation Particle Counter (CPC, Grimm) and an Optical Particle Counter (OPC, Grimm). As the CPC and OPC take the aerosol from the chamber at 0.3 and 1.2 l/min, the same flow of HEPA-filtered clean air is added during the experiment.

In Figure 2 is showed the real time aerosol evolution using the OPC in the closed environment. Every added portion of the test can be seen in the time evolution as peaks in the ENP number concentration in the experiment chamber. It is also worth noticing that the highest ENPs increase corresponds to those between 300 to 400 nm of aerodynamic particle size. Larger size ENPs show a moderate increase up to the end of the test. The almost total elimination of ENPs from the chamber is achieved in 3 h.[3] rise during nanopowder additions. The fraction of small-size ENPs, between 5 to 10^3 nm detected with the CPC is about thousand of millions of particles.

The TiO_2 ENPs from laboratory aerosols can be therefore identified using this labeling procedure. This procedure could be used as an adequate method to detect, analyze and identify ENPs in occupational enviroments, which are needed in the risk assessment schemes in nanotechnology.

Keywords: Nanoparticle, characterisation, flame spray, exposure
Presenting author email: jussi.lyyranen@vtt.fi

In this work a liquid flame spray process called nHALO® (hot aerosol layering operation) producing engineered nanoparticles (ENPs) used for coating and surface modification of materials was studied. The process reagents, which are usually nitrate salts and water or alcohol as carrier, are vaporised in a hydrogen-oxygen flame. In the flame, particles nucleate and grow via condensation and coagulation into nanosized particulate matter. The produced particles may be metal, metal oxide or multicomponent. The process was installed inside an enclosure to minimise particle emissions into the surroundings. The focus of the research was to characterise the particles inside the enclosure, in the surroundings and at the exit points of the enclosure where the workers may be exposed to the engineered particles.

Particle number concentration was measured with a TSI 3022 CPC and number size distribution with a TSI 3080 electrostatic classifier with a TSI 3085 Nano-DMA connected with a TSI 3775 CPC and controlled by the SMPS software and with an ELPI. Mass concentration was measured with a TEOM 1400a. Individual particle samples for electron microscopy (EM) analyses were collected with an aspiration EM sampler.

Average particle number concentration inside the enclosure varied from $1.0 \cdot 10^4$ to $2.1 \cdot 10^5$ 1/cm^3 and average mass concentration from 1.2 to 2.6 mg/m^3 during process operation. The highest particle concentration was observed when the furnace was heated and when the flame was on. The high peaks in the number concentration levelled out rapidly indicating a batch-type process and efficient ventilation inside the process enclosure (Fig. 1a). It should be noted that the process enclosure was not occupied by the workers.

Particle number concentration in the surroundings was typically $6.0\text{-}8.0 \cdot 10^3$ 1/cm^3, and average mass concentration 66 µg/m^3. It is noteworthy, that after the door opening at around 14:40 (scaled time), the particle number concentration stayed at higher level than before the door opening (white line in Fig. 1a). This was probably caused by the opening of the door to the enclosure at 14:56, 15:05 and 15:55 (Leppänen, et al.).

Comparing the number and mass concentration in the surroundings to the enclosure concentrations during the nHALO® process it was evident that the ventilated enclosure worked well in isolating the particle source from the surroundings.

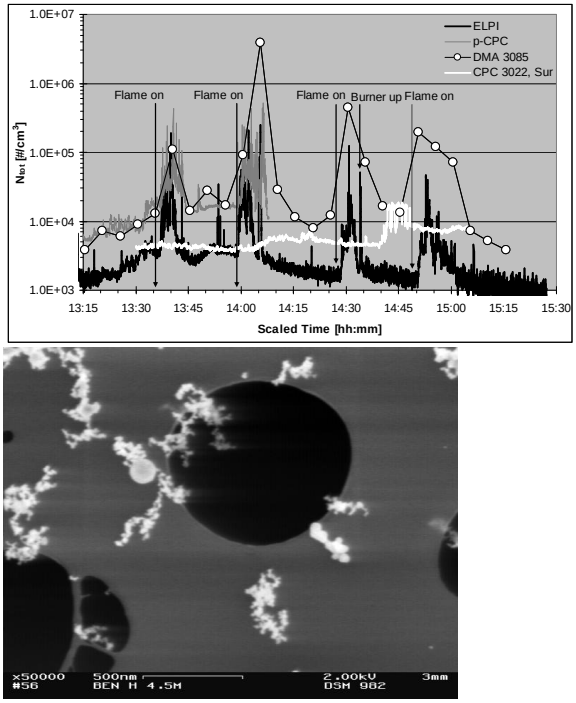

Figure 1: a) Particle number concentration for nHALO® inside the process enclosure and in the surroundings (white curve, scaled time) b) A scanning electron microscope (SEM) micrograph of the collected nanoscale particles from inside the enclosure. Particles were mainly aggregates, primary particle size approximately 20-30 nm.

This work was supported by the Finnish Funding Agency for Technology and Innovation, Beneq Oy and The Federation of Finnish Technology Industries.

Synthesis of copper nanoparticles by photochemical process

N. Nishida, A. Miyashita, and H. Tanaka

Department of Applied Chemistry, Faculty of Science and Engineering, Chuo University,
1-13-27 Kasuga, Bunkyo-ku, 112-8551, Tokyo, Japan
Keywords: Copper nanoparticle, optical property, photochemical process, STEM
Presenting author email: nnishida@kc.chuo-u.ac.jp

Since atmospheric nanoparticles are well known to be usually generated by sunshine, investigations of the generation of nanoparticles by photochemical process are regarded to be important in the basic nanoscience and applied nanotechnology. In addition, copper nanoparticles are also regarded to be important because of their high electrical, thermal conductivities and low cost. In this study, we have investigated synthesis of copper nanoparticles with single nanometer sizes by photoreduction of copper acetate at room temperature.

A detailed description of the experimental setup for nanoparticle production has been given elsewhere [1]. Copper acetate powder and PVP powder (polyvinylpyrrolidone, K = 15, Mw = 10000) were dissolved in ethanol. The mixed solution was photoirradiated using a high-pressure Hg lamp at room temperature.

When the solution was photoirradiated, blue color of the copper acetate changed to yellow. The more photoirradiation led the color deeper, and the color had finally turned deep red.

Figure 1 shows absorption spectra with photoirradiation at 0, 1, 5, and 18 h. In the spectrum at 0 h, a broad peak is observed at ~700 nm. This peak is ascribed to the Cu^{2+} ions. On the other hand, in the spectrum at 1 h, the broad peak at ~700 nm disappears. This disappearance indicates that the Cu^{2+} ions were reduced to Cu metal by photoirradiation.

In the spectrum at 5 h, a broad peak is observed at ~570 nm. This broad peak is ascribed to surface plasmon band for copper nanoparticles. Furthermore, in the spectrum at 18 h, this peak is prominently observed. These facts indicate that the nanoparticles were formed and grown by photoreduction. Additionally, the STEM observation supports that most of the nanoparticles were smaller than 10 nm indicator. Furthermore, the observed diameter for the nanoparticles depends on the concentration of copper acetate, implying that the observed nanoparticles are composed of copper atoms photoreduced from the copper acetate.

In summary, we have synthesized copper nanoparticles through the photoreduction of copper acetate at room temperature.

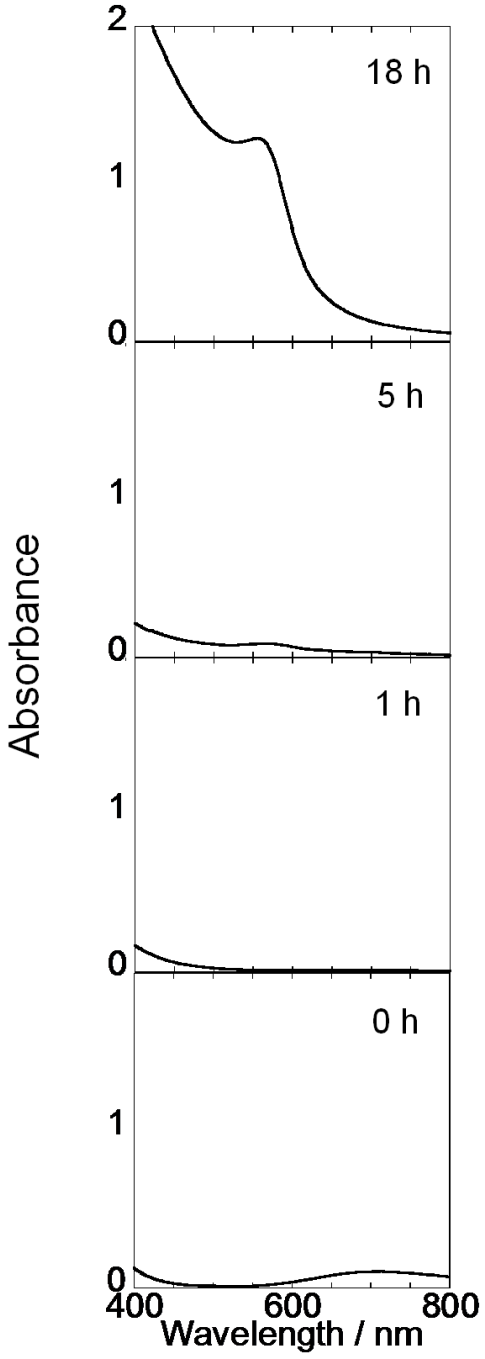

Figure 1. Absorption spectra with photoirradiation at 0, 1, 5, and 18 h.

Multiplex real time bioaerosol detection

Evgeny V. Usachev[1], Anna V. Pankova[2], Elina A. Rafailova[2], Oleg V. Pyankov[1] and Igor E. Agranovski[1]

[1]Griffith School of Engineering, Griffith University, Brisbane, 4111 QLD, Australia
[2]Department of Biochemistry, Kazan Federal University, Kazan, 420008, Tatarstan, Russia

Keywords: Bioaerosol detection, personal sampler, multiplex real-time PCR.
Presenting author email: i.agranovski@griffith.edu.au

Bioaerosols could cause various severe human and animal diseases and their opportune and qualitative precise detection and control is becoming a significant scientific and technological topic for consideration. In addition, over the last decades bioaerosol detection has become an important bio-defense related issue. Many types of portable and stationary bioaerosol samplers have been developed and, in some cases, integrated into automated detection systems utilizing various microbiological techniques for analysis of collected microbes.

In this project we used our recently developed personal bioaerosol sampler in conjunction with a real-time PCR technique. The main idea of the project was to investigate some possibility of using single fluorescent dye in multiplex format for qualitative detection of numerous targeted bioaerosols in one PCR tube making the suggested technology a reliable "first alert" device.

To prove the concept, we used the following experimental protocol. Two microorganisms, MS2 and T4 bacteriophages, were simultaneously aerosolized in the aerosol chamber (see details in Agranovski et al., 2005) and sampled by three personal samplers installed in parallel. On completion of sampling, the collecting liquid was mixed with PCR reagents and amplified to detect various

Firstly, it was found that the personal sampler has a collection efficiency higher than 90% even for small-sized viruses (>20 nm) and stable performance over extended operating periods for all combinations of microorganisms involved.

Figure 1 shows results of PCR amplification of MS2 and T4 in single format (one microorganism per reaction tube). As is seen, the results are perfectly correlated with the tenfold dilutions of the collecting liquid.

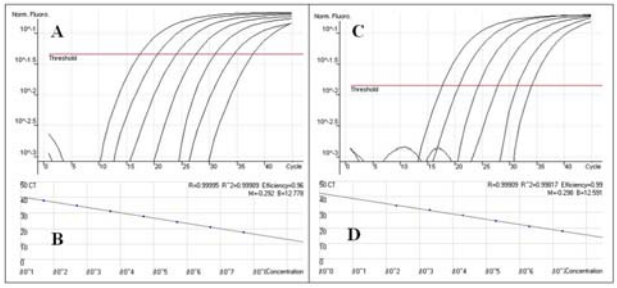

Figure 1. PCR amplification of ten-fold dilutions of MS2 and T4 phages in single format. A (results) and B (calibration curve) – for MS2; C (results) and D (calibration curve) – for T4 phage. Concentrations are presented in PFU/ml.

For the multiplex format, we used a mixture of primers and probes for both microorganisms trying to detect one out two targeted species. The results of these experiments are shown in Figure 2. As is seen, both targets were reliably detected in multiplex format and look very promising for development of hardware capable to identify a range of substances by compact portable devices.

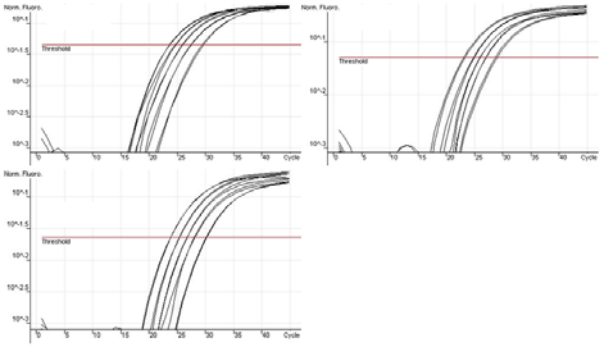

Figure 2. PCR amplification of phages MS2 (A), T4 (B) and their mixture (C) collected from the aerosol stream. PCR assays were performed in duplex format.

In addition, we used some experimentation to evaluate possibility to use PCR protocol for unpurified nucleic acids. It was found that for microorganisms used in this project (bacteriophages MS2 and T4) elimination of nucleic acids isolation and purification step during sample preparation does not lead to the system sensitivity reduction. This finding is extremely important allowing development of miniature bioaerosol monitoring instrumentation running PCR protocols directly on collected microorganisms and eliminating time consuming and cumbersome RNA/DNA purification step.

Development of atmospheric aerosol data by flicker noise spectroscopy method

V.A.Zagaynov, D.V.Vodyanik, Yu.G.Biryukov, A.A. Lushnikov, I.E. Agranovski, S.F.Timashev

[1]Karpov Institute of Chemical Physics, Vorontsovo Pole, 10, 105064 Moscow, Russia
Keywords: flicker noise spectroscopy, atmospheric aerosols.
Presenting author email: zagaynov@cc.nifhi.ac.ru

There are many various gas subsystems in the atmosphere and their parameters are mutually interrelated. This fact has to be taken into account during atmospheric aerosol monitoring to achieve the most accurate and representative results. The main goal of this study is to distinguish factors that determine the state of the atmosphere. To consider such problems, a phenomenological analysis of the primary experimental data $V(t)$ has to be performed. This analysis considers dynamics of measured aerosol characteristics and their correlations are obtained to be used for following mathematical modeling. The main preference of this method is its capability of quantitative characterization of correlated data.

At this stage, the relation between various parameters of the ambient air (particle concentrations, particle size distributions, SO_2 concentrations, strength of electric field) has been established enabling one to evaluate a nature of aerosol generation and age of the aerosol system. The chaotic time related dynamics of these systems is represented by the measured dynamic variable $V(t)$ over the time interval T. The carriers of information contained in the measured chaotic series, including time series $V(t)$, are sets of distinguishable irregularities, such as bursts, jumps, and discontinuities of derivatives of various orders that occur at each space-time level of the hierarchy of the system (it is assumed that $<V(t)>= 0$). Because of the distinguish ability of the irregularities introduced, the parameters characterizing the combined properties of types of parameters are distinguishably extracted in an analysis of incomplete cosine spectra.
To get quantitative criteria on autocorrelation and correlation between different values:

$$\sigma_i(\tau) = (< (V_i(t) - V_i(t+\tau))^2 >)^{\frac{1}{2}}$$

and

$$q_{ij}(\tau;\vartheta) = < \frac{(V_i(t) - V(t+\tau))(V_j(t+\vartheta_{ij}) - V(t+\vartheta_{ij}+\tau))}{\sqrt{2}\sigma_i \sqrt{2}\sigma_j} >$$

here τ – is time delay for autocorrelation, ϑ - time delay for correlation between two measured values. These calculated correlations present information on measured connection between two values. The nature of this connection is twofold: firstly, one process may be consequence of the previous process, which is resulted by the fact that these values are related by some definite equations. On the other hand these values may be related randomly. The values σ and q in the above equations could be used to analyze the nature of the process and evaluate is it random or consequential. For example, it was found during our atmospheric monitoring of Baikal lake region, that measured particle concentration in the atmosphere was changed due to some presence of anthropogenic pollutions, air transport and photochemical reactions $SO_2 \rightarrow$ aerosol particles. These values, including SO_2 concentration and aerosol particle concentration and size distribution were continuously measured and then analyzed. The calculated values of q, obtained for the atmosphere of Baikal Lake are presented in Fig 1.

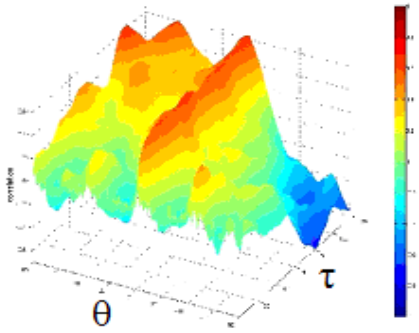

Figure 1. Correlation between SO_2 concentrations and total aerosol particle concentrations. ϑ - time shift between two values, τ – time shift for autocorrelation

This figure shows that for time shift ϑ =0 correlation is positive and has crucial meaning. At the same time for $\vartheta \approx 2$ hours this correlation again is positive. For both time intervals, $q \geq 0.7$ showing that the processes occurring at high gas and particle concentration are related by the some chemical and kinetics equations. The form of the relation may be obtained by mathematical modeling of these processes, by using calculated correlations, as shown in Fig.1.

Size distributions of particle-bound polycyclic aromatic hydrocarbons emitted from a diesel generator fueled with waste-edible-oil biodiesel blends

S.J. Chen[1,*], J.H. Tsai[1], K.L. Huang[1], C.L. Chou[2] and W.J. Yu[1]

[1]Department of Environmental Science and Engineering, National Pingtung University of Science and Technology, Pingtung County, Nei Pu, 91201, Taiwan
[2]Content Engineering Consulting Services, Ltd., New Taipei City, Zhonghe Dist., 23553, Taiwan
Keywords: Biodiesel, waste-edible-oil, polycyclic aromatic hydrocarbons, size distribution, generator.
Presenting author email: chensj@mail.npust.edu.tw

Diesel engines usually emit particulate matter (PM). Diesel exhaust particles (DEPs) mainly comprise fine and ultrafine particles (dia. <2.5 μm – 0.1 μm) such as carbonaceous matter, fats, polycyclic aromatic hydrocarbons (PAHs), and miscellaneous organic compounds, etc. (Kittelson, 1998; Reynold et al., 2000). Some studies have demonstrated that DEP exposure significantly affects human or animal bodies, and such exposure gives rise to cardiovascular and respiratory tract diseases (Yoshino et al., 1999; Sagai et al., 1996; Schwartz et al., 1996; Seaton et al., 1995). Although the use of biodiesel may significantly reduce PM emission from diesel engines (Lin et al., 2008; Tsai et al., 2010), it is necessary to evaluate the potential impact of DEP size distribution on health when using biodiesel.

In this study, the size distributions of particle-bound PAHs emitted from a biodiesel-fueled generator operated at stable energy output (110 V/60 Hz, 1800 rpm) loads (unload (0 kW) and 3 kW) were investigated. We tested two types of fuels: D100 (pure petroleum diesel) and W20 (v/v = 20% waste-edible-oil based/converted biodiesel/80% D100). The size distributions of particle-bound PAHs emitted from the generator using different fuels were measured with a micro-orifice uniform deposit impactor (MOUDI) and a Nano-MOUDI (with 0.01–18 μm aerodynamic diameters). Each sample was extracted in a *Soxhlet* extractor with a mixed solvent (n-hexane and dichloromethane 1:1 vol/vol) for 24 hr. The extracts were then concentrated, cleaned up, and re-concentrated by purging with ultra-pure nitrogen to exactly 1.0 mL for GC/MS analysis.

When operating at 0 kW (unload), the particle-bound Total-PAHs and Total-BaP_{eq} emitted from the diesel generator using D100 and W20 all exhibited single-peak distributions (both major peaks in 0.32–0.18 μm) (Fig. 1). Similar phenomenon was also observed at a heavier load (3 kW); the major peaks of Total-PAHs and Total-BaP_{eq} were in 0.032–0.010 μm and 0.32–0.18 μm for D100 and W20, respectively. Dissimilarly, Lin *et al.* (2008) found that the average particulate total-PAHs in five samplings displayed a trimodal distribution with a major peak in the Aitken mode (0.032–0.056 μm). Lower emission concentrations of Total-PAHs and Total-BaP_{eq} were observed for W20 than for D100 despite the loads; the reductions of Total-PAHs and Total-BaP_{eq} were ~50% and ~80%, respectively. Therefore, using waste-edible-oil biodiesel (W20) is helpful to reduce particle-bound PAHs emission from the diesel engine generator, especially for particles in ultrafine size range.

Platinum-based nanoparticles supported on cordierite as high active materials for catalytic ammonia decomposition

Chang-Mao Hung

Department of Vehicle Engineering, Yung-Ta Institute of Technology and Commerce, 316 Chung-shan Rd, Linlo, Pingtung 909, Taiwan, R.O.C.
Keywords: ammonia, selective catalytic oxidation, Pt-Pd-Rh nanoparticles cordierite substrate catalyst.
Presenting author email: hungcm1031@gmail.com

Ammonia (NH_3) is an extremely important component contributing to acidification and eutrophication of terrestrial ecosystems had attracted much attention in Taiwan. Typically, NH_3 is emitted during ammonium nitrate, nitric acid and urea production is present in livestock waste and vehicle exhaust, and is a byproduct of fossil fuel combustion, petroleum refineries and the refrigeration industry. Therefore, removal and control of NH_3 emissions in gas and waste streams are necessary due to increasingly stringent emission standards.

Till now, catalytic oxidation using dedicated catalysts increases the effectiveness of advanced oxidation technology potentially reducing oxidation reaction times and allowing oxidation to proceed under relatively mild operating conditions. The selective catalytic oxidation approach of ammonia (NH_3-SCO) in a stream to N_2 and H_2O can reduce NH_3 pollution. Cordierite, a crystalline magnesium aluminosilicate ($2MgO\text{-}2Al_2O_3\text{-}5SiO_2$) with a hexagonal structure, combines a relatively low thermal expansion coefficient with thermal shock resistance and sufficient refractoriness has been reported (Hung, 2009; Hung, 2010; Hung, 2010; Hung, 2011).This study elucidates NH_3 oxidation by selective catalytic oxidation (SCO) over a Pt-Pd-Rh nanoparticles cordierite substrate catalyst in a tubular fixed-bed flow quartz reactor (TFBR) at temperatures of 423-623 K. The overall selectivity of N_2 production was 12-68%, and that of NO production was 0-8% over the range of 11-98% NH_3 conversion at NH_3 concentrations of 800 ppm (Fig. 1). It is noteworthy that nitrogen gas was formed primarily by direct dissociation of the NO produced by oxidation of adsorbed NH_3. Therefore, the hypothesize that NH_3 and oxygen were adsorbed onto specific sites on the Pt-Pd-Rh nanoparticles cordierite substrate catalyst, promoting rapid conversion of NH_3 to nitrogen and water. Consequently, nitrogen was the dominant gas, and a small amount of NO was detected in the resultant stream. Fig. 2a shows that the catalyst surface is more aggregated and crystalline than observed in Fig. 2b. Rather, disaggregated and dispersed phases formed when the catalyst surface aged or when poisoning occurred due to plugging, implying that particle porosity changed (Fig. 2b). Generally, these crystal phases may be responsible for the marked activity of catalysts. These experimental results also confirm that the dispersion phenomena of the catalyst increase the efficiency of NH_3 removal.

Nanomaterials are already used in many consumer products today and the number of products available to consumers is expected to increase. As the exposure of people to nanomaterials is becoming more common, there is an increasing concern that the beneficial properties of nanoscale particles might have negative impact on human health and the environment. For example, it is expected that the increased surface to volume ratio will make particular chemicals more toxic because these particles will be more absorbable and capable to cross cell membrane or the blood-brain barrier. Today we lack knowledge on the hazards of nanomaterials and nanotechnology-based products as there is only limited data available on toxicology of and exposure to nanoparticles.

Since production of nanotechnology-based industrial and consumer products is dramatically increasing, the amount of products reaching the end of their life-cycle is also increasing. We do not yet know if and to what extent, toxic nanomaterials may be released or may leach from products to the environment during use or after use, i.e. during final treatment and/or disposal in land fills. In this presentation the focus will be on possible aerosol emissions during recycling and final treatment, i.e. incineration. Incineration was chosen because the number of incinerators has increased in Europe due to the ban on landfilling untreated municipal waste. The example cases studied are the recycling of coated glass panels and the incineration of CNT-containing composites.

Glass panels are coated for a number of reasons. For example, glass panels coated with nano-ZnO can be used as filter screens for lamps. The nano-ZnO coating protects the products in showrooms against bleaching. The biggest advantage, however, is the lifetime of the effect, which is in principle as long as the substrate exists. As these materials are chemically fixed to the glass panels, the recycling of the composite (glass with treatment) is not well understood. In this presentation an experimental setup for the mimicking of the established glass recycling process (by melting) will be presented. The results for aerosol emissions during recycling process of nano-ZnO containing glass are presented. These results include measuring of the nanoparticle emissions to air by means of aerosol instrumentation for ultra-fine particles. Elemental analysis of the emitted particles is also carried out.

Carbon nanotubes (CNT) containing epoxy composites have increased impact resistance, elongation to break and fatigue compared to traditional epoxies. These composite materials are suitable for filament winding, laminating, pultrusion, infusion and many other applications. These composites are for instance applied in the manufacture of sporting equipments, yachts and windmill blades. As they cannot be melted to another shape, they cannot be recycled as epoxy unlike many other plastic materials, but are disposed of at the end of their lifecycle. An important but still open question is the behaviour of CNT in incineration plants. Although there are reasons to expect that they will be totally oxidised, very little data or information exists so far on their final fate.

Results on emissions to air from waste incineration of CNT-containing composites will be presented, including the particle number concentration as well as the particle size, chemical composition and mass size distributions. The aerosol particles are collected and analysed for size, shape and chemical composition using electron microscopy. The composition of the ash is also analyzed.

Presenting author email: virgomez@unizar.es

An experimental study has been carried out to examine the effect of image force on the diffusional penetration of sub-10 nm particles through a laminar flow tube.

The experimental setup is shown in Figure 1. An evaporation-condensation NaCl aerosol was size-classified with a TSI short column DMA operated in open mode at a aerosol-to-sheath flow rate ratio of 2/20. Three different test monodisperse aerosols were used for the penetration experiments: (1) the singly charged particles as drawn from the DMA; (2) uncharged particles produced by passing the DMA-classified aerosol through a ^{241}Am neutralizer and an electrostatic precipitator (ESP) operated at a voltage sufficient to remove the charged fraction; and (3) a "globally" neutral aerosol, consisting of a mixture of uncharged, positive and negative particles, obtained by switching off the ESP voltage. Penetration of each of the test aerosols through a 100 cm long, 4 mm ID tube was determined form comparison of concentrations measured at the outlet of two tubes of lengths 20 and 120 cm. The use of a 20 cm tube as reference ensures the attainment of fully developed parabolic flow at the aerosol flow rate used in the experiments (2 lpm). Equal lengths of conducting Tygon tubes were employed for the connections AB and AC. Before the condensation particle counter (CPC), an additional ^{241}Am neutralizer was inserted to eliminate the possibility of counting errors due to the effect of charges on the condensation of the CPC working fluid onto the particles; with this arrangement, the three test aerosols were brought to the same charge equilibrium state before entering the CPC.

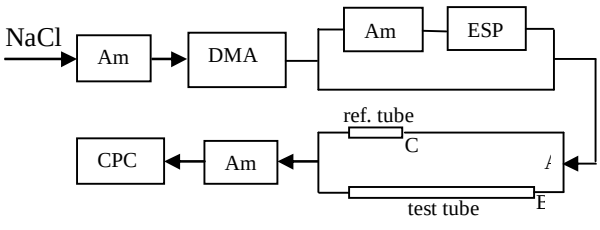

Figure 1. Experimental setup

The experimental results are shown in Figure 2. Penetration of uncharged particles (0) is fairly well predicted by the Gormley-Kennedy equation (full line). Each experimental value is the average of ten measurements. Penetration of the mixture of uncharged and charged particles (0,+,-) is slightly smaller than that of uncharged particles, and this may be attributed to the electrostatic attraction between the charged particles and the image charges induced on the tube wall (for particles under 10 nm the fraction of charged ones is very small, and this explains why the penetration differs little from that of the uncharged particles).

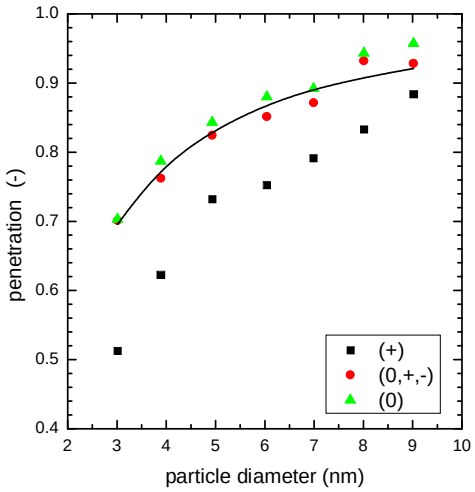

Figure 2. Experimental results

On the contrary, the penetration of the charged particles (+) is notably smaller than that of the other two test aerosols. However, according to the currently accepted theory this strong image force effect should not be observed for singly-charged nanoparticles. Indeed, the transport equation $\mathbf{u}\cdot\nabla n+\nabla\cdot\left(-D\nabla n+nZ\mathbf{E}\right)=0$ has been solved numerically using the expression given by Yu (1977) for the electric field, and the numerical results show that the effect of image force on penetration should be less than 0.1% for the particle size range below 10 nm. Electrostatic repulsion effects (space-charge) are absent in our experiments because the aerosol concentration was kept below 10^4 cm^{-3}. Clearly, the theoretical explanation of the above results needs further elaboration; we also intend to perform additional experiments, changing the aerosol flow rate and the tube radius.

Morphology of catalyst layers deposited by electrospray

S. Martin, P.L. Garcia-Ybarra and J.L. Castillo

Dept. Fisica Matematica y de Fluidos, Facultad de Ciencias, UNED, Madrid 28040, Spain
Keywords: Electrospray, Particle deposition, Deposit morphology, Fuel cell.
Presenting author email: jcastillo@ccia.uned.es

The morphology of granular deposits growth from aerosol particles depends on the aerosol particle dynamics over the collecting surface. Theoretical simulations of deposit formation (Rodriguez-Perez *et al*, 2005 & 2007) have shown that an increase in the particle arrival velocity leads to denser deposits whereas nanostructured deposits with open tree-like dendritic structures can be formed for weak particle velocities.

Based on these theoretical simulations, an experimental investigation is being carried out to grow platinum catalyst layers (for use as electrodes in Proton Exchange Membrane Fuel Cells, PEMFC) starting from the electrohydrodynamic atomization of a liquid suspension containing the catalyst Pt/C nanoparticles. This technique has demonstrated to be an efficient method of depositing catalyst layers especially in the range of ultra-low platinum loadings even below 0.1 $mg_{Pt}cm^{-2}$ (Martin *et al*, 2010 a&b). The advantages of the electrospray deposition method are numerous. Since the droplet size in the electrospray is controlled by the flow rate, the size of the deposited particle may be selected. As the spray is charged, it may be focused by an electric field in a particular position with any shape. Moreover, coalescence phenomena in the spray droplets are reduced due to the electrostatic repulsion between the charged droplets. Other remarkable benefits are the feasibility of the scaling up to bulk production and the inexpensive and simple experimental set up.

The range of the parameters governing the electrospray deposition has been studied under the scope of the preparation of optimum catalyst layers for PEMFC use. Thus, the domain for stable electrospraying was determined (Martin *et al*, 2011) showing that the range of liquid flow rates with a stable cone-jet electrospray can be substantially enlarged with a proper control of the voltages applied to the needle and to the collecting plate.

Furthermore, a classification of the different types of deposits according to the morphology (fractal-like, based on spheroids or compact deposits) has been carried out. The enclosed figure depicts the two first types of deposit structures for the same platinum loading of 0.1 $mg_{Pt}cm^{-2}$.

Nanostructured deposits with very high porosity (97%) and a large active area due to their dendritic growth were obtained for specific setting of the experimental parameters (*i.e*. needle-substrate distance, liquid flow rate, voltages applied to the needle and to the substrate and concentration of the catalyst ink).

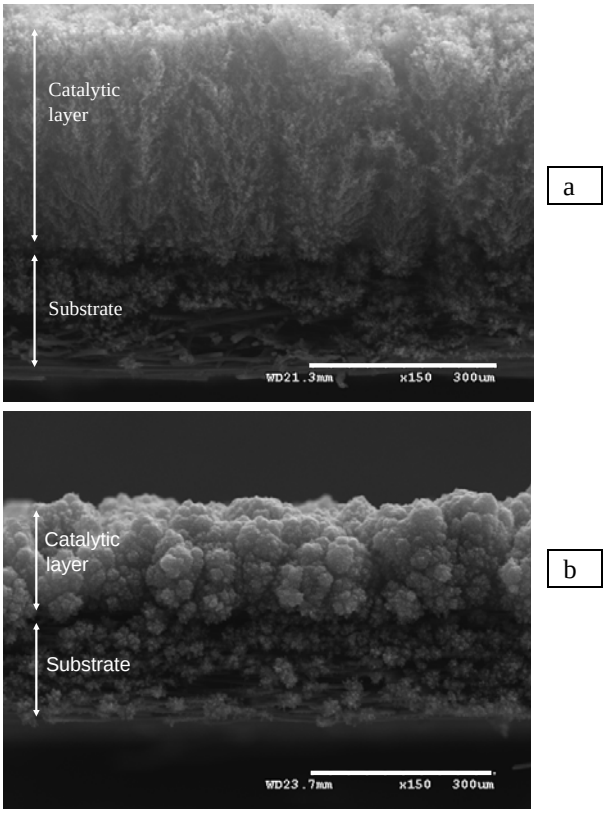

Figure. Cross-sectional SEM micrographs of the profiles of electrosprayed Pt/C catalytic layers over a carbon paper substrate (for the same catalyst loading). (a) fractal-like structures for a flow rate of 0.2 ml h^{-1}, and (b) Deposits based on spheroids for 0.5 ml h^{-1}. In both images the micron bar corresponds to 300 μm.

Measurement of particle size distribution in the gas phase. QCM- based procedure

F.N. Dultsev

Institute of Semiconductor Physics, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, 630090, Russia
Keywords: Aerosol size distribution
Presenting author email: fdultsev@thermo.isp.nsc.ru

QCM-based procedure for the determination of particle size within the nanometer-range is proposed. The essence of the procedure is the rupture of adsorbed aerosol particles from the surface of the quartz resonator during oscillations of the quartz resonator surface under dynamically increasing oscillation amplitude. It was established experimentally that the achievement of threshold values of the QCM surface oscillation amplitude (with an increase in voltage U_0 at the resonator plates) causes breakage of the bonds holding a body on the surface; the rupture event is accompanied by a sharp acoustic signal (click) at the high harmonics of the resonator.

Recording the intensity of the acoustic signal and the voltage at which it appears, one may extract the information about the properties of the detached body. The same quartz substrate acts as an integrated device playing several parts at a time: an active resonator and a sensitive microphone.

If the measurements are performed not at a fixed frequency of the chosen harmonics as described in (Dultsev *et al.*, 2000) but scanning within a frequency band around that value, this excludes the necessity of precise adjustment (tuning) of frequency, eliminates signal misalignment during measurements and allows one to achieve well reproducible results without any dependence on temperature, time or any random factors. .

Test measurements were carried out using the standard nanospheres Nano Glass Beads with the declared glass bead diameter 20-30 nm (Microspheres-Nanospheres a Corpuscular company, catalogue No. 149015-05). Deposition onto the surface was carried out from water suspension.

Measurements were carried out at the third harmonic; voltage U_0 at the resonator plates was linearly increasing during the sweep up to 5 volts. One can see in the plot that there are some threshold voltage values U_0 corresponding to quite specific values of surface oscillation amplitude, when the signal inside the band gives a sharp overshoot, which corresponds to particle rupture. This points to the presence of the particles of several types, with different binding strength values. It should be noted that the band of signal scanning over frequency was chosen with a small excess in order to exclude the loss of information. The integral plot shown in Fig. 1 represents the signal *versus* voltage $U0$ at the resonator plates, averaged over the band (200 points over scanning frequency). According to the plot, there are six types of particles in the test system; the six sharp peaks are marked with asterisks.

The use of the proposed procedure for measuring particle size distribution is shown in Fig. 3. Aerosol particles 20-30 nm in size were generated with a device described in (Ankilov *et al.,*2002). The generator was calibrated with the help of diffusion battery (Ankilov *et al.*, 2002). Varying the rate of flow through the generator we can vary particle size as one can clearly see in Fig. 2.

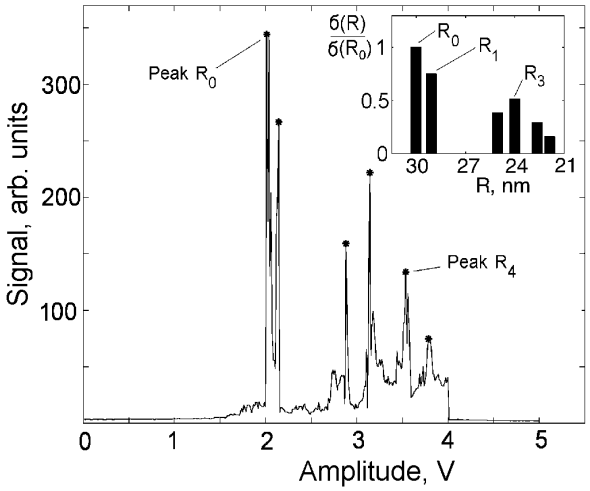

Figure. 1. Resulting rupture signal versus voltage supplied to the quartz resonator. The resulting particle size distribution is shown in the insert.

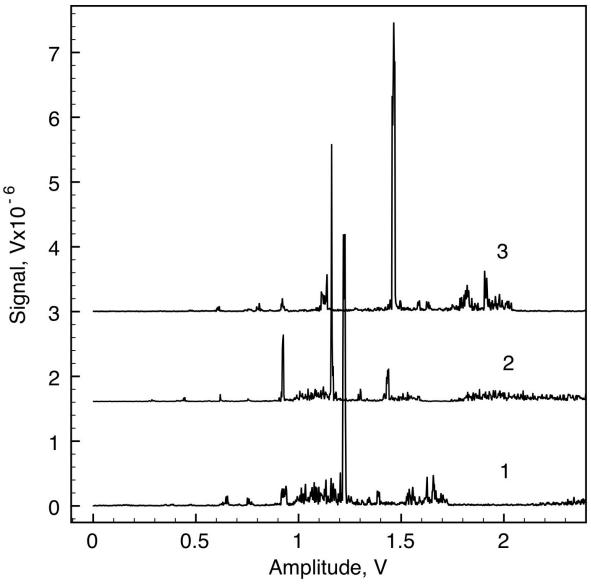

Figure 2. QCM measurements with different rates of gas flow through the generator for constant W filament temperature, curve 1 – chosen conditions, curve 2 - air flow decreased by10%, and curve 3 - air flow increased by 10%.

Cloud condensation nuclei (CCN) activity and oxygen-to-carbon elemental ratios following thermodenuder treatment of organic particles grown by α-pinene ozonolysis

M. Kuwata, Q. Chen and S. T. Martin

School of Engineering and Applied Sciences & Department of Earth and Planetary Sciences,
Harvard University, Cambridge, Massachusetts, 02138 USA
Keywords: CCN, secondary organic material, elemental ratio, volatility
Presenting author email: scot_martin@harvard.edu

Introduction CCN activity of aerosol particles is important as a regulator of cloud properties, including their brightness, lifetime, and precipitation. Although CCN activity of pure compounds is predictable from their chemical characters, CCN activity of secondary organic material (SOM) is not understood for quantitative prediction due to their complexity in chemical composition.

In the present study, we systematically controlled SOM chemical composition generated using the Harvard Environmental chamber (HEC) by (1) altering SOM concentration (M_{org}) in the HEC, and (2) increasing the thermodenuder (TD) temperature (T) connected to the HEC. SOM chemical composition was measured simultaneously with CCN activity. This experimental design allows us to relate CCN activity and chemical composition, as both M_{org} and T controls SOM chemical composition based on volatility.

Experiment The HEC is consisted of a 4.7 m^3 Teflon bag housed in a temperature controlled (25 °C) room. It was operated as a continuous stirred tank reactor, providing sufficient time to measure SOM. SOM was produced by dark ozonolysis of α-pinene (8 – 80 ppb) with the presence of 2-butanol as an OH scavenger. SOM concentration in the chamber ranged from 1.4 to 37μg m^{-3}, depending on α-pinene concentration. 30-nm $(NH_4)_2SO_4$ seed particles, those were provided from a differential mobility analyzer (DMA), were also continuously injected into the chamber. Ozone concentration and relative humidity were feedback controlled as 50 ppb and 40%, respectively.

SOM particles generated in the HEC were injected into a thermodenuder (TSI 3065), which was operated at bypass, 25, 60, 80, and 100 °C. The flow passed through the TD was split to three flows to measure size-resolved CCN activity (DMA-CCN counter(CCNC)), chemical composition (high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS), and number size-distribution (scanning mobility particle sizer (SMPS).

CCN activation curve measured by the DMA-CCNC was fitted by a sigmoid function to obtain dry activation diameter (d_{dry}) κ values, which is defined as $\kappa = i\, MW_{water}\rho_{org}/MW_{org}\rho_{water}$, were employed to represent CCN activity [i: van't Hoff factor, MW_x: molecular weight of x, ρ_x: density of x]. κ was iteratively calculated to reproduce d_{dry} obtained from size-resolved CCN spectra.

Results and discussion

We observed ~50% of decrease in M_{org} following TD treatment at 100 °C regardless of M_{org} in the HEC. This demonstrates that evaporation is the main process occurring in the TD. Elemental composition of SOM measured by the HR-ToF-AMS revealed that both M_{org} and T dependences are consistent in terms of volatility: oxygen-to-carbon (O:C) ratio increased for lower volatility compounds (lower M_{org}/higher T), while H:C ratio decreased for these conditions. This trend was further confirmed using a Van Krevelen diagram. All data points aligned on a straight line ([H:C] = -0.8 [O:C] + 1.8), including both M_{org} and T dependences. These results demonstrate that the main process occurring in the thermodenuder is evaporation of relatively volatile compounds.

κ did not depend on M_{org} at 25 °C, which may lead to predict that T also does not alter κ, considering the consistent dependences of elemental ratios on M_{org} and T. However, κ decreased at higher T. The magnitude of the decrease was significant (~20 % at 100 °C) at higher M_{org} (> 10μg m^{-3}), while the decrease was not significant at the low M_{org} (1.4μg m^{-3}).

These apparently contradicting results can be consistently interpreted as follows. TD evaporates relatively volatile materials, which cause decrease in M_{org} and changes in elemental ratios. At the same time, it enhances oligomer concentration in particles due to (1) evaporation of relatively volatile monomers, and (2) thermally induced oligomer formation reactions. These processes decrease κ, as oligomers have higher MW_{org} than original monomers. A variety of functional groups such as carbonyl groups is required for oligomerization reactions. Decrease in κ was significant at higher M_{org}, as relatively volatile carbonyl compounds could partition to particle phase due to higher concentration. This interpretation was supported by a model calculation employing master chemical mechanism coupled with SIMPOL vapour pressure prediction method, which predicted that carbonyl groups are depleted at lower M_{org}, while a variety of functional groups exist at higher M_{org}.

Keywords: nanoparticle agglomerates and aggregates, exposure, size distribution, UNPA

There are increasing interests in using nanostructured materials, because of their specific properties. The starting point is engineered nanoparticles (ENP), which are mass produced f. i. in the gas phase. Because of their high concentration they form agglomerates and the stronger bonded aggregates already during synthesis. The agglomerate/aggregate structures and sizes dictate the powder and material properties after dispersion in matrix material. Agglomerates/aggregates besides single nanoparticles from the matrix material may be unintentionally released into the workplace and environment during synthesis, further processing and handling. For risk assessment the exposure to agglomerates and aggregates has to be determined especially if there is a chance for them to break apart during transport in the environment. To discuss the impact of agglomerates/aggregates it is important to characterize the agglomerates/aggregates along their exposure pathway. Number-size distributions are therefore of the greatest value.

The most important tool for size distribution measurements thus far is the Scanning Mobility Particle Sizer (SMPS), which is based on the assumption that the particles are spherical. In case of agglomerates it delivers only equivalent values with respect to size (electrical mobility diameter) and also the concentration values are affected through different charging efficiencies.

In addition the agglomerate/aggregate size cannot be described by just one parameter. In case of loose agglomerates besides the agglomerate size the primary particle size is needed.

The recently developed Universal NanoParticle Analyzer (UNPA) [1] allows measurement of loose agglomerates, enabling determination of the primary particle size and the agglomerate distribution based on a model for loose agglomerates derived by Lall and Friedlander [2]. The largest difference between using a sphere and an agglomerate model in the data evaluation procedure occurs in the volume distribution calculation, which therefore has been used to check the agglomerate approach for data evaluation [3].

There does not exist a model for aggregates. The UNPA determines the number distribution as a function of the mobility diameter and with a second sensor the charges per particle as a function of the mobility diameter. We observed that this particle property changes, when the agglomerate becomes an aggregate and finally a sphere in a sintering process. This information can be used to determine the number concentration for aggregates. With the relationship between the mobility diameter and volume diameter, which may be determined by sintering experiments with monodisperse agglomerates or aggregates, number distributions of aggregates as a function of the aggregate volume can be derived.

The change can also be related to the difference in surface area per particle between aggregate and sphere derived from a model or from calibration with other techniques. In the presentation we will describe the data evaluation procedures and show examples of agglomerate and aggregate analysis.

The work was partially supported by the NSF grant (Award ID: 1056479) on "Real Time Measurement of Agglomerated or Aggregated Airborne Nanoparticles Released from a Manufacturing Process and Their Transport Characteristics".

Performance evaluation of the Airmodus PSM (nano CPC) in the sub 3 nm range.

M. B. ATTOUI
Paris East University, France

Keywords : nanoparticle CNC, mobility, growth, sizing,
Presenting author email: attoui@univ-paris12.fr

Detection and sizing of sub 3 nm particles in air is more and more growing interest in the atmosphere (Sipila et al 2010), in nanostructed material field (Peineke et al. 2010) and biochemistry nanoparticles such viruses and virus fragments, bacteriophages, DNA , proteins and protein complexes (Laschober et al 2007). Aerosol Faraday Cage is used as a detector in the sub 3 nm range charged particles since the detection efficiency of the best commercial version CPC –the TSI ultrafine CPC based on the well known work of Mark Stolzenburg and Peter McMurry (1991)- is 2.7 nm. Airmodus (Helsinki Finland) has introduced a commercial version - robust and transportable- CPC sensitive to sub 3 nm with 'high' detection efficiency (40% at 1 nm positive particles). This nano CPC-called PSM- is tested and characterized in this paper in the sub 3 nm range.

Detection efficiency of the PSM is measured – against and aerosol electrometer as a reference- for particles, ions and clusters. Particles of different composition including Sodium Chloride, Silver, Tungsten oxide, polyethylene glycol, proteins and sucrose), clusters of sucrose, nickel chrome and silver, standard positive ions of tetra-alkyl ammonium halides and sub 2 nm positive and negative droplets of ionic liquids are used in this study.

Experiments on the effect of the charge (polarity and number) are done with proteins and polyethylene glycol.

The figure 1 gives the measured detection efficiciency for hydrophilic positive and negative particles of sodium chloride while the figure 2 gives the results for hydrophobic positive and negative particles of silver. The particles are produced by evaporation condensation with an oven following the Sheibel and Porsthndorfer method. A high flow and high resolution DMA (Hermann and or Attoui type) is used to classify the particles generated by the oven.

Heating process of silver nanoparticles diameter-selected by DMA

D. Sugiura, N. Nishida, and H. Tanaka

Institute of Science and Engineering, Chuo University, 1-13-27 Kasuga, Bunkyo-ku, Tokyo, 112-8551, Japan.

Keywords: Ag nanoparticles, DMA, melting point, heating process.
bonganeko@gmail.com

It is well known that the physical properties of metal nanoparticles significantly depend on the particle diameter. Therefore it is essentially important to measure the physical properties with diameter-selected nanoparticles. Especially, heating behavior of the nanoparticles is fascinating because surface of the nanoparticles which depends strongly on their diameter is considered to be affected by heating. In this study, we have investigated heating process of diameter-selected Ag nanoparticles. The Ag nanoparticles prepared by a gas aggregation technique were diameter selected by a differental mobility analyzer (DMA). The heating process was monitored by ion intensity change passed through a heating furnace.

Ag nanoparticles were generated to heat Ag grains up to 1100 °C with N_2 gas flow under atmospheric condition. The Ag nanoparticles were then passed through ^{241}Am for ionization. Ionized Ag nanoparticles were diameter-selected by a DMA. The diameter-selected Ag nanoparticles were admitted into a heating furnace, and were counted by a condensation particle counter (CPC). In this measurement, the particle number was measured as a function of the heating temperature of the furnace. Particle number ratio was estimated from the particle number normalized by that value at 700 °C.

Figure 1 shows reciprocal-diameter dependence of temperature at half particle-number ratio. The temperature was found to decrease linerly with increasing the reciprocal diameter. When the dependence was fitted by a liner function, the intercept was estimate to be 966 °C. Because this temperature is quite close to that for melting temeperature of bulk silver (961 °C) , the measured temperature at half ratio indecates the melting temperature for the diameter–selected Ag nanoparticles. In addition, decrease of the detected particle-number can be explained by the melting because liquified nanoparticles evaporate Ag atoms from their surface and are vanished.

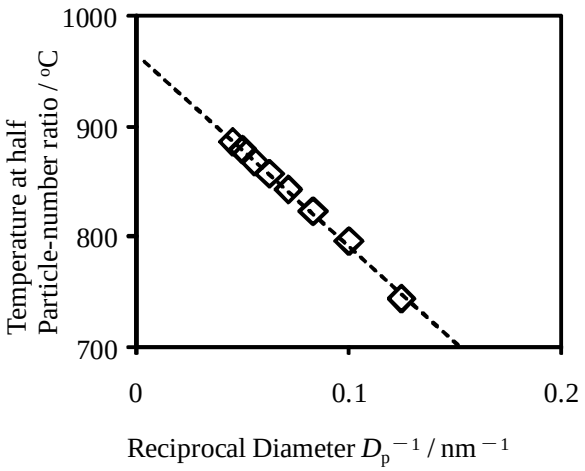

Figure 1. Diameter dependence of temperature at half particle-number ratio. Dotted line exhibits fitting line.

Color tunable nanophosphors made by flame aerosol synthesis

G. A. Sotiriou, M. Schneider, S. E. Pratsinis

Biological labels are used in bio-imaging and the ability to tag cells and biomolecules facilitates diagnosis and therapy. Even though organic dyes are used for such applications, their photobleaching inhibits their further employment. Quantum dots do not exhibit photobleaching and their emission color can be tuned by their size, however, their optical blinking and the high toxicity of their components restrict their use in bio-applications. An alternative strategy for such biolabeling applications are inorganic nanoparticles consisting of a host crystal matrix doped with lanthanide ions, the so-called nanophosphors. The color of these particles depends on the doping ion and not on their size, while their optical properties are superior to organic dyes and quantum dots.

One of the most studied ceramics as host matrix for phosphors is yttrium oxide (Y_2O_3). Several studies investigate the synthesis of nanosized Y_2O_3 based phosphors, and most often doped with Eu^{3+} ions because of its bright red emission. Such phosphor nanoparticles are made either by wet[1-3] or dry[4-6] synthetic routes, while it is not unusual that further annealing process steps are required to obtain the desired crystallinity.[7,8] Nanosized Y_2O_3:Eu particles have enhanced photoluminescence than their bulk counterparts, because of lattice distortions.[1] When Y_2O_3 is doped with another rare-earth element (e.g. Tb) the emission wavelength changes. In fact, this is exploited already by combining three different colored phosphors (blue, green, red) for white-light lamps.[9] For all rare-earth phosphors, there is an optimum concentration of the doping material.[10] This concentration, however, depends on several parameters, such as synthetic route or even the size of the phosphors.[11] The target of this project is the flame synthesis of Y_2O_3 nanoparticles doped with Tb^{3+} and Eu^{3+}. The co-doping of these ions in the Y_2O_3 matrix allows for the fine color tuning of the emission bandwidth.[12]

Figure 1 shows the control of the emitted color of the as-prepared nanophosphors by flame-spray pyrolysis [1]. Clearly, a color change from green to red can be observed. This shows that the emission spectra of the nanophosphors can be tuned by controlling the ratio of the doping atoms in the crystal Y_2O_3 matrix.

Nucleation of metals differ essentially from other systems nucleation and needs a detailed investigation. This work compares experimental routes of measurement of the nucleation rate from Zn and Bi vapor in a laminar flow chamber. The flow chamber consisted of a quartz tube (of i.d. = 0.7 - 1.0 cm) with an outer heater. A flow of Ar was supplied to the inlet with the rate 8 - 17 cm^3/c. A piece of metal (Zn, Bi) was put inside the heated zone, and that resulted in saturated vapor generation. At the outlet of the heated zone the temperature dropped down resulting in the nucleation onset. The concentration, size and shape of particles at the outlet of the tube was analyzed by TEM and automatic diffusion battery. The analysis of thermophoretic depletion of particle concentration in the region of temperature decrease, and the numerical simulation of nucleation coupled with the experimental axial and radial profiles of temperature have shown that the nucleation onset occurs within the layer of 1 mm near the wall of tube. Therefore, the axial profile and morphology of the wall deposit can give the information on the location of the region of maximum nucleation rate and the nucleation volume. However, there can be two different situations: the nucleation temperature T is less than the melting point (as it was in the case of Zn) and higher (Bi). In the first case it is easy to determine the nucleation rate, because the nucleation zone is easy to distinguish by the transition from smooth to powder-like deposit (Fig. 1a), the nucleation time may be estimated from the length of the initial increase in the wall mass deposit profile (Fig. 1b) and as the outlet particles are not aggregated (Fig. 1c) the nucleation rate can be estimated from the outlet particle concentration and the nucleation time. Thus, for example, for T = 660 K and supersaturation S = 15 the nucleation rate was found to be 10^{10} $cm^{-3}s^{-1}$.

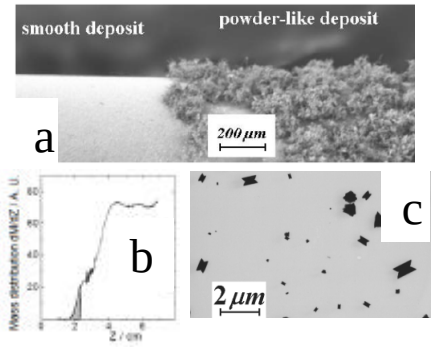

Fig. 1. Zn nucleation data :a) SEM image of wall deposit, b) wall deposit axial profile, c) TEM images of the outlet particles. Nucleation temperature T =660 K.

The situation is quite different in the case of Bi. At the outlet of the tube we observed the aggregates of small primary particles. Thus, to estimate the nucleation rate one should account the mean number of primary particles in aggregates. As the nucleation temperature is higher than the melting point, it is not possible to determine the nucleation zone just by the wall deposit SEM images. Additional methods are to be involved. One of them is light scattering. The light beam passes in the axial direction and the beginning of light scattering gives some information on the location of zone of maximum nucleation rate. Besides, the method of the "supersaturation cut-off" gives an additional information about the nucleation rate. The last experimental technique is as follows. A metal grid is inserted to the quartz tube perpendicularly to the flux. The outlet aerosol concentration is measured continuously. When the grid is downflow essentially after the nucleation onset point the outlet concentration is not disturbed by the presence of grid due to the low particle-to-grid diffusion deposition efficiency (because of the large size of particles). When moving the grid upflow the outlet concentration is decreasing (due to the vapor-to-grid deposition as well as the increase the particle-to-grid deposition efficiency) and the maximum rate of decrease of concentration corresponds to the region of maximum nucleation rate. The numerical simulation of vapor-to-particle transformation coupled with the experimentally measured axial and radial temperature profiles was also made. The simulation included wall vapor deposition, nucleation, particle growth due to vapor deposition and coagulation, particle wall deposition (diffusion + thermophoresis). An example of comparison of simulation results with the experimental measurements is shown in Fig. 3.

Formation of metal nanoparticles from supersaturated vapor is of interest due to both fundamental aspects and applications in nanotechnology. This paper is devoted to the experimental study of nucleation from Sb vapor in a laminar flow diffusion chamber (Fig.1a). The flow diffusion chamber consists of a quartz tube with a heater outside. Some amount of Sb was put inside the heated zone to generate the saturated vapor. At the outlet of the heated zone the temperature came down resulting in the vapor supersaturation and nucleation. The particle size and number concentration at the outlet of chamber was measured using diffusion aerosol spectrometer (Ankilov *et al*, 2002). The morphology of the outlet particles was thoroughly studied using JEOL-JEM 100SX TEM (Fig. 1b). At temperatures of the heater above 650 K the aggregates consisting of small primary particles were observed. The aggregate size, concentration (Fig. 2) and fractal dimension were studied as a function of heating temperature as well as size and number of primary particles per aggregate.

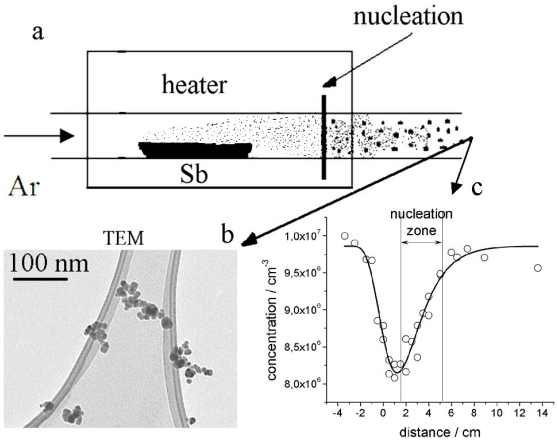

Figure 1. a) Experimental setup b) TEM image of aggregates c) Illustration of the "supersaturation cut-off" method.

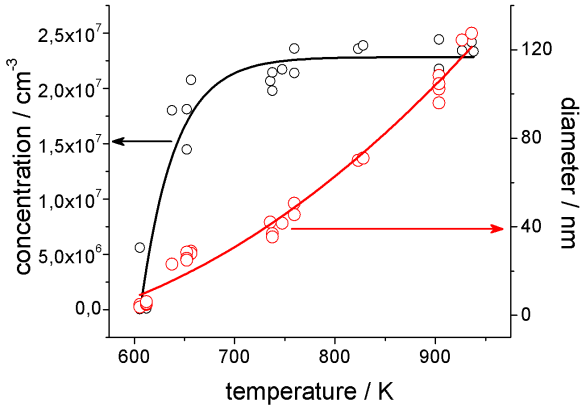

Figure 2. Aerosol concentration and aggregate size vs heating temperature.

"The supersaturation cut-off" method was used to find the approximate location of the nucleation zone (Rybin *et al*, 1975). The probe (metal grid with the diameter equal to inner diameter of the tube) was put inside the quartz tube perpendicularly to the flow. While changing the position of the probe we observed the changes in the concentration of the outlet particles (Fig. 1c). The method is based on the partially condensation of the vapor because of its diffusion on the grid. Thus, the homogeneous nucleation is reduced after the grid. Therefore, the approximate nucleation zone position can be found by the outlet particle concentration decrease. The vapor distribution inside of the generator was calculated from the diffusion mass transfer equation to estimate the supersaturation. The temperature field was determined experimentally using the chromel-alumel thermocouple.

The nucleation volume was estimated from the concentration and temperature profiles using the classical nucleation theory equation for nucleation rate. The number of particles formed in the nucleation zone can be determined using the outlet aerosol concentration and mean number of primary particles per aggregate. The coagulation rate estimations have shown that the coagulation + coalescence of liquid particles (before crystallization and aggregation) make a negligible contribution (<1%) to the decrease of aerosol concentration.

At nucleation temperature 456 K the supersaturation ratio was found to be 14.8 and the nucleation rate $3 \cdot 10^{10} cm^{-3} s^{-1}$.

Nano particles of N-modified TiO_2 photocatalyst for visible light catalysis have great potential application on the environmental and energy industry. The preparation for the titania-based visible light photocatalyst usually are carried out by liquid phase synthesis, while with the drawbacks, including long reaction time (1-24 hr), residual carbon matter, and high cost of precursors. Rapid gas phase synthesis of titania is not easily for control of operating condition and size distribution. Moreover, the modification of titania need be performed via multiple stages.

In this study, N-modified (or N-doping) TiO_2 particles are rapid synthesized in 0.14 seconds by an atmospheric-pressure microwave plasma torch. The continue microwave plasma system was assembled by a commercially available magnetron (National Electronics YJ-1600, 2.45 GHz) with maximum stationary power of 5 kW. A quartz tube are intersected the waveguide (ASTEX WR340) and the resonator perpendicularly. The powders were collected by 14-stage impactors (MOUDI) and were analyzed by XRD, TEM, UV-Vis spectrum, and XPS.

The experimental conditions are as follows: titanium tetrachloride solution with a $H_2O/TiCl_4$ inlet molar ratio = 8 was sprayed as aerosols into the reactor at 900 W, total flow rate of $NH_3/N_2/O_2$ mixtures (0.5/13.5/1.5) = 15.5 slm, and 550-600 for producing $TiO_{2-x}N_x$ powders.

The mass-fractionated particle samples were collected by 14-stage impactors (MOUDI), and then the size distributions were calculated. The results showed that the most of particles (in number) were in 5-10 nm stage impactor, reaching 97.8% of total particle number with the normalized particle number percentage ($dn'/d\log Dp$) reaching 324.8 (Table 1).

The photographs of powders by SEM and TEM show that the spherical TiO_2 with a primary particle of about 10 nm was found, and the secondary particles were aggregated by the primary particles. In addition, the XRD patterns show that the structural characteristics of powders for before and after sintering were mainly anatase crystallization with the average grain size being consistent with the primary particle size.

Elemental analysis by EDS shows that N atoms were about 0.17 at.%. Chemical bonding analysis by XPS confirms the N-doping. The N_{1S} peak could be fitted to three line shapes with binding energies at 395.8, 399.1, and 401.5 eV. These different binding energy peaks are fitted to N^{1+} at 395.8 eV, N^{2+} at 399.1 eV and N^{3+} at 401.5 eV, respectively. In this case, the total area of the N_{1S} peak was 21.2% of N^{1+}, 65.5% of N^{2+}, and 13.3% of N^{3+}. The N^{1+} is assigned to the TiN or $TiN_{X>1}$ bond. The most intense N^{2+} peak is attributed to the Ti-N-O or molecularly chemisorbed γ-N_2 bond. The other weak N^{3+} peak corresponding to higher energy bond was probably the O-Ti-N bond.

UV-Visible absorption spectrum was used to confirm the red shift of band gap to 510 nm (P25 at 396 nm) for N-modified TiO_2. The photocatalytic efficiency of unmodified and N-doped TiO_2 is consistent with commercial P25 powders for the duration of UV-light degradation. By visible light degradation, the conversion of methylene blue is about 2.5 times for N-doped TiO_2 than P25, indicating that by using MW plasma torch for producing N-modified, nano TiO_2 powders is an excellent approach.

Presenting author email: mirella.miettinen@uef.fi

Amorphous alloys of silicon and carbon are of interest because they have a great potential in number of applications in the electronic, chemical and mechanical industries; including e.g. transparent or doped thin films, catalysts, sensors, magnetic materials and high efficient solar cells. However, the characteristics of the particles such as composition (e.g. SiC, $Si_xC_yH_z$, $Si_xC_yO_z$), size, shape and degree of crystallinity have a high impact on their performance in various applications (Carter et al. 2005).

We have synthesized silicon-carbon nanoceramics from metalorganic liquid precursor hexamethyldisilane (HMDS, $C_6H_{18}Si_2$) in high temperature aerosol reactor at atmospheric pressure. The particle formation is based on the decomposition and subsequent reaction of a precursor in the reactor. Low-vapor-pressure decomposition or reaction products nucleate to form molecules or clusters and immediately grow to larger particles that agglomerate further.

The colour of the produced powder changed when the reactor temperature was increased and was yellow, red-brown, brown, brown-black and black at the temperatures of 800, 900, 1000, 1200 and 1400°C, respectively. TEM analysis showed that particles were agglomerated and amorphous at 800 °C, but that crystallinity of the particles clearly increased at higher reactor temperatures (Fig. 1). A cubic 3C-SiC crystal structure d(111)=2.52 Å (2.54 Å), d(220)=1.54 Å (1.54 Å), d(311)=1.31 Å (1.32 Å) (measured values in parenthesis) was observed at synthesis temperature of 1400 °C.

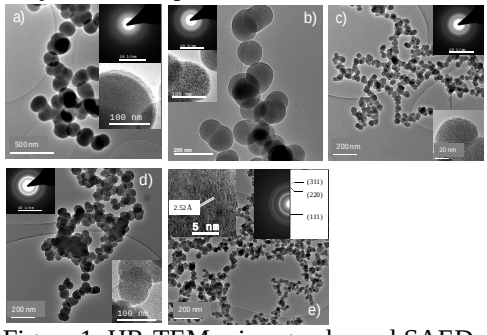

Figure 1. HR-TEM micrographs and SAED diffraction patterns of the produced particles at different temperatures: a) T = 800 °C, b) T = 900 °C, c) T = 1000 °C, d) T = 1200 °C and e) 1400 °C

The XRD pattern of the powders produced at 1200 and 1400 °C showed peaks of the cubic 3C-SiC crystal structure (35° d(111), 60° d(220), 72° d(311)). Based on the TEM and XRD analyses, the crystallite size of the powders was under 5 nm.

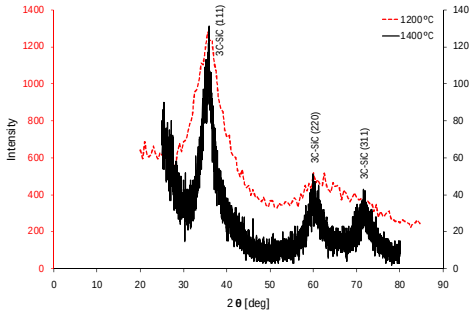

Figure 2. XRD patterns of the powders produced at temperatures of 1200 and 1400 °C

FTIR and NMR analyses showed that the composition of the powder evolved from the structure that contains SiC_4, H-Si and Si-CH_2-Si units at synthesis temperature of 800 °C towards inorganic, nanocrystalline 3C-SiC when the reaction temperature was increased to 1400 °C.

The preceramic produced at the synthesis temperature of 800 °C belongs to amorphous silicon-carbon alloys that are among the most promising nanomaterials today for technologies such as high efficiency solar cells and transparent or doped thin films. On the other hand, the cubic 3C-SiC nanocrystalline silicon carbide that was produced at higher reaction temperatures is an attractive semiconductor and high temperature structural material e.g. in nanocomposites and electroceramics. Thus our synthesis method opens up a possibility for continuous, highly adjustable production of silicon-carbon nanoceramics with desired composition.

This work was funded by the Finnish Funding Agency for Technology and Innovation (TEKES) in the Active Nanocomposite Materials project (40072/08).

Ibuprofen nanoparticle formation from supersaturated vapor in the flow chamber

A.V. Samodurov[1,2], A.M. Baklanov[1], A.A. Onishchuk[1] and S.V. Vosel[1]

[1] Institute of Chemical Kinetics and Combustion, SB RAS, Novosibirsk, 630090, Russia
[2] Novosibirsk State University, Novosibirsk, 630090, Russia
Keywords: homogeneous nucleation, nanoparticles, ibuprofen
Presenting author email: samodurovav@gmail.com

Ibuprofen is a popular nonsteroidal anti-inflammatory drug. However health effects occur when using it as tablets or injections. Nanoparticle administration of ibuprofen via lungs can reduce therapeutic dose of this drug and diminish side effects.

The ibuprofen nanoparticles formation has been investigated in this work. The flow chamber was made of quartz tube (inner diameter 0.5 cm) with an outer heater. Argon was used as a carrier gas. Gas flow entered the inlet of the chamber (Fig. 1). Racemic ibuprofen (Ratiofarm, Germany) was put in the hot zone inside the tube. A saturated vapor was formed inside the chamber. The temperature dropped down at the outlet of heater resulting in vapor supersaturation and nucleation. The aerosol concentration at the outlet of the chamber was measured with the Automatic Diffusion Battery.

The supersaturation "cut-off" method was used to determine experimentally the approximate position of homogeneous nucleation zone. A metal grid was inserted into the tube perpendicular to the gas flow and number aerosol concentration at the outlet of the chamber was measured as a function of the grid coordinate (Fig. 2). This method is based on the fact that homogeneous nucleation is inhibited due to the vapor condensation on the grid. As can be seen from Fig. 2 the outlet number aerosol concentration changes sharply when grid is moved from 2 to 5 cm. This means that nucleation proceeds more intensively in this region.

Mean vapor concentration was found from the difference between the mass of a vaporized substance and the mass of the substance condensed on the inner wall of the chamber. The latter mass was found by cutting the tube with condensed substance, dissolving ibuprofen in isopropanol and measuring optical density at the 272.5 nm (ε = 243.4 $mol^{-1} \cdot l \cdot cm^{-1}$). It allowed us to determine radial and axial ibuprofen vapor concentration profiles using the numerical solution of mass-transfer equation in the chamber from 2 to 5 cm. Also radial temperature profiles were measured at the temperature drop zone. Then radial profiles of supersaturation ratio were calculated. Maxima of these profiles as function of axial coordinate are shown in Fig. 2. Axial profile of nucleation rate J_{cl} was calculated from supersaturation ratio maxima profile. Classical nucleation formula was used to calculate J_{cl}. Properties of bulk liquid ibuprofen (density, surface tension) were additionally measured as there were no literature data concerning this substance.

A specified position of homogeneous nucleation zone was found as the position of maximum of J_{cl} curve (Fig. 2). Experimental nucleation rate J_{exp} was determined from the volume of homogeneous nucleation zone and the outlet number concentration of aerosol particles. A width at the half of the height of nucleation rate J_{cl} curve was used as nucleation zone length. Analogous procedure was performed to find the zone radial thickness. The calculated nucleation zone volume had a value of $3 \cdot 10^{-8}$ m^3 and experimental nucleation rate had a value $J_{exp} = 2 \cdot 10^{13}$ $m^{-3}s^{-1}$. The supersaturation ratio in the homogeneous nucleation zone was equal to 10 (see Fig. 2); the temperature of nucleation was equal to 311K.

Basing on experimental data a model of homogeneous nucleation of ibuprofen vapor was developed. It included homogeneous nucleation of supersaturated vapor, particle growth and diffusion of ibuprofen molecules to the wall of the chamber. Coagulation of particles has been shown to give negligible effect.

Financial support for this work was provided by the Siberian Branch of Russian Academy of Sciences (SBRAS): Interdisciplinary Integration Project No. 3 and SBRAS-Taiwan Collaboration Project No. 151.

Key words: homogeneous nucleation, nanoparticles, sulfur
Presenting author email: valiulin@kinetics.nsc.ru

Sulfur, as fine powder, can be used for polymer production, for agriculture and medicine. The application of sulfur nanoparticles for storage batteries can double their capacity as compared with standard lithium-ion storage systems. Sulfur nanoparticles synthesis from the vapor phase is the most convenient way since it produces high purity material in one step. The sulfur nanoparticle formation mechanism via homogeneous nucleation from a supersaturated vapor in a flow diffusion chamber (Fig. 1) was investigated in this work. The flow chamber consisted of a glass tube (of i.d. = 1.2 cm) with an outer heater. A flow of Ar was supplied to the inlet with the rate 15 cm^3/c. A spoon with sulfur was inserted inside the heated zone (saturation zone), and that resulted in saturated vapor generation. At the outlet of the heated zone the temperature dropped down resulting in the nucleation onset. Number concentration and size distribution of aerosol particles at the outlet of reactor were measured by a diffusion spectrometer of aerosol (DSA) and a photoelectric counter AZ-10. Morphology of nanoparticles (Fig. 2) was observed using a transmission electron microscope (TEM). The crystal structure of nanoparticles of sulfur was studied by the X-ray analysis.

The approximate location of the homogeneous nucleation region was determined experimentally using the "supersaturation cut-off" method. Round metallic grid with diameter equal to the inner diameter of the tube was inserted into the tube perpendicularly to the flow (Fig. 1). Due to the vapor-to-grid condensation the homogeneous nucleation was suppressed downstream and the outlet concentration was decreased. The concentration of particles at the reactor outlet was changing is most essentially when moving the grid in the range of axial coordinate 15 to 25 cm (Fig. 3), which means that the nucleation rate is the highest in this location.

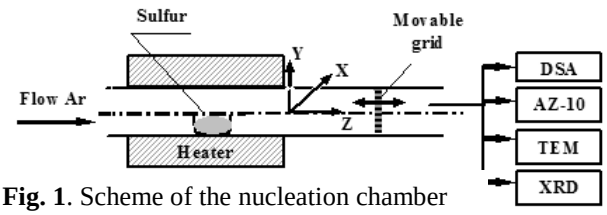

Fig. 1. Scheme of the nucleation chamber

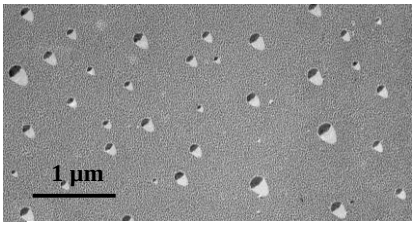

Fig. 2. TEM image of particles.

The rate of sulfur evaporation in the saturation zone and the axial profile of wall vapor deposition rate were measured experimentally. The difference between these two quantities gave the vapor concentration n averaged over the tube cross section vs. the axial coordinate Z. Then using the experimental function n(Z) the radial profiles of sulfur vapor concentration were determined solving the mass transfer equation for 15< Z <25 cm. The temperature radial and axial profiles were measured by a chromel-alumel thermocouple. The supersaturation radial profiles as calculated from the concentration and temperature profiles have demonstrated a maximum for the radial coordinate 0 to 0.1 cm. The maximum supersaturation vs. axial coordinate is shown in Fig. 3. To evaluate the nucleation volume the rate of nucleation J_{cl} was estimated by the classical formula (Fig. 3). The nucleation zone was considered as that within the half maximum of J_{cl} which gave nucleation volume of about V_n=0.202 cm^3. It was found that thermophoresis and coagulation give no contribution to aerosol outlet concentration. Finally, using the estimated value of V_n and the outlet particle concentration 9.5×10^3 cm^{-3} the nucleation rate was estimated $J_{exp} \approx 7\cdot10^5$ $cm^{-3}\cdot s^{-1}$. The supersaturation and temperature were estimated as S = 1200 and T = 308 K, corresponding to this value of nucleation rate.

Production and coating of functional nanocomposite materials are studied for industrial applications. The capacity of anode materials for Li-ion cells could be increased for anode materials by using copper coated silicon particles, and the permeability and the permittivity of polymer composites could be enhanced with magnetic nanoparticles for GHz frequency range EM wave absorbers.

In this work we used previously developed gas phase hydrogen reduction method (Forsman et al. 2008) that uses metal chlorides as precursors. The experimental setup was utilised for in-situ copper coating of cobalt particles to produce magnetic core-shell copper-cobalt nanoparticles. The apparatus used was further modified to allow copper coating of micron sized silicon and nickel particles. Commercial Ni (OM Group, Inc., NiHP No. 68, Nickel Fine Powder) and Si (NOAH silicon elemental powder 99% ≤10 µm) powders were used in these studies. The nickel and silicon core particles were conducted to the reduction part of the reactor using a fluidised bed aerosol generator (TSI 3400A). N_2 gas was used as carrier in all experiments. The produced powders were characterized for crystal structure, purity as well as magnetic properties.

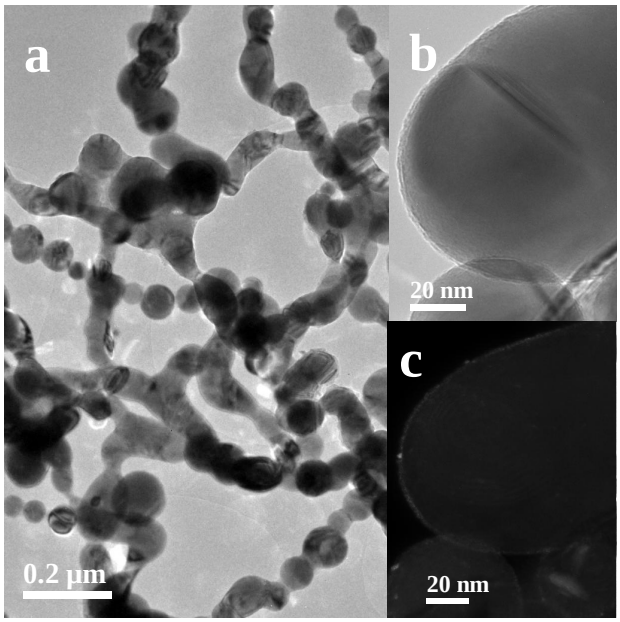

Figure 1. TEM micrograph of copper coated cobalt particles (a). Insert b) shows a coated Co particle at higher magnification. In c) the corresponding dark field image indicates the copper coating on the particle surface.

Tapered Element Oscillating Microbalance (TEOM) and filter samples were used for mass concentration measurements. Fourier Transformation Infrared Spectroscopy was used to monitor the HCl reaction product.

The produced powders were characterised using electron microscopy (SEM and TEM). Image analysis of TEM micrographs gave particle mean diameter of 56 nm and standard deviation of 12 nm for Co+Cu particles. According to X-ray fluorescence analysis the mass concentration of copper and cobalt were 31 m-% and 68 m-%, respectively.

Ni and Si core particle sizes were <100 nm. Based on TEOM measurements, the mass ratio of the produced Ni/Cu and Si/Cu powders was estimated to be 7:12 and 2:1, respectively.

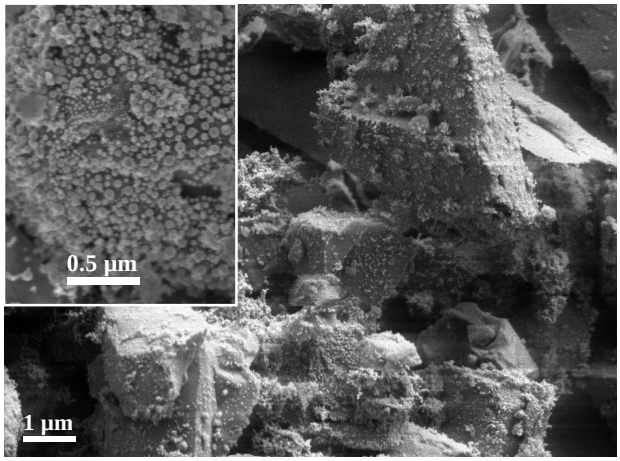

Figure 2. SEM micrograph of copper coated silicon particles. The insert shows the coating particles in more detail.

This work was partly supported by ActKom project (no. 40072/08) funded by the Finnish Funding Agency for Technology and Innovation (Tekes), SAFT, OMG Kokkola Chemicals Oy and Nokia Oyj.

Key words: nucleation, nanoparticles, sulphur, critical diameter
Presenting author email: anatoli@kinetics.nsc.ru

The properties of critical nucleus are important to know in studying the thermodynamics of phase transition. There is a deficit of approaches for the experimental measurement of critical nucleus size, because the living time of critical cluster is very low (often in gas-to-liquid nucleation it is 0.1 - 10 μs) and its concentration is also very small. In our laboratory the experimental method for measurements of the critical nucleus diameter was developed. In this article we demonstrate this method for sulphur vapor nucleation. The experimental set-up consists of a horizontal flow nucleation chamber (Fig. 1). The sulphur vapor is generated inside the chamber with the concentration just below the homogeneous nucleation limit. Air was used as a carrier gas. The idea of the method is in sending seed particles to the nucleation chamber. Tungsten oxide particles are used as seeding ones generated by a hot wire generator with the average size being varied in the range 4 to 15 nm. Fig. 2 compares the inlet seeding particles spectra (upper pictures) with the spectra of particles measured at the outlet of chamber. It is possible to see that when the seeding particles diameter d is less than about 7 nm no vapor-to-seeding particle deposition occurs and the outlet spectrum is almost identical to the inlet one (Fig. 2a). When the inlet diameter is larger than about 8 nm the original spectrum transfers to a single mode outlet spectrum with the mean diameter of about 70 nm, i.e. all the original particles were increased in diameter due to the heterogeneous nucleation (Fig. 2c). When the inlet mean diameter is about 7 nm the single peak in the original size spectrum is transformed into two peaks at the outlet (Fig. 2b). One of these two peaks is referred to the original particles with the diameter less then the critical one (small size part of the original spectrum), the other peak is referred to the seeding particles with the diameter larger then critical one (large size part of the original spectrum). The comparison of the outlet and inlet spectra gives the critical diameter $d_{crit} \approx 7.0$ nm.

To determine the nucleation temperature and supersaturation the metal grid was inserted to the nucleation chamber perpendicularly to the flux and the outlet particle concentration was measured as a function of the grid axial position (Fig. 3). For comparison the outlet concentration of particles as measured in the grid experiment without the vapor of sulphur is shown (which demonstrates the seeding particle-to-grid deposition efficiency) and the axial temperature profile is given as well. As seen from Fig. 3 the seed particles + sulphur vapor curve for outlet concentration have a minimum at the axial coordinate $Z \approx 1$ cm (the outlet edge of the oven is taken as zero). The reason for the outlet concentration increase for $Z > 1$ cm is in the particle size growth due to the sulphur vapor-to-particle deposition. Therefore, $Z \approx 1$ is assumed to be the nucleation onset coordinate. The nucleation temperature and supersaturation were estimated to be 330 K and 7.5 respectively.

Numerical Analysis of particle growth in a microwave-driven plasma reactor and comparison with experimental data

M. Giglmaier, J.F. Quaatz, J. Matheis and N.A. Adams

With this work we present a numerical analysis of particle growth within a micro-wave driven plasma reactor. The commercial solver Ansys CFX is used to analyze flow field and heat fluxes in the facility. The mixing of the injected gaseous precursor is modeled by scalar transport. A bimodal monodisperse model, a moment model (Jeong 2004), and a sectional model (Hounslow 1988) are implemented and modified to describe the decomposition of the precursor tetraethyl orthosilicate (TEOS), and the subsequent particle growth. Numerical results are compared with experimental data (Abdali 2010).

To investigate the particle growth of silica particles a microwave-driven plasma reactor connected to a hot-wall reactor was constructed at the University of Duisburg-Essen. A parameter study was carried out to gain a better understanding of factors affecting particle size, size distribution, and particle morphology. Samples were analyzed by transmission electron microscopy (TEM). A sketch of the reactor is shown in fig 1.

Our contributions to this development are detailed 3D CFD simulations that provide a detailed insight into flow physics and particle- growth processes. First, a simplified geometry was considered, and the bimodal monodisperse model was applied (Giglmaier 2010). The governing equations for the flow are the 3D time dependent Favre-averaged Navier-Stokes equations for compressible mixtures of gases. For an accurate prediction of the fully turbulent flow and dominant mixing mechanisms an explicit algebraic Reynolds stress turbulence model (EARSM) is applied. Heating by the micro-wave antenna is efficiently modelled by adding a source term to the energy equation. Due to the short residence time of the flow within the microwave antenna the phase change to plasma can be neglected, and the flow is modelled as an ideal gas. The decomposition rate of the precursor is prescribed by an Arrhenius-equation. Because of the high super-saturation in the wall furnace nucleation is neglected. A consideration of sintering effects is not necessary as the experiment delivers spherical particles. We demonstrate that the particle size in each finite volume of the CFD-calculation can be predicted. A comparison of experimentally observed sizes with the calculated particle sizes is shown in fig. 2-3. Upon varying the reactor pressure the numerical prediction follows the expected behaviour, and the resulting particle size fits the measured one. However, the experimentally observed maximum of the particle diameter at a precursor mass concentration of 2.2% was not reproduced by the current numerical model. Abdali et al. suggested that at low precursor concentrations nucleation might be important for the prediction of the correct particle size. We will evaluate this assumption by taking nucleation into account. Furthermore, we present a detailed numerical analysis of the flow within the plasma reactor including the assessment of the implemented particle models. In particular we will demonstrate the ability of the sectional model (Hounslow 1988) to correctly predict the particle-size inhomogeneity due to multidimensional flow, especially due to local recirculation regions.

Synthesis of the Pt/Al_2O_3 catalyst particles by MOCVS/MOCVD process at atmospheric pressure

Kun Gao[1], Martin Seipenbusch[1] and Gerhard Kasper[1]

[1]Institute for Mechanical Process Engineering and Mechanics, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany
Keywords: CVD, catalyst, particle sizes, catalytic activity.
Presenting author email: kun.gao@kit.edu

Catalysts have been used in over 90% of the chemical industry since the first catalyst revolution: the Haber – Bosch process. Because of its significant impact on the chemical industry, the catalyst industry becomes the largest single economic activity today [1]. There are still lots of work to do, such as development of new catalysts and synthesis methods, increasing catalytic activity, selectivity and also lifetime of catalysts.

Usually, noble metal catalysts like Pt or Pd are supported by a thermally stable material, on which the active species form highly dispersed spots. First of all, the present work deals with the synthesis of supported catalysts (Pt/Al_2O_3) by a MOCVS/MOCVD process at atmospheric pressure. Pt/Al_2O_3 is an important catalyst for catalytic reforming (petrol reforming) and can also be used as exhaust catalyst. Nanostructured Al_2O_3, due to its high surface area (100 – 600 m^2/g), like SiO_2 and TiO_2, is used today as an important support substance for supported catalysts.

In this work, Al_2O_3 was prepared with precursor $(C_4H_9O)_3Al$ (Aluminium tri-sec-butoxide) by a MOCVS (metal-organic Chemical Vapour Synthesis) process at 1000 ℃ and atmospheric pressure.

$$(C_4H_9O)_3Al + O_2 \rightarrow Al_2O_3 + H_2O + CO_2$$

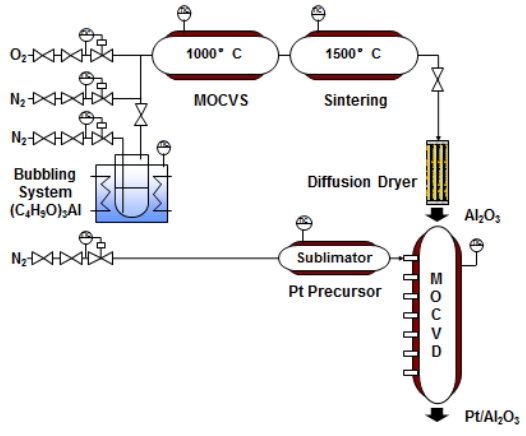

Figure 1. Experimental set up for the synthesis of the Pt/Al_2O_3 catalyst particles by MOCVS/MOCVD process

After the CVS reactor the aerosol (Al_2O_3 nuclear with N_2) was sintered in a sintering furnace at 1500 ℃. The Al_2O_3 particles were coated with Pt in the next step MOCVD (metal-organic Chemical Vapour Deposition) and two different Pt precursors for the MOCVD were used here: $MeCpPtMe_3$ and $isoPrCpPtMe_3$.

Table 1. Properties of the two Pt precursors [2]

Precursor	Properties
$MeCpPtMe_3$	vapour pressure: 6.93 Pa at 23 ℃ decomposition temperature: 120 ℃ melting point: 23 ℃
$isoPrCpPtMe_3$	vapour pressure: unknown decomposition temperature: 122 ℃ melting point: -38 ℃

The experimental set up is shown in the Figure 1. The Pt precursor molecules from the sublimator decomposed on the surface of the Al_2O_3 carrier particles at different decomposition temperatures in the MOCVD reactor. The Pt particle sizes were determined by TEM (Transmission Electron Microscopy) image analysis (Figure 2.), comparing with the catalytic activity.

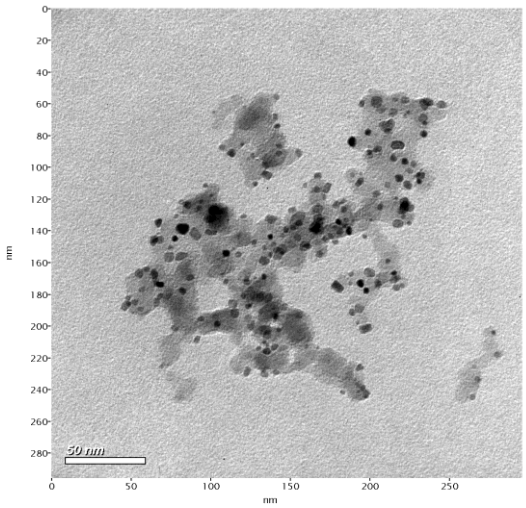

Figure 2. TEM images of Pt/Al_2O_3 particles by MOCVS/MOCVD process

Session 4P: Poster Session A:
Atmospheric Aerosols - Specific Aerosol Types

Activity Size Distribution and Residence Times of Radioactive Aerosols in the Arctic Atmosphere

Alexandra Ioannidou[1]*, and Jussi Paatero[2]

[1] Department of Physics, Aristotle University of Thessaloniki, 54124, Thessaloniki, Greece
[2] Finnish Meteorological Institute (FMI), Observation Services, P.O.Box 503, FI-00101 Helsinki, Finland

Keywords: AMAD, radioactive aerosols, size distribution, arctic aerosols
*Presenting author email: anta@auth.gr

The objective of this work is to define the aerodynamic size distribution of naturally occurring radioactive aerosols of ^{7}Be in the boreal atmosphere. The Arctic Research Centre of the Finnish Meteorological Institute (FMI) at Sodankylä, Finland (67°22' N, 26°38' E, 180m asl) offers unique possibilities for carrying out research on atmospheric radioactivity in the northernmost continental Europe.

Beryllium-7 is a cosmogenic radionuclide ($t_{1/2}$ = 53.3 d) with an important fraction of its production taking place in the upper troposphere. Soon after its formation ^{7}Be is attached to atmospheric aerosol particles (Porstendörfer et al., 1991; Papastefanou & Ioannidou, 1995; Eleftheriadis et al., 2007).

Aerosol samplings were carried out in the open air (2 m above the ground), at Sodankylä. The aerodynamic size distribution of ^{7}Be aerosols was obtained by using a high volume 6-stage cascade impactor with a regulated air flow rate of about 0.57 m^3 min^{-1} (20 cfm) and Efficient Cutoff Diameters of 0.39, 0.69, 1.4, 2.1, 4.2 and 10.2 μm.

Two collection periods were chosen. One during 26-Mar-2010 – 10-Apr-2010. And the secont one from 27-Jul – 9-Sept-2010. The length of each collection period was 48 h. Glass fiber filters were used as impaction substrates. The filters were measured for ^{7}Be with HPGe gamma spectrometry

The activity median aerodynamic diameter (AMAD) ranged from 0.54 μm to 1.05 μm (avg 0.83 μm) (Table 1). More than 75% of the ^{7}Be activity was found to be associated with particles smaller than 1.3 μm (Fig. 1). Finally, the age of aerosol particles was defined in the order of week.

During the first three samplings it was snowing and the temperature was below zero degrees. Only in these cases the AMAD values were strongly anticorrelated with ^{7}Be activities (R=-0.96, p<0.17522), while they are strongly correlated with RH% (R=0.99, p<0.09207). A weak anticorrelation (R=0.34, p<0.44869) was observed between the AMAD values and ^{7}Be activities during the summer period. During high RH% conditions condensation processes become more intense, resulting in increased particle sizes. But this associated with possibly higher scavenging rates of aerosols does not necessarily alone explain the anticorrelation between the AMAD and the ^{7}Be activities. The air mass origin associated with synoptic scale weather phenomena may contribute to that. Air masses coming from the North Atlantic Ocean usually have a low ^{7}Be activity concentration (Paatero & Hatakka 2000). On the other hand these air masses are usually moist thus enhancing the particle growth by condensation.

Table 1. Experimental Data

Start of sampling	^{7}Be (mBq m^{-3})	AMAD (μm)	σ_s
26-Mar-10	5.01	0.92	2.00
29-Mar-10	2.57	1.05	1.87
1-Apr-10	3.91	1.01	2.09
4-Apr-10	0.70	0.54	1.81
7-Apr-10	2.37	0.73	1.94
20-Jul-10	3.72	0.87	2.86
27-Jul-10	6.88	0.90	2.19
3-Aug-10	2.93	1.05	2.95
10-Aug-10	1.20	0.82	3.06
17-Aug-10	3.89	0.63	2.48

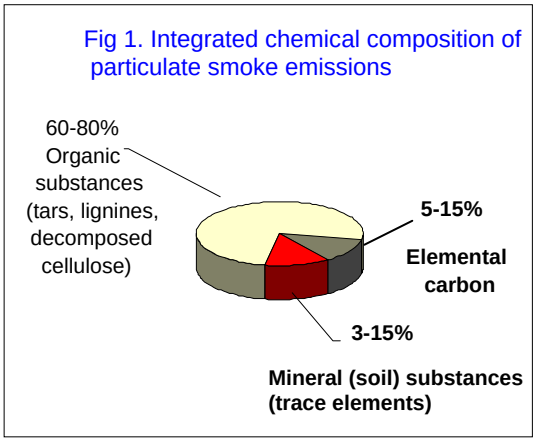
Chemical composition and dispersal property of smoke emission from forest fires in Siberia

Yuri N. Samsonov

Institute of Chemical Kinetics and Combustion, 630090, Novosibirsk. Russia,
Keywords: forest fire, emissions, chemical composition, elemental carbon, carbonaceous particles
samsonov@kinetics.nsc.ru

The fires in boreal forests of Siberia (about 550 mil. ha) burn 10-14 million hectares annually. The burning of forest biomass results in emission into the atmosphere of large quantities, 300–500 million tons annually, of the gaseous combustion products and the solid/liquid smoke particulates. Our study of smoke emissions from more than 30 modeling fires conducted over two forest territories of Siberia in 2000-2010 (in collaboration with researchers from the USDA Forest Service and Canadian Forest Service), show that the total amount of particulate matter emitted during a typical fire is 0.2- 1 t/ha. These values represent 1-7% of the total biomass, 15-30 t/ha, consumed during a fire depending on the pre-fire weather conditions, the biomass qualities, and the combustion rates. The above share of particulate matter seems to be small, but just the fine particles, particularly those containing a great amount of elemental carbon (soot, char, black carbon), can disturb the heat transfer in the air through the effects on the scattering and the absorption of solar radiation. The emission of large quantities of smokes can, possibly, affect climatic processes (presumably atmospheric cooling?). The potential climatic impacts from the gaseous products (hypothetically atmospheric warming?) and from the particulate emission act contrary to each other, but they depend strongly on the chemical, dispersal and morphological properties of smoke particulates. Thus, we are in need of quantitative data on the smoke emission from the large-scale forest fires to predict the possible changes in chemical and optical conditions of the atmoshere, to create and verify the computational models for global climate or regional weather, and to control the respiratory quality of the near-ground air.

The mentioned above modeling fires, including those conducted at the forest plots of 200 x 200 m, mimic properly the gas-and-aerosol emissions from the wildland fires. The advantage of the modeling fires is that they are carried out under prescribed conditions. In this case, it is possible to record the kinds and the pyrological properties of forest fuels, to register the weather conditions before and during fires, to measure the amounts of burned biomass, the rates of fire spread and the energies released. The smokes were sampled by pumping through the polymeric fine-fiber and the glass-fiber filters. The Synchrotron Radiation X-Ray Fluorescence is used to determine the trace element composition (K, Ca, Fe and other 15-17 elements). The quantities of organic matter and elemental carbon are measured by gas chromatography. Fig.1 shows a typical composition of particulate emissions. Fig.2 shows the typical distribution functions measured *in situ* with an optical counter/analyzer depending on the combustion conditions. One can see that 90-95% of the particulate matter consist of fine particles which can strongly influence the optical and chemical conditions of the atmosphere.



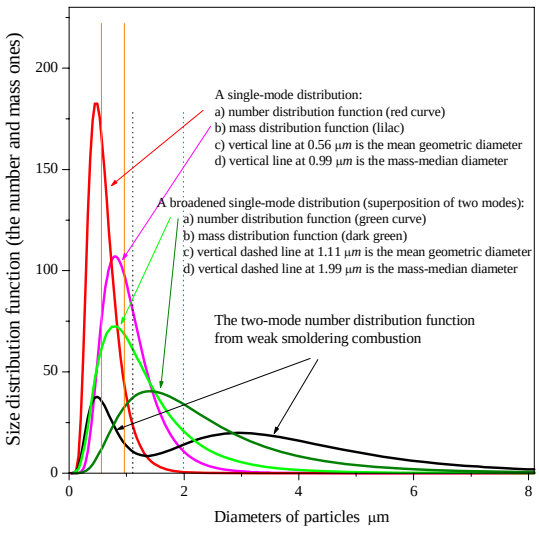


Fig. 2. Size distribution functions of fine fractions of smoke emissions upon different combustion conditions:
the number function: a percentage of particles per a one micron size range, % of particles μm^{-1}
the mass function: a percentage of emission mass per a one micron size range, % of mass μm^{-1}

Analysing roadside Particle Number Concentrations using Boosted Regression Trees (BRT).

N.Z.Yahaya, J.E. Tate and M.R.Tight

[1]Institute for Transport Studies, University of Leeds, UNITED KINGDOM
Keywords: particle number concentration, street canyon, stochastic boosted regression trees, wind factors
Presenting author email: tsnzy@leeds.ac.uk

The influence of traffic flow and wind factors on roadside Particle Number Concentration [PNC] have been continuously surveyed for a 12 month period around a congested urban traffic signal controlled junction intersection in the suburb of Headingley, City of Leeds, UK. The experimental work was conducted at the semi-permanent 'Instrumented Junction' research site. Instrumentation includes: traffic flow and speed sensors, above roof-top and in-street sonic anemometers and four air quality stations measuring ultra-fine PNC.

Analysis has demonstrated significant variations in PNC between the stations, largely influenced by the prevailing and in-street winds, building geometries, background concentrations and tidal traffic flows. There is strong evidence of along canyon flow channelling at the sites located in irregular street canyon environments, with air-flows commonly parallel to the street axis. Across-canyon air-flows were also observed, which led to elevated concentrations on the leeward side of the street canyon at two of the monitoring stations as shown in Figure 1.

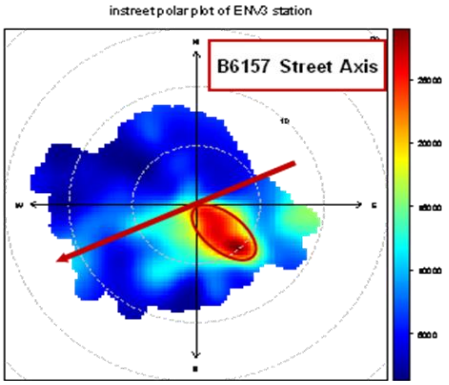

Figure 1. Bivariate polar-plot of [PNC] at ENV3

An new approach methodology to analyse PNC, Stochastic Gradient Boosting, or Boosted Regression Trees (BRTs) (Friedman, 2001, Friedman, 2002) is used to explore the relative influence of a variety of source and meteorological variables on PNC at the urban roadside locations. BRTs differ substantially from traditional regression-based approaches. Simple regression models only provide a single relationship between response and predictor variables BRTs are constructed of multiple regressions models. The BRTs were fitted using the 'gbm' package (R Development Core Team, 2008 and Ridgeway, 2007). Sensitivity testing of model parameters has been carried out (e.g. learning rates (0.005-0.5), number of trees (1000-10000) and interaction depth (1-10)) to identify the optimal parameterisation.

The BRT analysis has provided an importance rank of predictor (relative influence) variables expressed as a percentage. Figure 2 illustrates the relative influence results for site ENV1. It was found that the most important variable was the roof-top wind direction, followed by the traffic flow and vehicle speed. The roof-top wind speed was also found to be a significant influence on PNC concentration. These phenomena are in line with expectations as wind direction and speed are known to strongly influence dispersing air-flows and concentrations in street canyons.

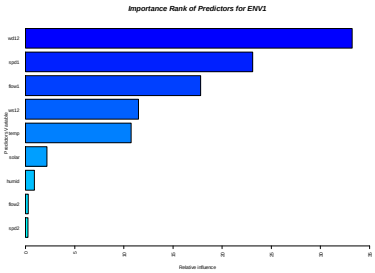

Figure 2. Relative importance of the PNC predictors at ENV1.

A clear benefit of BRTs for air pollution applications in particular PNC study, is their ability to model complex variable interactions and non-linear effects, which are the norm in air pollution research and can be difficult to determine using traditional statistical approaches.

Chemical and mineralogical composition of particulate matter released from agricultural operations

A. Malaguti[1], C. Telloli[2], M. Berico[1], C. Vaccaro[2], M. Mircea[1]

[1]ENEA, National Agency for New Technologies, Energy and Sustainable Economic Development, via Martiri di Monte Sole 4, 40129, Bologna, Italy

Keywords: agricultural aerosols, chemical composition, mineralogical composition
Presenting author email: mihaela.mircea@enea.it

The aerosol produced by agricultural operations has significant contribution to the atmospheric aerosol loadings and, therefore, its impacts on visibility, climate forcing and human health should be considered.

This work shows the chemical and mineralogical composition of agricultural aerosols produced during wheat harvest threshing, ploughing and wheat seeding as a function of size. The sampling was carried out on 25 June 2009 for wheat harvest threshing, on 7 and 8 October 2009 for ploughing and on 17 November 2009 for wheat seeding, near Comacchio Valleys (44 ° 36' 40.79" N - 12° 04' 10:52" E,-1m), in Po valley in the north east of Italy, close to the sea.

The aerosol was sampled with an 9-stage Andersen-Marple impactor with a quartz fiber filter SKC 225-1826 1.2µm R-100, and with a modified Millipore Swinnex 47 Polypropylene holder with a quartz fiber filter Pallflex® Air Monitoring Filters Tissuquartz™ 2500 QAT-UP, within the dust plume generated by the agricultural machines.

The chemical composition of sampled aerosol was extracted from the filter and analyzed by Inductively Coupled Plasma Mass Spectrometry (ICP-MS) (X Series spectrometer from Thermo Electron Corporation collision/reaction cell CCT^{ED}) (Heal, 2005; Pekney, 2005). The analyses show that the aerosol chemical composition released during wheat harvest threshing, ploughing and wheat seeding operations is similar with soil composition (Fig. 1).

The surface morphology of sampled aerosol particles studied by Scanning Electron Microscopy (SEM) (CARL-ZEISS EVO 40) shows the presence of fungal spores, bacteria, pollens, fragments of plants, etc.

This work is part of the MINNI (Integrated National Model in support to the International Negotiation on Air Pollution) project, funded by the Italian Ministry for Environment and Territory and Sea and carried out by ENEA.

Identification of Eyjafjallajökull volcanic ash particles collected in Munich in spring 2010 by Raman microspectroscopy

S. Huckele[1], B., Weinzierl[2], R., Niessner[1], C., Haisch[1], T., Baumann[1], N. P. Ivleva[1]

[1]Technische Universität München, Institute of Hydrochemistry, Chair for Analytical Chemistry, Marchioninistr. 17, Munich, D-81377, Germany
[2]Deutsches Zentrum für Luft- und Raumfahrt (DLR), Institut für Physik der Atmosphäre, Oberpfaffenhofen, D-82234, Germany
Keywords: Eyjafjallajökull, particle characterization, fingerprint, Raman microspectroscopy (RM)
Presenting author email: Natalia.Ivleva@ch.tum.de

During the eruption of the volcano Eyjafjallajökull in Iceland in April/May 2010, about 140 million m³ of ash were belched into the atmosphere to over 8000 m height. This ash cloud was dispersed all over Europe and reached the Munich area on April 16, 2010. Due to the amount of ash in the atmosphere, air traffic was grounded in 23 European countries for several weeks.

In 17 flights, operated by Deutsches Zentrum für Luft- und Raumfahrt (DLR), particle samples in the airspace near the eruption and over Europe (April/May 2010) were collected. It was found that the volcanic particles mainly consist of silica grains mixed with various minerals indicating their basaltic origin. Analyses of the ash collected near the eruption zone (DLR, May 2, 2010) showed a varying chemical composition in the different particle size fractions. The Si/Al-ratio was about 3.6±2.8 and the Fe/Si-ratio was about 0.33 (Schumann *et al*, 2010; Pskarsson, 2010).

In parallel, aerosol samples were collected at ground level in an urban setting at the Intitute of Hydrochemistry of Munich using an electrical low pressure impactor (ELPI) and in precipitation using a wet-only/dry-only sampler. As the ash particles could serve as a tracer for airborne particles, the seeping waters in the vadose zone were collected and analyzed. All samples were studied using Raman microspectroscopy (RM). Based on the effect of an inelastic light scattering by molecules, RM provides fingerprint spectra and allows the distinction of a wide range of chemical substances in air particulate matter with the spatial resolution of an optical microscope (Ivleva *et al*, 2007).

Figure 1 shows representative volcanic particles collected in the DLR flights near the eruption zone (a, May 2, 2010), from the air space over Munich (b, April 16, 2010), and particles collected with the ELPI at ground level in Munich (c, April 16-19, 2010). The Raman spectrum of the particle from the air space near the volcano (a) shows characteristic, broad peaks near 140, 315, 380, 420, 540, 720 and 850 cm^{-1}. The spectra of the volcanic particles collected in the airspace over Munich (b) and at ground level (c) demonstrate similarities with the particles close to the volcano. The differences between spectra suggest aging of the particles during the transport with the ash plume and during precipitation. Additionally soot, sodium nitrate and titanium dioxide particles were identified in particular matter sampled on ground level, indicating anthropogenic influence.

In order to interpret the Raman spectra of volcano particles and to characterize their chemical composition a wide range of reference materials: iron(III) oxide (α-Fe_2O_3, hematite), aluminium oxide, quartz, basaltic rock minerals as well as volcanic ash from the ground near Eyjafjallakökull was analyzed. Although the Raman spectra of hematite and quartz are characterized by very narrow peaks we found the similarities in their positions compared to the broad bands in spectra of volcanic particles collected by DLR flights near the eruption (a). This suggests that the ash particles contain iron(III) and silicon oxides. Thus RM is an effective method which enables for the identification and chemical characterization of individual volcanic particles.

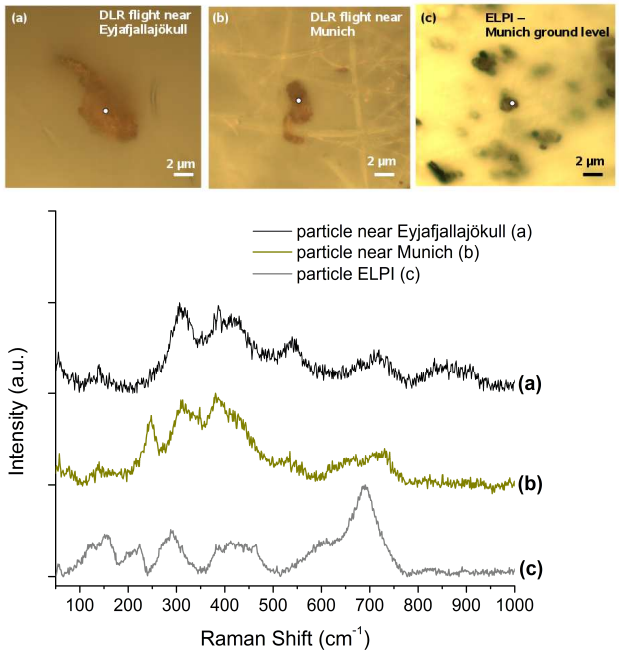

Figure 1. Optical images and corresponding Raman spectra of particles collected in the air space close to the volcano (a), over Munich (b), and particles sampled at ground level in Munich (c).

Characterization of particulate trace elements in Tehran air

F. Halek and A. Kavousirahim

Department of Energy & Environment, Materials & Energy Research Centre, Tehran, P.O.Box 14155-4777, Iran
Keywords: particulate matter, PM_{10}, $PM_{2.5}$, trace elements, Tehran air pollution.
Presenting author email: f-halek@merc.ac.ir

Tehran, the capital city of Iran with over 10 million populations, is facing great risk from various pollutants, especially suspended particulate matters (Madanipour, 2006; Atash, 2007). It is well established that inhalable particles carry higher concentrations of many potentially toxic trace elements such as Pb, Cd, V, Fe, Zn, Cr, Ni and Mn (Liu et al, 2000; Harrison and Yin, 2000). Trace elements are released into the atmosphere by human activities, such as combustion of fossil fuels and industrial activities; and natural sources such as forest fires, oceans and volcanoes (Querol et al, 2007; Rajsic et al, 2008; Yatkin and Bairam, 2008). The concentration of particulate matter in Tehran increases drastically in the winter time and as the result, Tehran experiences such days quite often, forcing schools to close and people with heart and lung problems to stay home.

Experimental

In this study, the experiments were carried out during winter (Jan., Feb. and March) 2009 to determine the concentration of PM trace elements, as well as elements characterization of PM and source assessment. Four different sites including: Vanak Square (VS), Arjantin Square (AS), Sadeghieh Square (SS) and North Karegar Avenue (NK) all located in the north-western parts of Tehran were selected for samplings. This part of Tehran is highly populated and jammed with traffic and also many schools, universities, commercial areas, terminals, and hospitals are involved in their daily activities. Daily 24 hrs sampling started at 8:00 A.M. Sampling height was chosen according to average height of Iranian people which is 1.65 m (Haghdoost et al, 2008). Studied 11 trace elements and their limit of detection (LOD) are listed in Table 1 were investigated

PM_{10} and $PM_{2.5}$ collections were done using cascade impactors (Sierra Ins., USA) on Wathman glass fiber filters (type GF/A). All the samples were acid digested according to the method EPA-3051, using microwave oven (Mile Stone - ATC - FO 300 - Italy). The filtrates were analyzed for the elements, according to EPA-6010 method, using Inductive Coupling Plasma instrument (ICP-ARL 3410, Switzerland).

Table 1. Studied elements and attributed LOD (mg/l).

Element	Zn	Fe	Pb	Mg	Al	Cu
LOD	0.001	0.0005	0.01	0.00002	0.02	0.0003
Element	**S**	**Ti**	**Mn**	**Cr**	**As**	
LOD	1	0.1	0.0001	0.002	0.05	

Results & Discussion

Table 2 lists the average concentrations of different elements on PM_{10} and $PM_{2.5}$. The total concentration of these elements in PM_{10} and $PM_{2.5}$ is more or less the same to the concentration of Fe alone in the particulates. Among these elements, As and Mn have more health risk in human.

Table 2. Average concentrations of different elements on PM_{10} and $PM_{2.5}$ (μg/m^3).

	Zn	Fe	Pb	Mg	Al	Cu
PM_{10}	26.60	7.87	0.94	20.15	0.12	1.92
$PM_{2.5}$	24.26	3.73	0.58	12.08	0.08	1.37
	S	**Ti**	**Mn**	**Cr**	**As**	
PM_{10}	3.00	1.56	0.42	0.33	0.27	**SUM: 63.17**
$PM_{2.5}$	1.11	0.96	0.32	0.30	0.20	**SUM: 44.98**

The list suggests that the tendency of PM_{10} and $PM_{2.5}$ in combining with the elements is different. For example, trace elements such as Cr and Zn are more combined with $PM_{2.5}$, while PM_{10} contained more S and Fe. The total concentrations of all the trace elements attributed with PM_{10} averaged to be 63.17 μg/m^3, while for $PM_{2.5}$ was 44.98 μg/m^3. This lead to the ratio of $C(PM_{2.5})$ / $C(PM_{10})$ = 0.71, which suggests that more trace elements in Tehran atmosphere are combined with smaller particulate matter. Since the smaller particles can accumulate deeper in lungs, therefore the smaller the size of the particles the more dangerous they become for human health.

It is noticed that the concentrations of the Zn, Mg and Fe are much higher than the other elements. In addition, iron could be found as one of the constituents of soil in the various forms of its salts. The concentrations of the other elements compared to these 3 elements, are low and could be considered as anthropoid sources emitted mostly from the industrial activities. The order of PM elemental concentration in different sites was: NK > VS > SS > AS.

Characterization of particle size distributions of powdery building materials aerosol

T. Prasauskas[1], D. Martuzevicius[1], E. Krugly[1] and L. Kliucininkas[1]

[1]Department of Environmental Engineering, Kaunas University of Technology, Radvilenu pl. 19, LT50254, Kaunas, Lithuania

Keywords: Air pollution, powdery building materials, particulate matter, resuspension, particle size distribution

Presenting author email: tadas.prasauskas@ktu.lt

Introduction

There have been numerous studies assessing the potential aerosolization of various contaminants from building materials and its relation to respiratory problems. These emissions are most often the cause of respiratory problems, whilst many may increase susceptibility to asthma and allergies, and in some cases they include highly toxic and carcinogenic substances. Polluting particles can also be a problem during the demolition phase. A wide range of common building materials emit particles and gases that carry a variety of health risks (Berge, 2009). Thus, particle size distribution is an important physical property of solids with respect to potential health impacts.

Methods

We have aimed to identify particle size distributions of various powdery building materials by two aerosol generation methods: fluidization and gravitation (Gill et al., 2006). These two methods represent actual industrial activities, such as pneumo transportation and unloading, and are easily modelled in laboratory conditions. Various powdery building materials aerosols was generated in laboratory by fluidization (dust is resuspended by direct entrainment into airflow in a tube) and gravitation (a source sample fell as a discrete slug through the air into an enclosed chamber, from which dust is evacuated) methods. Particle size distribution was determined for 11 materials: cement, chalk, clay, coarse sawdust, fine sawdust, gypsum, hydrated lime, masonry grout, quartz sand, sand, structural lime.

Using the fluidization method, 0.1 g of powdery building material was inserted into the injection tube. The material sample was dispersed into the experimental chamber by the short-term gust of compressed air. The air was withdrawn from the chamber via sampling tubes together with sampled particles. In case of gravitation method, 1.0 g of powdery building material was dropped from 40 cm height into an enclosed chamber, from which dust was evacuated. In both cases, particle size distribution was determined by the Aerodynamic particle sizer (APS) (3321, TSI Incorporated) and optical particle counter (OPC) (3016, Lighthouse worldwide solutions). Aerosol was sampled by separate Tygon tubes at the same height (20 cm from the chamber bottom).

Results

The PSDs of resuspended particulate matter from powdery building materials were rather similar by both fluidization and gravitation methods, with exception of coarse sawdust and sand, which varied substantially comparing to other materials. According to APS data (number concentration (dN) the highest mode by fluidization method was assessed for fine sawdust and equal to 3.278 μm, and the lowest for gypsum - 1.981 μm (Table 1.). In case of gravitation method highest mode also was assessed for fine sawdust - 3.523 μm and the lowest for coarse sawdust 0.542 μm.

With respect to mass concentration (dM), the highest modes by the fluidization method were determined 19.810 μm and 15.960 μm for coarse sawdust and sand, respectively. The lowest mode was determined for the gypsum - 2.839 μm. In case of gravitation, the highest modes were assessed for coarse sawdust and chalk (19.810 and 13.820, respectively) and the lowest one for gypsum (3.051 μm).

Table 1. Value of modes (dN and dM) of building materials.

Building material	Fluidization		Gravitation	
	Mode, μm		Mode, μm	
	dN	dM	dN	dM
Cement	2.288	3.278	2.642	3.523
Chalk	2.288	3.051	2.642	13.820
Clay	2.642	3.523	3.051	4.068
Coarse sawdust	2.642	19.810	0.542	19.810
Fine sawdust	3.278	5.048	3.523	5.829
Gypsum	1.981	2.839	2.288	3.051
Hydrated lime	2.288	4.371	3.051	4.698
Masonry grout	2.458	3.523	3.278	4.371
Quartz sand	2.642	4.371	2.642	3.786
Sand	2.288	15.960	3.278	4.698
Structural lime	2.129	4.371	2.642	5.048

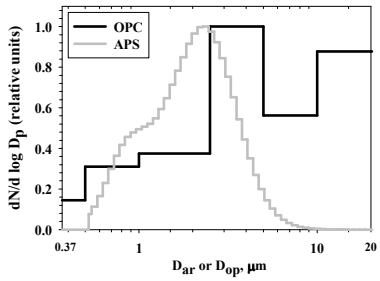

Figure 1. Particle size distribution (dN) of cement during fluidization by APS and OPC.

The comparative analysis of highest aerosol modes generated by fluidization and gravitation methods revealed general trend that slightly higher modes of number (dN) and mass (dM) concentrations were observed for aerosols generated by gravitation method.

Monitoring of the Particulate Matter Deposition Around Port of Koper

G. Jereb[1], B. Marzi[2], F. Cepak[2], G. Dražič[3] and B. Poljšak[1]

[1] University of Ljubljana, College of Health Studies, Poljanska 26 a, 1000 Ljubljana, Slovenia
[2] Port of Koper, Vojkovo Nabrežje 38, 6000 Koper, Slovenia
[3]Department for Nanostructured Materials, Jožef Stefan Institute, Jamova 39, 1000 Ljubljana, Slovenia

Keywords: particulate matter, deposition, monitoring, coal and iron ore

Port of Koper already introduced several dust control measures in order to reduce dusting in the environment from the EET terminal (coal and iron ore manipulation and storage place). Dust control measures include construction of an 11 m high anti-dust emission wall, spraying the body of the landfill with water and wet cleaning of the transportation roads around the landfill at least twice per day. For assessment the effectiveness of such preventive measures long-term monitoring of particulate matter deposition is rather reasonable approach. Therefore three one year measurement campaign were adopted. During time interval 2009/10 it was the third year of monitoring of the particulate matter deposition in the observed area. First campaign started in October 2005 and lasted until October 2006; the second measurement campaign was conducted in 2007/08 and the last one in the period 2009/10.

The amount of particulate matter deposition was determined gravimetrically, samples were qualitative and quantitative analyzed using SEM EDXS. Chemical analysis on annual samples was also carried out in order to determine the amount of selected (Fe, Al, Cu, Zn, Cd, Pb, Cr, Ni, As) metals.

The study was designed to assess the dustiness in the region and determine the difference between vertical and horizontal (contribution of wind) deposition. Additionally the impact of background and correlation between dust deposition, the weather (especially extreme) and the activity at the Port of Koper was evaluated.

During the preliminary study, which was carried out during 2005/06 (Figure 1) extreme values of particulate matter deposition in Port's surroundings were detected. Values exceeded the monthly limiting value by a factor of 12. Also yearly limiting value was exceeded. In time period 2007/08 (Figure 2) and 2009/10 (Figure 3) elevated levels of suspended particles were not detected. The reason for relatively lower values of dust deposition might be in weather conditions (low wind in the observed directions), but also in precautionary measures taken by the Port of Koper. These anti dust measures are obviously an effective approach to reducing or limiting emissions of dust particles to the surroundings.

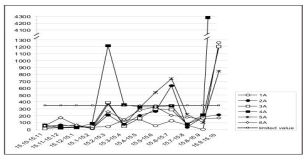

Figure 1: Particulate matter deposition - 2005/06

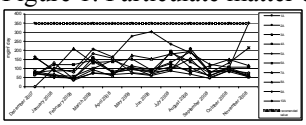

Figure 2: Particulate matter deposition - 2007/08

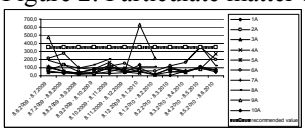

Figure 3: Particulate matter deposition - 2009/10

Based on the results of measurements of particulate matter deposition on other locations (results were obtained in annual reports of the Environment Agency of Republic of Slovenia - ARSO, 2005 - 2009) in Slovenia, where particulate matter deposition is also measured (most sampling sites are located in the vicinity of major power plants), a comparison with particulate matter deposition around Port of Koper was performed. The results indicate that the area around the Port of Koper, despite the fact that the levels decline during last years, is still burdened with high dust deposition (higher than in comparable locations in Slovenia - Figure 4).

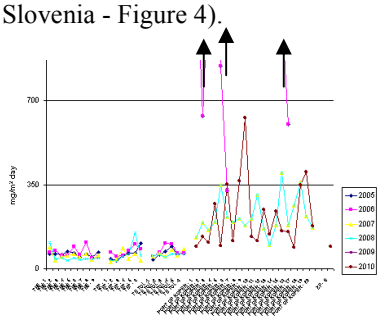

Figure 4: Particulate matter deposition - comparison of different locations around Slovenia

Efficiency of CMA as a dust binding agent

C. Bennet[1], M. Gustafsson[1] and G. Blomqvist[1]

[1]Environment, Swedish National Road and Transport Research Institute, Linköping, SE-581 95, Sweden
Keywords: road dust, dust binding, emission factor, measurements.
Presenting author email: Cecilia.Bennet@vti.se

Calcium Magnesium Acetate, CMA, is used for dust binding in the Austrian and Italian cities Klagenfurt, Bruneck and Lienz in order to reduce the contribution of road dust to PM_{10}. The effect of this method is evaluated within the EU Life project CMA+.

One method is to make controlled experiments where the tyre-pavement emission is investigated (Gustafsson et al., 2009). In the laboratory four studded tyres are spinning on an orbital pavement and the emitted particles are measured by SMPS, APS and TEOM instruments. The CMA is applied and the resulting changes in the aerosol are analysed.

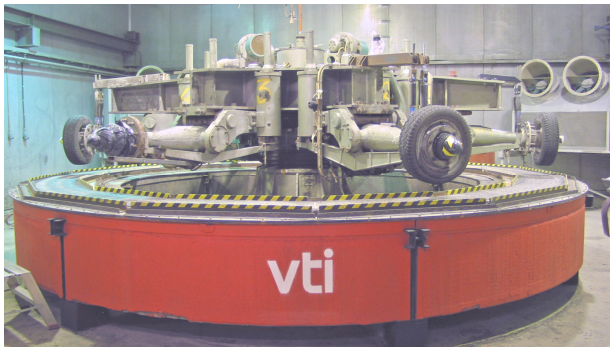

Figure 1. Experimental setup for emissions of the interaction between tyre and pavement.

Two parameters are characterising the effect of the dust binding agent. The maximum decrease in the concentration and the duration of the effect (Figure 2)

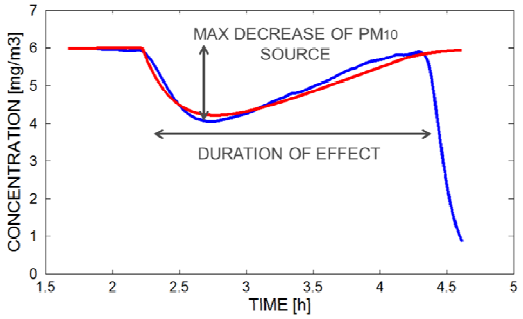

Figure 2. Definitions of the two parameters that characterise the effect of the dust binding agent.

The results can be translated to emission factor and show an effect that is increasing with dose (Figure 3).

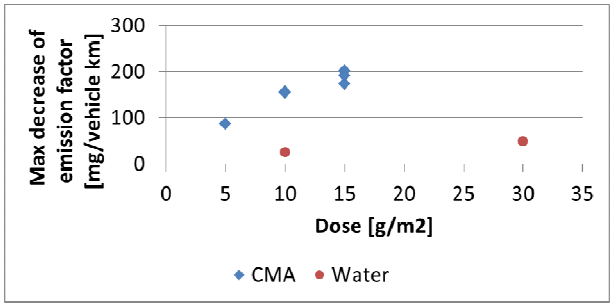

Figure 3. The absolute maximum decrease of the emission factor assuming a constant deposition velocity in the room. A normal emission factor for the studded tyre setup is between 290 and 570 mg/vehicle km.

The measurements also indicate that the number of particles is *increasing* when the PM10 is decreasing as an effect of the application of CMA (Figure 4). This result is interesting as the health effect might be more sensitive to number of particles than to PM_{10} or $PM_{2.5}$. The reason might be a change in the emission itself, a change in the deposition to surfaces in the room or the change of larger particles that act as a sink to the smaller more numerous particles.

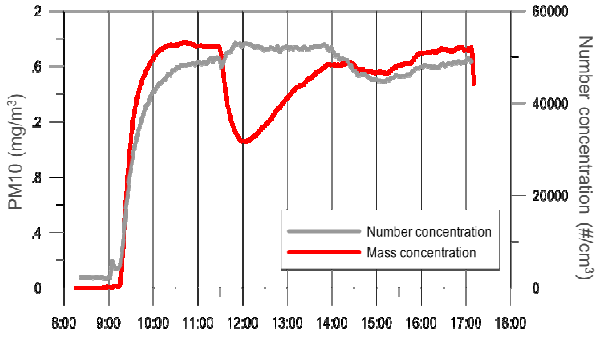

Figure 4. Concentration of particulate mass (PM10) and number concentration when CMA is applied in the road emission experimental setup.

This work was supported by the EU Life project CMA+.

Keywords: Elemental composition, PIXE, Number size distribution, Size-segregated aerosols
Presenting author email: eyubero@umh.es

Las Hogueras de San Juan is the biggest festival of the city of Alicante (southeaster Spain) celebrated every June. Throughout this festival, huge quantities of firecrakers and sparkles are burnt everyday in the city centre during a few minutes. This event represents an unusual but important source of atmospheric particles, especially metals. To evaluate "in situ" the impact of craker and sparkle burning on the levels and composition of atmospheric particles, both the fine and coarse fractions of the aerosol were collected by a streaker sampler with 1-h time resolution; a multistage cascade impactor (SDI, Dekati) was also used. PIXE analysis of these samples allows the assessment of hourly resolution elemental time trends and elemental size distributions, respectively. The temporal evolution of the number of particles was determined by an optical particle counter (GRIMM). Results obtained by the whole campaign will be presented; here, some examples concerning the 1-hour time resolution concentration data are shown.

Figs. 1-2 show the concentrations (ng/m^3) of Cl and K (fine fraction), Ba and Sr (fine fraction). All these elements have very sharp peaks, every day, in correspondence of the time of mascletas burning (3.00 p.m.) and lasting only few hours (the quick decrease after the events can be explained by sea breeze). A similar time pattern is also shown by Mg, Si, V, Cr, Mn, Co, Cu, Zn, Br, Rb, Sr, Ba, Pb. All these elements clearly represents the firework-related elements.

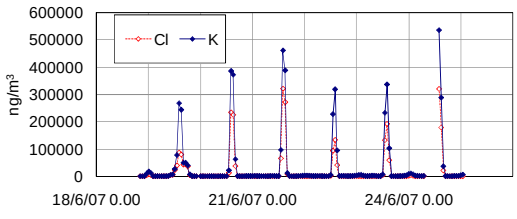

Fig. 1. Fine mode Cl and K concentrations (ng/m^3)

K and Cl reach very high concentrations of about 500 μg/m^3 and 300 μg/m^3 in the fine fraction, with an increase of a factor more than 1500 respect to background levels. Other elements related to firework colors like Sr, Al, Mg, Ba, Cu, Co, Zn, Pb also present a large increase, reaching concentrations of about many μg/m^3 (while their normal values are around some ng/m^3) with increase factors of more than 100 (more than 1000 for Sr) for the fine fraction respect to background levels.

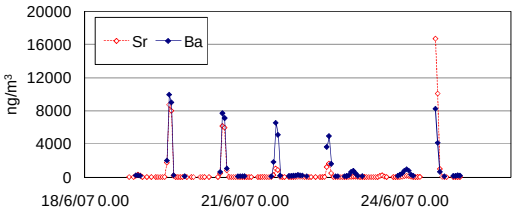

Fig. 2. Fine mode Sr and Ba concentrations (ng/m^3)

For all these elements, an increase of their concentrations is also present in the coarse fraction, but less pronounced.

Also most of the elements of crustal origin like Fe, Ca, Si, Ti, etc. show a temporal pattern similar to that reported in fig 1 and 2, but with a higher increase in the coarse fraction than in the fine one. In sharp contrast to what seen for the elements reported in fig 1 and 2, the ratio between the concentration of these elements during the mascletà and during the background period is constant, pointing out, hence, that the concentration increase is not due to the combustion products but to the resuspension of crustal origin material deposited in the ground where the explosions take place. This hypothesis is confirmed by the calculation of the Enrichment Factors (EF) using Si as reference element. All these elements show EF close to 1. The resuspended soil dust concentration varies from 44 to 130 μg/m^3, while the background concentration is normally less than 10μg/m^3.

This work was supported by the Spanish Ministerio de Educación y Ciencia under the GRACCIE project. (Consolider-Ingenio 2010, program 22422).

New Year´s Day Fireworks: Elevated particle area and number concentrations at an urban background station in Germany 2009 - 2011

H. Gerwig[1], W. Pecher[1] and K. Wirtz[1]

[1]Section Air Quality Standards and Monitoring Methods, UBA – Federal Environmental Agency, 63225 Langen, Germany.

Keywords: tracheobronchial particle area, particle number, fireworks, New Year´s Day

For the protection of human health the European Union defined PM_{10}- and $PM_{2.5}$ limit values. But particle number and particle area become more important because of epidemiological studies and toxicological studies giving evidence of its negative health effects (Knol *et al.*, 2009).

Traffic is supposed to be one of the largest sources of particle number concentrations (Birmili *et. al.*, 2009, Löschau *et al.*, 2010). Also fireworks are known sources for elevated particle mass concentrations (Ponten *et al.* 2003) but result only in combination with low wind speed and bad air exchange to an exceedance of the daily PM_{10} limit value (Branis, 2003).

During New Year's Eve and New Year´s Day (NYD) in Germany in almost all parts of the country fireworks are ignited in large quantities. Most of these activities take place before and after midnight. The same day is often characterised by low number of vehicles during the whole year. Only 50 % of the average number of vehicles was observed during NYD compared to the average of other days of a year in Dresden, Germany (Gerwig, 2005).

Table 1 average, max. particle number and tb area conc. in 2009 and 2010; max minute conc. during New Year's Day 2009 - 2011.

1-h av.	NSAM $\mu m^2 \cdot cm^{-3}$	UCPC $p \cdot cm^{-3}$
av. 2009	6.1	10 600
av. 2010	5.8	11 200
max. 2009	33	65 000
max. 2010	26	65 000
max 1 min av.		
NYD 2009	89	57 000
NYD 2010	17	22 000
NYD 2011	49	35 000

The urban background station was situated in Langen, Germany: 15 km south of Frankfurt a. M. with residential areas to the south and west. Two different particle measuring instruments (TSI Inc.) were running continuously (12-08 – 01-11, 1 min av.) on a rooftop at 14 m above ground with cut of at 1 µm. Meteorological data was collected by WS600 (LUFFT GmbH).

- Deposited tracheobronchial (tb) particle area 0 - 1000 nm: NSAM.
- Particle number concentration 3 - 1000 nm: UCPC 3776.

From 2008 to 2009 the average concentration (s. Tab. 1) of tb particle area was about 6 $\mu m^2 \cdot cm^{-3}$ and particle concentration 11 000 $p \cdot cm^{-3}$.

During NYD 2009 max. 1 min av. of 89 $\mu m^2 \cdot cm^{-3}$ tb particle area concentration was detected accompanied with lowest wind speed (< 1 m s^{-1}) and wind from a nearby residential area. Temperature was between -7 to -1 °C.

During NYD 2011 the tb particle area concentration rose by a factor of ten compared to time periods before and after fireworks. In NYD 2011 wind came also from residential area but higher wind speed of 2 $m \cdot s^{-1}$ occurred.

During NYD 2010 the lowest max. tb particle area was observed while wind came not from residential areas at wind speed of 2 $m \cdot s^{-1}$.

We found, that NYD fireworks from a residential area is a source for elevated particle area and particle number concentration at an urban background station.

Size-selected Ag nanoparticle clusters deposited on carbon nanotubes

T. Shinohara, N. Nishida, H. Tanaka

Institute of Science and Engineering, Chuo Univ. 1-13-27 Kasuga, Bunkyo-ku, Tokyo, 112-8551, Japan

Keywords: Ag nanoparticle cluster, carbon nanotube, cluster number, fission.

Presenting author email: hnznshubiduba1354@yahoo.co.jp

Nanoparticle clusters which are composed of nanoparticles are expected to open a new world of the nanomaterials because of their characteristic structures. For example, we have synthesized Ag nanoparticle clusters which can be regarded as a combination of surface-active Ag nanoparticles and surface-inactive C_{60} nanoparticles [1]. In this study, we have investigated the deposition of the Ag nanoparticle clusters onto carbon nanotubes. Cluster number of the Ag nanoparticle clusters was selected by a differential mobility analyzer (DMA). Their structures were analyzed by scanning transmission electron microscope (STEM).

Ag nanoparticles were produced by a gas aggregation method and were passed through C_{60} vapor. The nanoparticles thus produced were admitted into an ionizer equipped with radioactive ^{241}Am and were size-selected by a DMA. The selected nanoparticles were electrically collected onto CNT deposited on a Mo grid, and were analyzed by STEM. Number of the constituent Ag nanoparticles was estimated from the STEM images. In addition, number for the intact nanoparticle clusters themselves was also estimated for the clusters collected directly onto a collodion-coated Cu grid.

As shown in fig 1 (a) , the number for the isolated cluster on CNTs is observed to be smaller than that for the intact nanoparticle clusters. This indicates that the gas-born nanoparticle clusters dissociate some nanoparticles when they were deposited onto the CNTs.

On the other hand, the number for the two clusters located at nearest neighbor is good agreement with that for the intacts. This agreement indicates that fission of the nanoparticle clusters proceeds in the deposition process.

In addition, the number for the three clusters located at nearest neighbor is found to be larger than that for the intacts. This indicates that the nanoparticle clusters are not fragmented into three or more.

[1] Tanaka, H. and Maeda, F. (2009) *Chem. Phys. Lett.* **484**, 37-40.

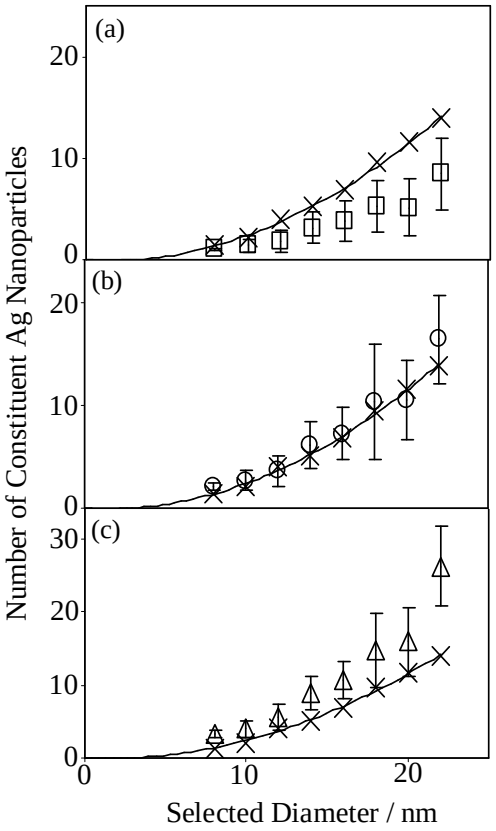

Figure 1. Diameter dependence of number of the constituent Ag nanoparticles for (a) isolated clusters, (b) two clusters located at nearest neighbor , and (c) three clusters located at nearest neighbor. The plots (×) and solid lines exhibit number for the intact nanoparticle clusters themselves.

Chiroptical property of Ag triangular nanoplate protected by chiral molcules

Y. Kojima, N. Nishida and H. Tanaka

Institute of Science and Engineering Chuo University, 1-13-27 Kasuga Bunkyo-ku, Tokyo, 112-8551, Japan

Keywords: chirality, Ag-triangular nanoplate, circular dichroism spectra, surface plasmon resonance.

Presenting author email: yacchi.kojima@gmail.com

Ag triangular nanoplates have attracted much attention because their specific structure induces the novel optical properties such as surface plasmon resonance (SPR) which is different from Ag nanoparticles. On the other hand, metal nanoparticles protected by chial molecules have also attracted much attention because their chiroptical property is specifically different from the chiral molecules themselves. In this study, we have synthesized Ag triangular nanoplates protected by chiral molecules. Produced nanoplates were analysed by scanning transmission electron microscope (STEM), optical absorption spectroscopy and circular dichroism (CD) spectroscopy.

Ag triangular nanoplates were synthesized under irradiation of ultraviolet lights for $AgNO_3$ ethanol solution in the presence of PVP at room temperature as described previously [1]. The Ag nanoplate solution was mixed with methanol solution of enantiopure D-form penicillamine (D-Pen). After the mixed solution was stirring, precipitation with dark blue was formed. This precipitation was further washed with ethanol. The structure of the products thus obtained was analyzed by STEM. In addition, water solution of the products was measured using UV-Vis spectrometer and CD spectrometer. In addition, the products using L-Pen instead of D-Pen were also examined in the same procedure.

Figure 1 shows typical STEM image of the products. The triangular nanoplates with 130 nm are observed in the STEM image. Because this shape is the almost same as that for the Ag triangular nanoplates before the addition of D-Pen, the addition process of D-Pen does not affect on the structure of the nanoplates.

Since the nanoplates added with D-Pen were well dispersed with water, the products are found to have hydrophilic property. Taking into consideration that the nanoplates before the addition of D-Pen were decomposed by water [1], this hydrophilic property indicates that the produced nanoplates were protected by D-Pen molecules which are known as hydrophilic molecules.

When absorption spectrum for the nanoplates added with D-Pen was measured, characteristic absorption was observed. Because this can be ascribed to the SPR for the Ag triangular nanoplates, shape of the nanoplates does not be affected by the water dispersion.

When CD spectrum for the nanaplates addition with D-Pen was measured, two major cotton effects differs from that for the D-Pen molecules themselves, these effects are considered to be induced by protection of D-Pen molecules. In fact, CD spectrum for the nanoplates added with L-Pen, was measured as almost mirror-image one for that with D-Pen. This observation supports that the observed Cotton effects are induced by the protection.

In summary, Ag triangular nanoplates protected by the D-/L-penicillamine were successfully synthesized by the present method. Their chiroptical property is induced by the protention of D-/L-penicillamine.

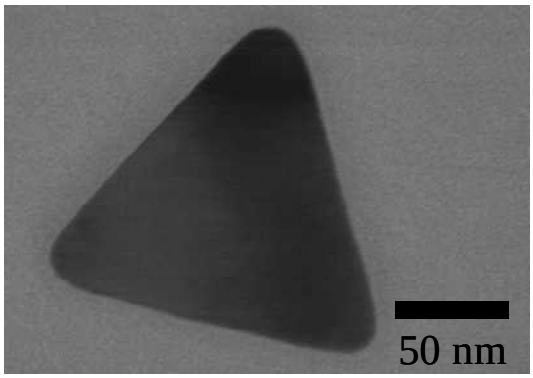

Figure 1. STEM image of precipitates obtained by addition of D-Penicillamine.

Presenting author email: ykbahk@ifu.baug.ethz.ch

In recent years, various kinds of engineered nanoparticles are used in a large number of applications such as sports equipments, semiconductor devices, etc. Carbon nanotubes (CNTs) are well known as the structual material for industrial composites. Due to its geometrical similarity with asbestos, airborne CNTs are important in inhalation exposure studies, air pollution and atmospheric sciences (Wang et al, 2011). This paper presents results of dipersion of carbon nanotubes (CNTs) and relation between the geometrical length and electrical mobility size of airborne CNTs. The relationship between the length and mobility size of CNTs is significant for a real-time measurement of airborne nanoparticles.

Experimental results of different types of CNTs, including multi-walled CNTs (MWCNTs) with diameters of 40 – 45 nm and 80 – 90 nm, and single-walled CNTs (SWCNTs) with diameters of 5 -10 nm, are reported in the study. These CNTs were aerosolized from suspensions with either atomizer or electrospray. For example, MWCNTs Baytubes, BMS, Germany with diameters about 40 – 45 nm were dispersed in different solvents using the nitric acid refluxing method. An atomizer was used to generate airborne MWCNTs with solvents such as DI water, ethanol and isopropyl alcohol (IPA).

In order to classify the generated airborne CNTs, differential mobility analysers (DMAs) are used. The mobility size distribution of airborne CNTs was also measured with the scanning mobility particle sizer (SMPS). Classified CNTs are collected on Nuclepore track-etched membranes (Pore size 400nm, whatman, UK) and analysed with scanning electron microscopy (SEM). Collected CNTs are also measured with transmission electron microscopy (TEM).

Experimental results show that MWCNTs suspensions in IPA provided better and longer dispersion condition than in other solvents. The mode of the mobility size distribution was 60-65 nm as shown in Fig. 1. Classified CNTs were collected at several points in the mobility size range from 65nm to 300 nm. Fig.2 shows SEM image of collected MWCNTs with 75 nm mobility size. Length of the CNTs was obtained by SEM and TEM analysis. For each mobility size, the average length of a large number of collected CNTs was estimated.

These results were compared with theoretical model. Kim et al. (2007) developed a model for the mobility size of nanowires. Vainshtein and Shapiro (2005), Lall and Friedlander (2006) developed models for the mobility size of agglomerates. The results of these models for straight chain type of agglomerates are used to approximate CNTs. Comparison with our experimental results show that the models give satisfactory results with proper choices of parameters.

Peculiarities of particle generation by laser ablation of nickel

V. Dudoitis, V. Ulevicius, G.Raciukaitis and N. Spirkauskaite

Center for Physical Sciences and Technology
Vilnius, LT-02300 Lithuania
Keywords: laser ablation, nanoparticles, formation, size distribution.
email: ulevicv@ktl.mii.lt

Laser ablation is attracting even an increasing attention as a new technique to prepare nanoparticles from the metals, which has been widely used for a variety of applications in the science and technology, for example, nickel particles as magnetic materials for information storage Liu *et al* (2007), Gonzalez *et al* (2007), Lee and Chang (2004). However, a series of characteristics of the generated particles by laser ablation are not fully known. The investigation of the particle formation kinetics in the ambient air during the laser processing are essential to understand the mechanism of their formation. The aim of this study was to characterize the difference of particle formation by laser ablation of nickel due to the laser irradiation type (ns, ps) in varied media.

Particle-free ambient air or the argon gas were delivered to a closed dynamic chamber. Two different types of lasers were used: one with the nanosecond (NL640, λ=1064 nm, τ=15 ns), another with the picosecond (PL10100 λ=532 nm, τ=10 ps) pulse duration (both from Ekspla Ltd.). The lasers were working at a high pulse repetition rate (from 10 kHz to 100 kHz). Laser beam was steered at a scanning speed: 10 - 1000 mm/s.

The particle number concentration was measured with a condensation particle counter (UF-02) (cut-size at 4.5 nm) and their size distribution with the differential mobility particle sizer (ELAS-5MC) (working range: 10 – 200 nm). The average air temperature in the chamber was 25^{o}C (for argon 18^{o}C), the relative humidity of claen air 25 - 30%.

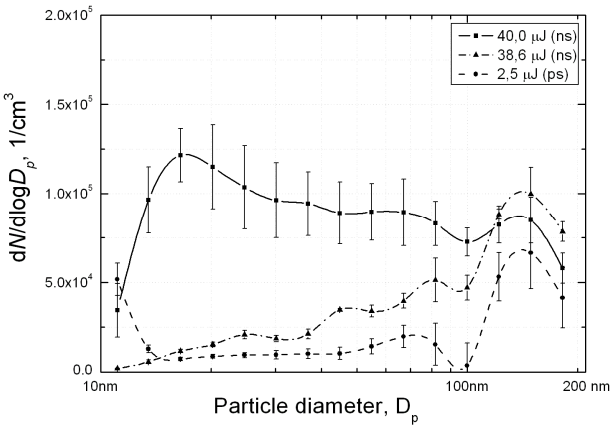

Figure 1. Dependence of generated particle size distribution on the laser pulse energy during the ns and ps laser ablation of nickel **in the ambient clean air**.

Nanosecond and picosecond lasers' ablation data gave different aerosol formation results. It was observed in experiments with picosecond laser ablation that applied pulse energy, repetition rate and beam scanning speed had influence on particle formation (Figs. 1,2).

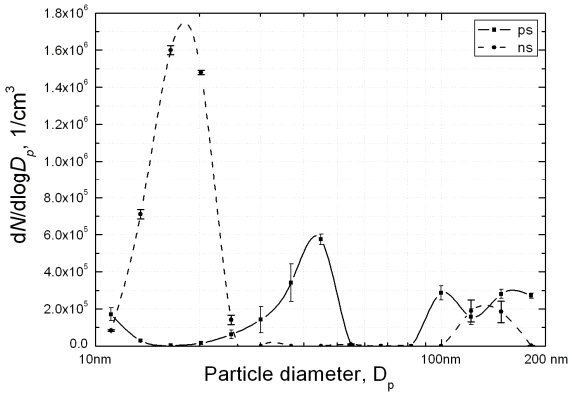

Figure 2. Dependence of generated particle size distribution on laser pulse energy during the ns and ps laser ablation of nickel **in the argon gas**.

The particle size distribution of generated particle varied in shape and concentration due to the applied laser parameters: pulse duration, energy and repetition rate, and beams scanning speed. Wide size particle distribution (Fig. 1) during the ns laser ablation in the ambient clean air can be related with the influence to the particle formation processes from gas phase and futher condensation and coagulation. The most intensive nickel particle generation in ambient air was observed with these nanosecond laser parameters: 10 kHz, 200mm/s (Fig.1). Very different particle size distribution of the nickel was observed in the argon gas. Increase pulse energy led to the formation of a narrow size distribution of the nanoparticles in the argon gas (Fig.2).

This research has shown that the aerosol particle size distribution and concentration depend on laser characteristics, laser operating parameters and the target material. The methods of aerosol measurement were able to monitor variations in particle size distribution, depending on the processing parameters and varied media.

Presenting author email: moravec@icpf.cas.cz

Cobalt and cobalt oxide nanoparticles have attracted substantial research effort in recent years because of their potential applications such as protective materials, catalysts, magnetic data recorders, batteries and gas sensors (Jang *et al.*, 2004). Nanoparticles are frequently coated with SiO_2 to improve their functionality and biocompatibility (Teleki *et al.*, 2008). In this work, we studied CoO_x-SiO_2 binary nanoparticle synthesis by metal organics chemical vapor deposition (MOCVD) using organo-compound precursors cobalt acetyl acetonate (CoAA) and tetraethyl orthosilicate (TEOS).

Particles were synthesized in an externally heated tube flow reactor with i. d. 25 mm and the length of heated zone 1 m. Experiments were performed in an inert atmosphere using nitrogen as a carrier gas (pyrolysis) as well as in oxidizing atmosphere at 10 vol. % of oxygen in the reaction mixture (oxidation). Particle production and their characteristics were studied in dependence on reactor temperature (T_R), concentrations of precursors (P_{CoAA}, P_{TEOS}), oxygen concentration (c_O), and reactor flow rate (Q_R). Precursor concentrations were controlled by the variation of the saturator temperature (P_{CoAA}) or by carrier gas flow rate through the saturator (P_{TEOS}). The particle production was monitored by scanning mobility particle sizer (SMPS, TSI model 3936) and samples for particle characterization were deposited onto TEM grids using nanometer aerosol sampler (NAS, TSI model 3089) and on Sterlitech Ag filters. Particle characteristics were studied by HRTEM, SAED, EDS, XRD and XPS.

The particle production was affected by all investigated parameters, in particular by concentrations of precursors (P_{CoAA}, P_{TEOS}). Particle characteristics were predominantly a function of the chemistry of precursor decomposition, but they were also affected by reactor temperature and concentration of precursors. At lower T_R, particles had broader size distribution, typically from 5 to 25 nm, at T_R 900 °C, the typical particle size varied between 5 and 10 nm.

Particles produced by pyrolysis were XRD amorphous and selected area electron diffraction (SAED) patterns were usually rather week. HRTEM images revealed lattice fringes in the cores of particles, which were typically indexed as hexagonal Co or, in some cases, cubic Co_3O_4. Samples prepared by oxidation showed much better developed SAED patterns and also XRD confirmed cubic CoO and cubic Co_3O_4 crystalline structures. XPS analysis showed Si in the oxide state in the surface layer of particles prepared both in an inert and oxidizing atmosphere. Co-O bonds were identified in the samples prepared by oxidation and mixture of Co-Co and Co-O as well as C-CH_x, C-O and C=O bonds were detected in particles prepared by pyrolysis.

From the above mentioned we can conclude that Co nanoparticles encapsulated in SiO_2 and partially decomposed CoAA were synthesized in an inert carrier gas, and mixture of CoO and Co_3O_4 covered by SiO_2 were prepared in an oxidizing atmosphere.

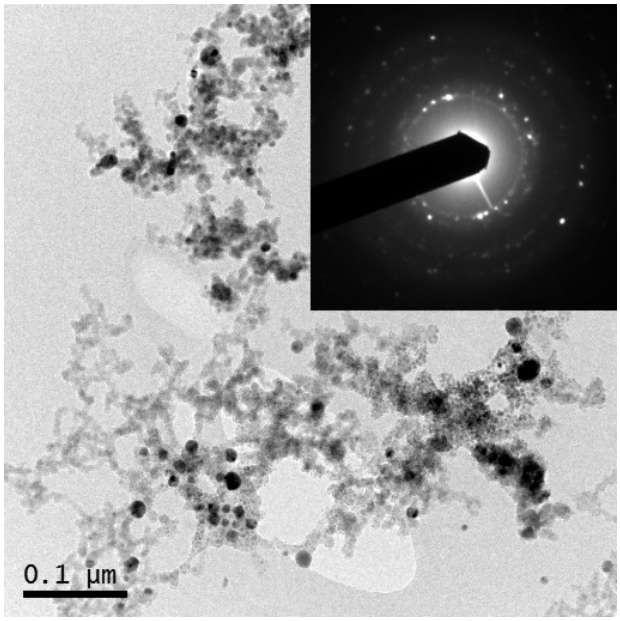

Figure 1. HRTEM image and SAED pattern of particles prepared at T_R=700°C, c_O=10 vol. %, P_{CoAA}=0.32 Pa, P_{TEOS}=1.89 Pa, Q_R=800 cm^3/min.

For the production of nanoparticles at a commercial scale flame processes are most frequently used [Kammler, 2001]. Despite the simplicity of the set-up, the process control is rather complex. Consequently, a profound knowledge of the particle formation mechanism during combustion in dependence of process conditions is required. As minor changes of the process parameters may have a huge impact on the product, there is a huge demand for non-invasive advanced optical measurement tools.

We have studied the formation of silica from a Hexamethydisiloxane (HMDSO) precursor dissolved in ethanol [Mädler, 2002]. Figure 1 shows the burner and the schematic diagram of the process.

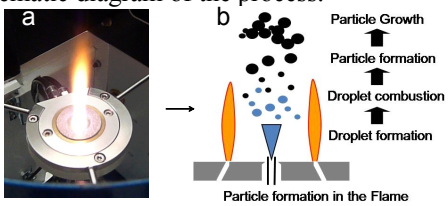

Figure 1. a) burner (Tethis NPS 10); b) particle formation in the flame

As a first step the flame shape was characterized by chemiluminescence imaging under various conditions. Therefore the integral OH chemiluminescence signal was imaged on an ICCD camera for different flame conditions. Furthermore the distribution of the liquid ethanol regime was studied. Figure 2 shows OH chemiluminscence images on the left and an averaged Mie scattering image on the right.

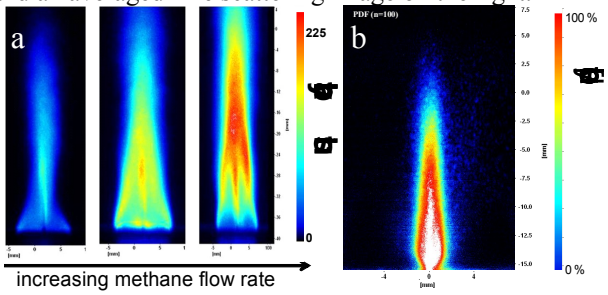

Figure 2. a) OH chemiluminescence images of the flame with increasing methane flow rate (from left to right); b) probability density function of 100 Mie scattering images

Averaged Mie scattering and chemiluminescence images provide complementary information about gas and the liquid phase distribution. These results allow the allocation of pointwise measured scalar quantities within the flame. Pointwise temperature information was achieved by using dual-broadband rotational CARS for oxygen. The CARS system used is based on a multimode frequency-doubled 30 Hz Nd:YAG laser system (Spectra Physics, PRO 250-30) with a pulse energy of 500 mJ at 532 nm. 90 % of the energy was split off to pump a broadband dye laser (DCM). The dual-broadband rotational CARS signal was generated by two broadband dye laser beams and one frequency-doubled Nd:YAG laser beam. The DCM dye, centered around 630 nm with a width of 500 cm^{-1}, produced approximately 25 mJ per pulse. In order to obtain high spatial resolution in the point measurements, a three-dimensional BOXCARS configuration with a focusing lens of f = 300 mm was used. The probe volume was measured to 2 mm. A sanity-check proved that the probe volume is sufficiently small to resolve the dimension of the flame. The CARS signal was dispersed by a 0.5-m spectrograph (Triax 550) equipped with a 2400 g/mm grating and recorded by a CCD camera (PCO 2000). Beside gas temperature results by using the RCARS spectra of oxygen also diffusion of nitrogen at some flame positions could be observed and quantified. Temperature and composition evaluation from CARS spectra has been done with a computer code which compares the experimental spectra with a spectrum out of a pre-calculated library.

The obtained data reveals the location where nitrogen of the surrounding air penetrates the flame, respectively the liquid ethanol regime. Furthermore, the influence of evaporative cooling of the ethanol on the flame temperature could be observed. In a nutshell the results show that the CARS technique is a strong tool to to gather relevant temperature and composition information within the spray combustion. Accordingly, significant improvements in the understanding of the flame spray pyrolysis could be achieved.

The authors gratefully acknowledge the funding of the German Research Council (DFG), which, within the framework of its 'Excellence Initiative' supports the Cluster of Excellence 'Engineering of Advanced Materials' at the University of Erlangen-Nuremberg.

Exposure Measurement in an Industrial Production Facility for CNT-imbedded Nanocomposites

Wang, Jing[1,2], Thompson, Drew[3], Li, Lin[3] and Pui, David Y.H.[3]

[1]ETH Zurich, Institute of Environmental Engineering, 8093 Zurich, Switzerland
[2]Empa, Analytical Chemistry, 8600 Dübendorf, Switzerland
[3]Particle Technology Laboratory, University of Minnesota, Minneapolis, 55414, USA

Keywords: exposure, CNT, composite, dispersion.

The unique properties of carbon nanotubes (CNTs) have led to their increased usage in advanced materials. CNTs are used in structural composites for sporting equipment, conductive plastics, electron field emitters, semiconductor devices, etc. As more industries incorporate CNTs into consumer products the opportunities for worker exposure will rise. The National Institute of Occupational Safety and Health (NIOSH, US) plans to develop recommended exposure limits (RELs) for ultrafine titanium dioxide and CNTs for the period of 2009–2012 (NIOSH 2009).

We measured exposure in an industrial production facility for CNT-imbedded nanocomposites (Wang et al. 2011). In the extrusion operation, CNTs were mixed with melted polymer and other compounds to produce nanocomposite pellets. First polymer was melted and mixed with CNTs. The mixture was extruded from a die into a water bath. Cooled strands passed through a dryer before entering a cutter. The pieces were fed into a second extruder with CNT dispersing agent. At the exit of the second extruder the strands were pelletized. The pellets passed through a shaker and a cyclone for size selection.

A suite of instruments was used to obtain air-borne particle number concentration, surface area concentration, and size distribution data. The instruments were placed in the closed room near the extrusion system. The measurement results are shown in Fig. 1. Very high airborne concentrations were observed during full production of the CNT-embedded pellets. The particle number concentration increased to about 90,000 – 100,000 #/cm^3 and the particles were mainly in the range of 30 – 90 nm. We believe that volatile polymer fumes were a major particle source. This is corroborated by the observation that the particle concentrations were highest near the extrusion barrel and vapor was visible at the extrusion barrels.

We also used a filter to collect samples for electron microscopic analysis. We found a number of CNT agglomerates on the filter. The sizes of the CNT agglomerates are in the range of 1 µm to 20 µm. The individual CNTs are much smaller, with the diameter of about 40 nm. Further research is needed to find out the fraction of CNTs in the total particle concentration.

Dispersion plays a significant role in CNT studies as CNTs often form large agglomerates of the order of microns when provided by manufacturers. We developed an electrospray system to disperse and aerosolize CNT colloidal suspensions with controlled degree of agglomeration. The droplet size produced by electrospray can be monodisperse in the range of 20 to 500 nm and controllable by varying the electrical properties of the liquid and the liquid feed rate. The aerosolized CNTs were used in toxicity studies (Kim et al. 2010, Wang et al 2011).

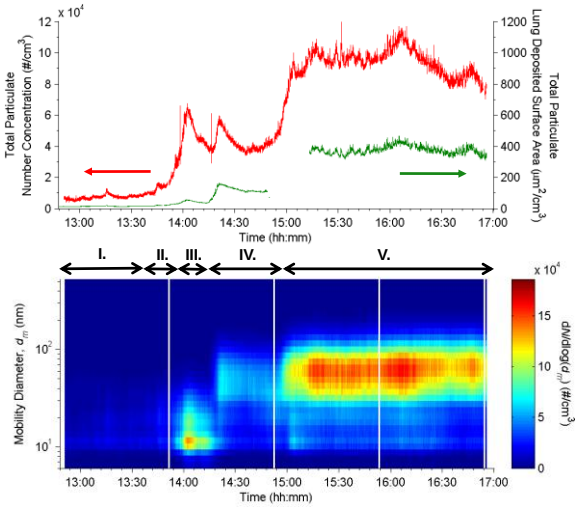

Figure 1. Measurement for air-borne particles during the extrusion operation for CNT-imbedded nanocomposites. Upper panel shows the total number concentration and lung-deposited surface area concentration; lower panel shows the evolution of the particle number-size distribution.

Optical online particle measurement in hot gases up to 450°C and in chemically aggressive gas components

M. Schmidt, S. Schütz

Palas® GmbH, Greschbachstr. 3b, 76229 Karlsruhe, Germany
Keywords: high temperature aerosols, combustion aerosols, particle size distribution, number concentration
Presenting author email: schmidt@palas.de

Currently the combustion and gasification fuels from biomass and the corresponding limitations concerning particle emissions are a point of scientific as well as public discussions. The quantity of particle emissions is depending on the process parameters and the particle separators used in the process. Their effect on the clean gas emissions is an example for the need of optical particle measurement systems in hot gases, which additionally may be contaminated with chemically aggressive gas components.

To avoid the condensation of tar which is produced in the gasification of biomass, the optical particle size and concentration measurement must be carried out in gas temperatures above 450°C. Otherwise the particle measurement may be falsified by condensation of tars or other gas components or by the aggregation of particles during or prior to the measurement.

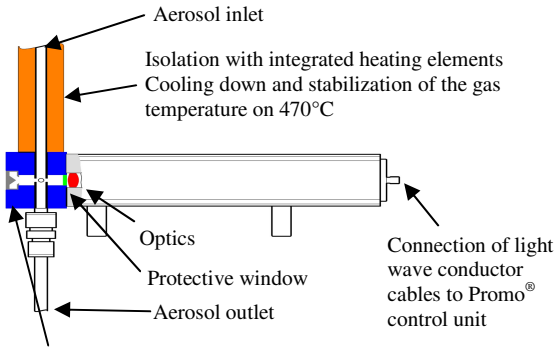
The particle size and concentration measurement at these high temperatures is performed with the Promo® aerosol spectrometer system in combination with a newly developed welas® 2070 T470 aerosol sensor.

A further special advantage of this system is that the velocity of the particles carried by the gas flow is being measured simultaneously with the single particle measurement. Thus the values of measured concentrations can easily be calibrated with regard to the operating conditions.

The selection of appropriate materials for the sampling tubes and the gas flow inside the optical sensor can minimize corrosion effected by gas components as e.g. sulfuric acid or hydrochloric acid.

The problems occurring during particle measurement in hot gas flows as well as advantages and limitations of this measurement method are discussed. The measurement data is evaluated and presented in this paper.

Setup of the aerosol sensor:



Ceramic application for aerosol guiding
+ Temperature resistant
+ Further down cooling of the aerosol temperature on approx. 450°C
+ Easy exchangeable integrated protection window
+ Easy detachable ceramic application for cleaning

Complete setup:

The Universal Nanoparticle Analyzer (UNPA) facilitates a new, on-line and near real time method to characterize airborne nanoparticles. Based on the parallel measurement of particle number concentration and particle charge concentration of DMA-classified nanoparticles, UNPA measurements and data analysis derive the agglomerate or aggregate number size distribution, information about the degree of agglomeration as well as the mean primary particle size of lose agglomerates (Wang et al., 2010).

First UNPA prototypes were built and evaluated by the University of Minnesota and by BASF Company. This lead to the development of a commercial version of UNPA by TSI Inc. In order to compare both instrument versions and to test the applicability of different sampling and dilution systems, measurements were made at the hot wall reactor at IUTA, Duisburg. During the tests, the hot wall reactor produced Si nanoparticles. For all selected conditions (C.1 to C.5, see Table 1), the temperature in the hot wall reactor was controlled at 1000 °C. The silane feed flowrate was either 1 l/min (C.1 to C.3) or 0.7 l/min (C.4 and C.5). Temperature after quench (~ 150 °C), pressure (~ 60 kPa) and process safety (high hydrogen content in the process gas) had to be considered for sampling and dilution: UNPA requires near ambient inlet conditions and optimum particle number concentration is 10^5 to some 10^6 cm^{-3}.

Table 1. Sampling and dilution configurations, silane feed flow rate, diluted aggregate particle number concentration and number mean aggregate diameter.

Condition	Sampling Configuration	SiH_4 Flowrate [l/min]	Total UNPA Concentration [cm^{-3}]	Mean Diameter [nm]
C.1	ED+DP	1.0	2.7e5 ± 1.1e4	208 ± 0.7
C.2	PRD+ED	1.0	2.7e6 ± 3.3e5	236 ± 0.5
C.3	PRD+ED	1.0	1.3e6 ± 7.0e4	239 ± 1.1
C.4	PRD+ED	0.7	1.4e6 ± 9.6e4	228 ± 1.1
C.5	CP+ED	0.7	8.8e5 ± 9.4e4	220 ± 2.1

For all 5 conditions, an ejector diluter (ED) was used to draw the sample from the process. Upstream of the ED, two different probes were tested: A porous tube diluter (PRD) provided by University of Eastern Finland and a coolable probe (CP) with integrated dilution provided by Karlsruhe Institute of Technology. Also tested (C.1) was a combination of the ED followed by a probe built by the University of Duisburg Essen with dilution right at the sampling probe tip and secondary dilution by a built-in ejector (DP). This probe had to be placed downstream of the ED because the built-in ejector was limited to an inlet pressure of approximately 85 kPa. Size distributions measured with UNPA operated in SMPS mode demonstrate that - at least from 50 to 300 nm - no significant differences in size-dependent transfer through the probes were observed. Dilution ratios were 510:1 (C.1), 190:1 (C.2, C.3 and C.4) and 300:1 (C.5).

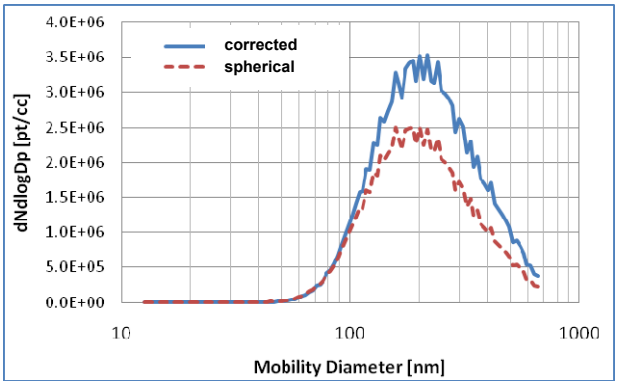

Figure 1. Spherical and corrected aggregate number size distribution, example taken from condition C.4

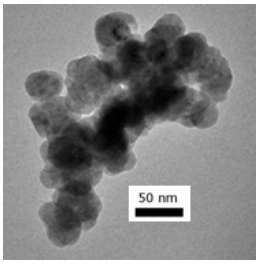

Figure 2. TEM example from Condition C.2

Figure 1 shows an example for UNPA size distribution correction due to particle structure. UNPA measurements also indicate that the analyzed Si-particles have a relatively open structure, as confirmed by TEM images (see Figure 2). Mean *primary* particle sizes reported by UNPA were around 25 nm (C.2 to C.5) and 34 nm (C.1). These diameters were in good agreement with TEM analysis (e.g. 26±7 nm for C.2). Results from both UNPA instruments compared very well.

Ultrafine particles in flue gas from waste-to-energy (WTE) plants

S. Cernuschi[1], M. Giugliano[1], S. Ozgen[1] and G. Ripamonti[1]

[1]DIIAR Environmental Section, Politecnico di Milano, Milano, 20133, Italy
Keywords: ultrafine particles, waste to energy plants, bag filter, condensable particulate matter.
Presenting author email: senem.ozgen@polimi.it

The research on the emission levels of particulate matter is recently focused on ultrafine (UFP) and nanoparticle size fractions, with dimensions included in the range from 0.1 µm down to few nm. Particular attention in this field has been paid to combustion activities, with most of the available investigations focused on vehicle sources and very few limited studies for stationary energy production systems.

Present work reports the main findings of extensive field investigations at four municipal waste-to-energy (WTE) plants, equipped with flue gas treatment configurations included in most recent Best Available Techniques reference options, and addressed to the evaluation of UFP stack emissions (EC, 2006).

Measurements were conducted with a specifically designed sampling line, assembled for evaluating UFP of primary as well as condensable origin and equipped with a dilution system and a particle counting device for measuring total particle number and size distributions at different dilution ratios (Figure 1) and for raw undiluted flue gases. Particle number concentrations and size distributions were measured with an electrical low pressure impactor (ELPI™), capable of giving values for 12 different size intervals in the range 7 nm - 10 µm.

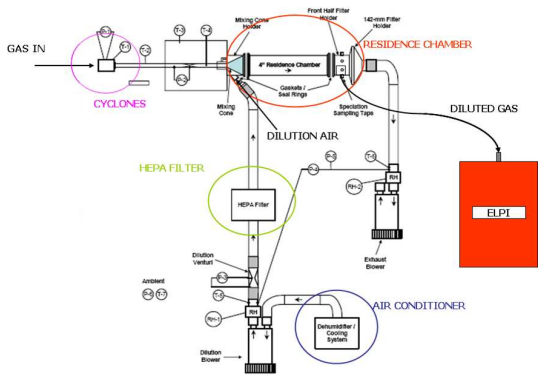

Figure 1. Scheme of dilution sampling and PM measurement system.

Mean number concentrations of UFP resulting from cold sampling tests are included between $5 \cdot 10^3$ and $3 \cdot 10^5$ particles cm^{-3}, with the ultrafine fraction largely prevailing in size distributions. Table 1 shows the average, minimum and maximum values of UFP concentration and the relative contribution of UFP to the total particle number emitted from the four WTE plants.

Results, as a whole, address also some differences arising from the flue gas treatment process design (FTPD), with the utilization of wet scrubbing that seems to affect the presence of primary UFP as well as their formation from condensable origin with respect to dry treatment systems.

Table 1. UFP number concentration (cm^{-3}).

Plant ID	FTPD	UFP concentration (cm^{-3})		%UFP
		average	min-max	
WTE1	dry	1.3E+04	$1.8 \cdot 10^3$ - $5.6 \cdot 10^4$	95%
WTE2	dry	5.3E+03	$3.7 \cdot 10^2$ - $4.2E \cdot 10^4$	93%
WTE3	dry+wet	5.8E+04	$1.2 \cdot 10^4$ - $1.3 \cdot 10^5$	95%
WTE4	dry+wet	2.7E+05	$1.0 \cdot 10^4$ - $5.0 \cdot 10^6$	97%

FTPD: Flue Gas Treatment Process Design

Finally, measurements across a pilot scale fabric filter demonstrate very efficient removal in the UFP size ranges of interest, with extended capabilities for reducing the emitted particles from condensable origin (Figure 2).

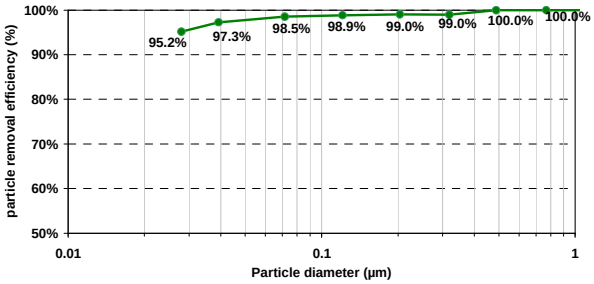

Figure 2. Bag filter submicron particles removal efficiency.

The research program was conducted by LEAP (Laboratorio Energia e Ambiente Piacenza) and Politecnico di Milano with the financial support of FederAmbiente, Italian Federation of Public Environmental Services.

Measurement of soot size distribution in flames by inversion of angular light scattering

Caumont-Prim C., Yon J., Coppalle A. and K.-F. Ren

UMR 6614 CORIA, Avenue de l'université, BP 8, 76801 Saint Etienne du Rouvray, France.

Keywords: soot particles, fractals, aggregates, light scattering
Presenting author email: yon@coria.fr

Soot particles are produced by combustion processes. Since a long time, these particles give rise to numerous investigations for their modelling and due to their important implications in human health, flame radiative transfer and climatic impact. Among other information, the determination of soot size distributions at different Height Above the Burner (HAB) in flames is essential. The soot size distribution is determined often by using ex-situ granulometers, after sampling of the particles. But the quenching of aggregation process in the sampling is difficult and raises the question of representativeness of the results (Ouf *et al.* 2010). For this reason, optical measurements are more adapted. By knowing the temperature of the flame, Dynamic Light Scattering technique permits to determine a mobility diameter. But without any more information, soot size distribution can't be derived by this technique. Moreover, soot particles are not spherical and their specific fractal morphology has to be taken into account. Thanks to a simple theory called Rayleigh – Debye – Gans for Fractal Aggregates (RDG-FA theory - Dobbins *et al.*, 1991), measurement of static light scattering can be interpreted in order to determine another size parameter called gyration radius. The inversion by this theory to infer the gyration radius of monodisperse aggregates has been recently validated (Caumont et al. 2010).

Some authors (Dobbins & Megaridis 1991, Köylü 1994) have proposed to determine a representative gyration radius of the polydisperse population with this optical technique. But two distinct radii can be calculated if particles are suspected to scatter only in Guinier or in Power Law regime and that assumption cannot be done without knowing the researched size distribution. Koylu & Faeth (1996) and Iyer *et al.* (2007) proposed an inversion method to calculate the characteristics of the soot size distributions by coupling scattering and extinction measurements. But this method relies on the knowledge of the soot optical index which is unfortunately not accurately known. That's why it is necessary to develop a new approach which doesn't need any primary knowledge.

The present work presents a new inversion method for the determination of the soot size distribution in flames by measuring the scattered light at different angles. It consists in determining for each studied angle, by using the RDG-FA theory, a gyration radius $Rg^*(\theta)$ of a monodispersed population of the same optical behaviour as that of the real polydisperse population.

The $Rg^*(\theta)$ function thus determined informs us polydispersity of the soot. For example, in monodisperse case, $Rg^*(\theta)$ must be constant. In contrary, the variation of this function informs us of the range of polydispersity. So, by supposing the nature of the size distributions (lognormal or self-preserving), it is possible to determine, by this technique, governing parameters of these distributions.

In the present study, that inversion method is proposed to determine the soot size distributions at different HAB in a laminar diffusion ethylene flame.

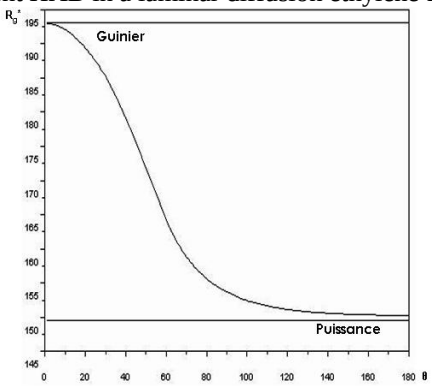

Figure 1. Theoretical dependence of Rg* to the scattering angle for a polydisperse population of soot.

Presenting author email:perrone@le.infn.it

Carbonate carbon (CC) is often not considered in atmospheric aerosol chemistry studies which comprise the measurement of elemental carbon (EC) and organic carbon (OC). The reason for this may be its low contribution to fine particle mass in most area along with the difficulties in its analytical determination in atmospheric aerosol collected on filter matrices. Carbonate particles are expected to significantly contribute to the Mediterranean PM mainly during the intrusion of air masses from North Africa. However, the CC fraction in particulate matter may not be negligible if high concentrations of mineral dust, either natural (natural erosion, sand storms) or originating from street abrasion or construction sites are present. Some thermal–optical methods have recently been used to determine carbonate carbon, along with different organic fractions and EC and it has been shown that the interference of CC with the signal of EC or OC may lead to overestimations of either of these two carbon fractions during thermal-optical analysis (Karanasiou et al., 2010). The use of a sample pretreatment with HCl fumes to eliminate CC prior to the thermal analysis is suggested to avoid the interference by carbonate particles. We have used the sample pretreatment to identify the CC contribution to the flame ionization detector (FID) signal from TOT measurements and implement a numerical procedure to determine CC, EC, and OC levels. The time evolution analysis of the FID signal before and after the treatment with HCl fumes of TSP and PM2.5 samples, has revealed that the CC peak may occurs within the 220-250 s time interval and that it is characterized by a full-with-at-half-maximum (FWHM) $\Delta t^* = 25\pm3$ s, in accordance with previous studies. We have assumed that the CC volatilization contributes to the FID signal with a pulse which can be fitted by a Gaussian function with the peak at the time t_i (within the 220-250 s time interval) and the FWHM width $\Delta t_i = 25\pm3$ s, to determine CC levels. In particular, we have calculated the Gaussian function area ascribed to the CC volatilization and the area of the calibration signal, to quantify CC levels in the analyzed PM samples. This calculation has been carried out through a fitting procedure, in which the FID signal is represented as a weighted sum of Gaussian functions, $S(t)$, through an algorithm implemented by ourselves in Matlab®. In fact, we have assumed that $S(t)$ can be represented by the following relationship:

$$S(t) = \sum_{i=1}^{N} a_i \, e^{-(t-t_i)^2/2\sigma_i^2} \qquad (1)$$

where a_i, t_i and σ_i represent amplitude, peak-time and standard deviation of the Gaussian function i and N represents the total number of Gaussian functions. The FID signal has at first been interpolated with cubic splines to obtain a straightforward calculation of its first and second derivatives. Then, through the analysis of the second derivative minima we have automatically identified the number N of Gaussian functions composing $S(t)$. A FWHM $\Delta t_i = 25\pm3$ s has been imposed to the Gaussian function ascribed to CC, in accordance with experimental results. We have assumed that CC level uncertainties are mainly due to the uncertainties of the parameters defining the Gaussian function fitting the CC volatilization signal. The implemented technique has been tested by determining CC, OC, and EC levels in 26 TSP and PM2.5 samples which have simultaneously collected over south-eastern Italy, in the Central Mediterranean. We have found that uncertainties on CC levels vary from 0.1% up to 9% and from 0.2% up to 20% in TSP and PM2.5 samples, respectively. It has also been shown that OC levels may be quite overestimated mainly in the coarse fraction, if the CC contribution is not accounted for. Figure 1 shows as an example Ca^{2+} and CO_3^{2-} levels (calculated from CC concentrations) in the 26 analyzed TSP samples. The good correlation between Ca^{2+} and CO_3^{2-} levels support the reliability of the implemented technique: carbonate-containing mineral dust is often associated with calcium. The anion deficit defined as an excess of positive charge, which is often found in Mediterranean PM samples, has been used in some Mediterranean studies to infer and estimate carbonate mass concentrations.

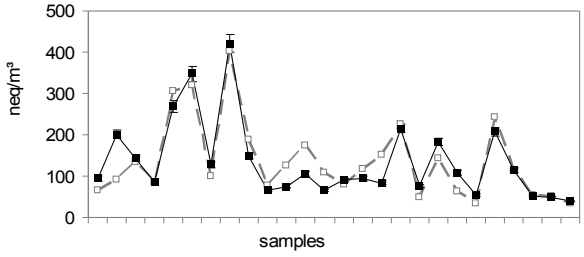

Fig. 1 Ca^{2+} (full boxes) and CO_3^{2-} (open boxes) levels (neq/m^3) in the 26 analyzed TSP samples

Fluxes of volatile and non-volatile elements in small-scale biomass combustion systems

Torben Seidel & Hans Ruppert

Dept. of Sedimentology and Environmental Geology, Geoscience Center, Goettingen University, Goldschmidtstrasse 3, D-37077 Goettingen, Germany
Keywords: biomass burning, concentration, fluxes, heavy metals
Presenting author email: tseidel1@gwdg.de

The application of biomass as an energy supplier may play an essential future role due to the greenhouse effect, the shortage of fossil energy sources and the striving autonomy from fossil fuels. Biomass combustion in Europe is widely applied e.g. for residential heating in stoves and boilers and combined heat and power plants on an industrial basis. The growing contribution of biomass burning may have an adverse influence on its acceptance due to the arising emissions of harmful inorganic and organic substances inducing health problems.

Especially for in house burning facilities reliable measurements of concentrations and fluxes of heavy metals in the flue gas are lacking.

For a reliable reconstruction of element fluxes and for input/output balances, the originating ashes e.g. grate ash, heat exchanger ash and fly ash are collected. The manually fueled furnaces tend to have recovery rates way higher than 100% whereas automatically fuelled furnaces have recovery rates slightly lower than 100% of the theoretically ash content determined at 550°C.

To collect the hazardous fly ash, an innovative filter holder with a 150mm diameter consisting of PTFE was applied in our study. It guarantees sufficient material for the inorganic analysis and assures a low contamination background.

In the ideal case the amount of elements contained in the unburnt biomass should be identical with the combined element amounts in the different ash fractions. Especially the recovery rates of the environmentally or health relevant elements such as Cd, Zn, Sn, Tl, and Pb of burnt wood or straw in automatically fuelled furnaces are fairly low (Figure 1) suggesting that they leave the chimney as molecules or ultrafine particles. Other elements such as Co, Mo, Cr and Ni features likewise recovery rates lower than 100% attributed to a contamination of the fuel e.g. by an abrasion of the cutting mill at the preparation. Elements like Ca, Ti, Mn, Ba, Fe, REE (represented by La) and Zr have recovery rates higher than 100% indicating a contamination e.g. due to the refractory lining materials of the furnaces.

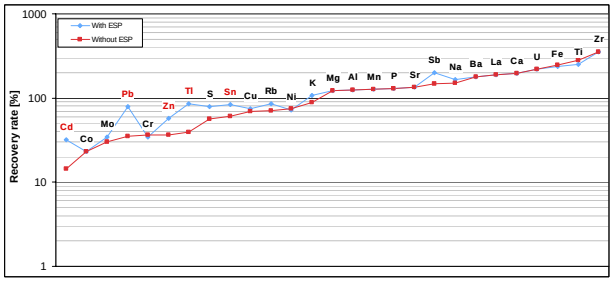

Figure 1. Recovery rate (%) of elements by burning wood-chips in a 30 kW boiler (combined element amounts in grate ash, internal heat exchanger ash, ESP ash and fly ash divided by the element amounts contained in the wood chips)

Electrostatic precipitators (ESP) in the exhaust gas stream can diminish the dust load e.g. from 55mg/Nm^3 to 18mg/Nm^3 at 13% O_2 respectively for a 30kW boiler fuelled by spruce wood-chips. Therefore the amount of risky elements can be diminished if the elements are bound on particles but not if they are in a gaseous state. Figure 2 shows the fluxes of a number of elements in a 30kW boiler with downstream ESP fuelled by spruce wood-chips. The application of an ESP decreases the dust load and lowers the emission of associated elements such us Cd, Zn, Pb, and Tl. Nevertheless, some fractions of the most volatile elements are not retained.

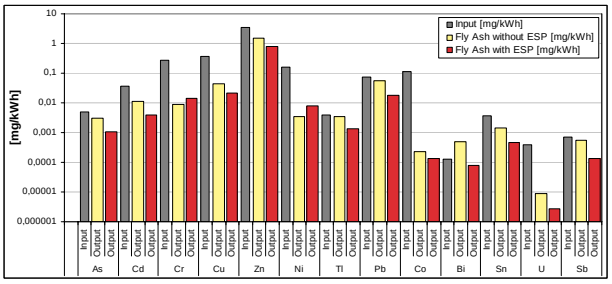

Figure 2. Input and fluxes [mg/kWh] of elements in a 30kW boiler fuelled by spruce wood-chips without and with ESP

A flue gas condenser (FGC) can diminish the dust load in the exhaust gas e.g. from 13mg/Nm^3 to 11mg/Nm^3 at 13% O_2 respectively for the same boiler fuelled by straw-pellets. The retention potential of a FGC for total suspended particulate matter is extremely slight. By enhancing the heat efficiency, however, it can slightly diminish the emission of dust and associated elements per energy unit (Figure 3).

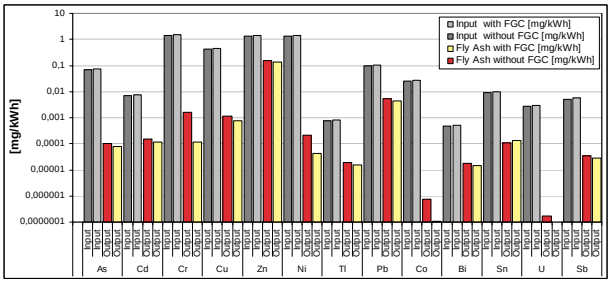

Figure 3. Input and fluxes [mg/kWh] of elements in a 30kW boiler fuelled by straw-pellets without and with FGC

A reduction of the dust load in the exhaust gas by applying secondary steps is connected with a decreased flux for most of the risky elements.

To assess the environmental impact of a furnace, fluxes of elements are much more relevant than simple concentration data. In addition, only element fluxes enable the comparison of emissions from different furnaces and fuels under different burning conditions, etc.

Chemical composition of smoldering combustion products of some forest materials and cellulose

S.A. Popova and V.I. Makarov

Institute of Chemical Kinetics and Combustion, Novosibirsk, 630090, Russia
Keywords: biomass burning, laboratory experiments, wood smoke, cellulose
Presenting author email: popova@kinetics.nsc.ru

Wild forest fires and prescribed burning are known as a powerful source of environmental pollution. Smoke emission, evolved by biomass burning, can produce effect on the chemical, optical, and radioactive properties of atmosphere, forest ecosystems, and various biological media (soil, water, plants, etc.). It is difficult to determine a reliable relation between the initial composition of forest combustible materials and the chemical composition of the resulting emission upon biomass burning when herbage, vegetative and soil cover burn. Since the capacity and composition of burning products depend on the type of combustible material, burning phase (flaming or smoldering), weather conditions, etc., of necessity are the laboratory experiments on the combustion of individual plant materials.

In the present work, the quantitative data on the chemical composition of gaseous products and particulate matter emitted by smoldering combustion of the dominating vegetation of the Siberian boreal forests (pine tree (Pinus sylvestris), Siberian larch (Larix sibirica), marsh tea (Ledum palustre), and lichen (Cladonia sp.)), are presented. Experiments were conducted using a modernized laboratory setup described by Edye and Richards (1991). However, as compared to (Edye and Richards, 1991), the smoke emitted was first deposited on a glass-fiber filter (particulate matter) and then frozen out by cooling at -50ºC (gaseous products). It is worth noting the gaseous products are the low-molecular organic substances condensed at low temperatures. The chemical composition of the smoldering combustion products of forest materials was determined by gas chromatography/mass spectrometry. Emission of carbon dioxide, carbon monoxide, methane and other gases was not measured.

It is experimentally demonstrated that during the smoldering combustion of the various types of forest material, 1-2% of the burnt plant biomass transform into particulate matter and almost the same is the amount of combustion products resulting from freezing.

Essential distinctions are observed in the composition of the smoldering combustion products of various materials. For example, guaiacol (2-methoxyphenol) and its substitutes, resin acids and other compounds are emitted by the smoldering combustion of pine tree and Siberian larch. Syringol (2,6-dimethoxyphenol) and its substitutes are emitted by marsh tea burning. The data obtained confirm conclusions (Simoneit *et al*, 1993) about the distribution of methoxyphenols with respect to the wood type, i.e., that the syringol derivatives are dominant in deciduous wood, and the guaiacol derivatives prevail in the coniferous one.

The absence of aromatic compounds in the lichen combustion products is assigned to the fact that there is no lignin in the cellular walls of mushrooms and algae. The content of levoglucosan in lichen smoke emission is shown to be much higher than that of other burnt materials.

In addition, we have studied the cellulose thermal degrade products. Note that furfural, produced by the freezing of combustion products, is one of the dominant components of forest materials and cellulose smoke emission (fig. 1.).

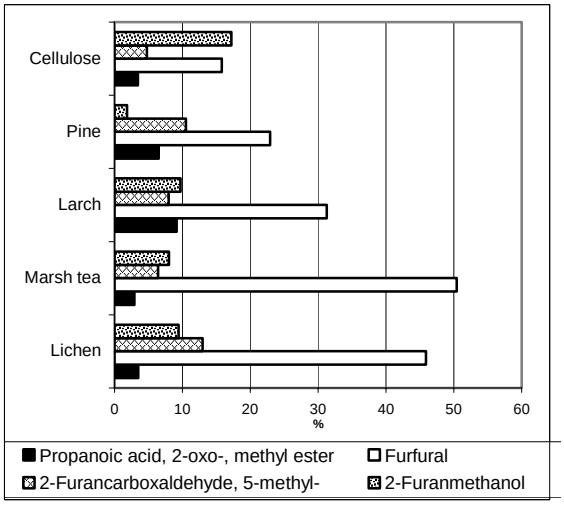

Figure 1. Distribution of organic substances in gaseous fraction.

Keywords: NOx, Low-temperature SCR, Ti-Cu-Mn, NH_3 oxidation
Presenting author email: wscha@kunsan.ac.kr

Selective catalytic reduction (SCR) of nitrogen oxides (NOx) with ammonia is one of the prospective process for cleaning the flue gas for stationary source. In this process, NOx contained in flue gases is reduced to N_2 and H_2O by ammonia:

$$4NO + 4NH_3 + O_2 \rightarrow 4N_2 + 6H_2O$$

It is well established commercial technology, which employing V_2O_5/TiO_2(anatase) promoted with WO_3 or MoO_3. The optimum operating temperature window of this catalyst is in the range of 300~400□, which makes necessary to reheat the flue gas after the electrostatic precipitator and de-sulfurizer(150~250□).

For the reasons above, there have been strong interests to develop high active SCR catalysts for low temperature(<250□). Success in developing such a catalyst would significantly improve the economics of SCR.

To increase the catalyst activity of manganese oxides, various transition-metal oxides were incorporated as a promoter, such as MnOx-CeOx, Cr-MnOx, Mn-Cu, Fe-Mn catalysts. Among the these catalyst, mixed oxides containing Cu and Mn as main metal element have been reported to be very active for complete oxidation reaction at low temperature. This can help the facile formation of NO_2 and promoted the NO reduction with ammonia at low temperature.

In our study, Mn-Cu bimetallic oxides and Ti mixed Ti- Mn-Cu tri-metallic oxides compared SCR activity for low temperature.

Table 1. Textual property and surface atomic concentrations determined by XPS of Mn-Cu and Ti-Mn-Cu catalysts.

Sample	SBET (m^2/g)	XPS atom(%)				
		Mn	Cu	O	Ti	Mn/Cu
Mn-Cu	195.4	18.8	8.4	72.8	-	2.24
Ti-Mn-Cu	141.1	21.9	9.5	66.1	2.4	2.31

Water vapour is one of the main components in the flow gas and frequently leads to catalysts deactivation. NOx conversions of Mn-Cu bimetallic oxides catalyst were decreased by water vapour. But Ti-Mn-Cu tri-metallic oxides catalyst which made by TiO_2 powder mixing is more resistant to water vapour.

On wet condition, adsorption O-H on surface of Mn-Cu bimetallic oxides promotes NH_3 oxidation. Beside, NH_3 is competitive adsorption with water vapour on Ti-Mn-Cu tri-metallic oxides.

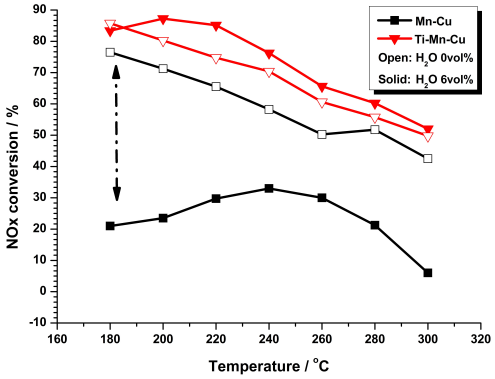

Figure 1. NOx conversion over Mn-Cu and Ti-Mn-Cu catalysts. Reactants: 800ppm NO, 800ppm NH_3, 3 vol.% O_2 and 0, 6 vol.% H_2O. GHSV was 60,000 hr^{-1}.

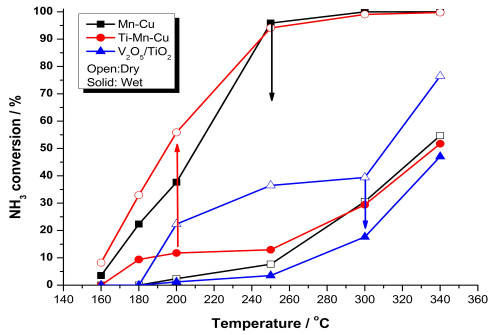

Figure 2. NH_3 oxidation over Mn-Cu, Ti-Mn-Cu and V_2O_5/TiO_2 catalysts. Reactants: 800ppm NH_3, 3 vol.% O_2 and 0, 6 vol.% H_2O. GHSV was 60,000 hr^{-1}.

Infrared spectroscopy of diesel and biofuel combustion particles

E.D. Kireeva[1], O.B. Popovicheva[1], and M. Vojtisek-Lom[2]

[1]Institute of Nuclear Physics, Moscow State University, 119991, Moscow, Russia
[2]Department of Vehicles and Engines, Technical University of Liberec, Liberec, Czech Republic
Keywords: combustion particles, biofuels, surface chemistry, hygroscopicity.
Presenting author email: elenakireeva2@gmail.com

The growing anxieties about the environmental impacts of fossil fuels and their future availability have resulted in the intensive development of alternative energy sources. Vegetable oil based biofuels – oils in their pure, non-esterified form and their methylesters (FAME - fatty acids methylesters, also called biodiesel)– are commonly used as alternative fuels in existing engines. Compared to diesel fuel, they have similar energy density, lower sulphur and aromatic contents, lower greenhouse gas emissions. Rapeseed, soybean, sunflower, palm and other oils can be produced from local renewable resources. However in spite of spreading of vegetable oils as biofuels the climate impact of their emission into the atmosphere is poor understood. The main reason of this situation is limited information concerning the composition, surface chemistry, and hygroscopicity of combustion particles produced by burning vegetable oils. This work is devoted to investigation of surface chemistry of diesel and biofuel combustion particles using the Infrared (IR) spectroscopy.

Particles produced by burning diesel fuel EN 590 (DF) and vegetable oils, namely heated rapeseed oil (HRO), HRO with ethylhexylnitrate, and heated palm oil (HPO) were sampled from the exhaust of a diesel-electric locomotive and a Zetor 1505 tractor engine at different engine operation conditions (fast idle, full load, ISO 8178C-1, ISO 8178C-2) (Vojtisek-Lom *et al* 2009). PallFlex filter samples are measured by Fourier Transform IR (FTIR) spectroscopy using Shimadzu IRPrestige-21 spectrometer in a transmission mode. The spectra of loaded filters and blank filter are obtained with respect to the atmosphere, then the scaled subtraction is performed and the baseline correction is applied. Identification of IR absorption bands for each particles type is carried out according organics and ions database (Coates, 2000). The relationship between IR bands of polar carbonyl C=O and non-polar aliphatic C-H functional groups allows an estimate of the extent of the particle oxidation (Cain *et al* 2010). The comparative analysis of surface chemistry of combustion particles produced by diesel and biofuels is carried out as well as the impact of different engine load on the surface properties.

The IR spectra of combustion particles from Zetor tractor engine produced by burning DF and HPO at ISO 8178C-1 load are presented in Figure 1. The main characteristic band of black carbons, including DF particles is one at 1590 cm^{-1} which is assigned to aromatic C=C stretching vibrations, which can be augmented by adsorbed oxygen. The absence of this band on the spectra of HPO particles, as well as on other biofuel-produced particles, may have a relation to their amorphous structure, quite different from the ordered morphology of soot microcrystallines, formed when insufficient polyaromatic hydrocarbons are available during the soot inception. The prominent feature of all biofuel-produced particles is the significant bands of oxygenated functional groups. Vibrations of carbonyl C=O groups are found at 1701-1790 cm^{-1}, together with a wide band of hydroxyl O-H group in a range 3300-2500 cm^{-1} they may be assigned to carboxylic acids. The high hygroscopicity of the particle surface is proved by hydroxyl O-H vibrations at 2100-2190 cm^{-1}. The bands of vibrations in the range 1550-1475 cm^{-1} and 1650-1580 cm^{-1} could be assigned to N-O nitrogroups and N-H groups in amines and nitro compounds which can be formed as a result of biofuel burning.

This work allows decreasing the uncertainties in chemical identity of original combustion particles produced by burning diesel and vegetables oils and in comparisons of their environmental effects.

Evaluation of a high temperature particle sampling setup for separation of inorganic and organic phase using laboratory model compounds

Keywords: High temperature, aerosol sampling, biomass

P. Nilsson*, A. Malik, M. Lindskog, J. Pagels, J. Rissler, A. Gudmundsson, M. Bohgard and M. Sanati
Ergonomics and Aerosol Technology, Lund University, P.O. Box 118, SE-22100, Lund, Sweden
*Presenting author email: patrik.nilsson@design.lth.se

The particulate matter formed in gasification processes are dominated by carbonaceous compounds (Gustafsson, 2007). Volatile material such as tars may pass high-temperature cleaning devices in the gas-phase and condense at lower temperatures downstream the cleaning system. In order to achieve efficient removal of particles it is therefore crucial to investigate the mechanisms of fine particle formation in thermochemical conversion of biomass and also fully characterize the particulate matter present in the product gas.

The aim with this work was to design a dilution setup with which the solid fraction could be separated from the volatile fraction, preventing it from contributing to the particle phase as the temperature was reduced for subsequent particle characterization. Model aerosols, for combustion and gasification processes, consisting of inorganic compounds (KCl) or soot internally mixed with a tar model compound (Dioctylsebacete, DOS) were generated. The dilution setup consisted of a high temperature dilution probe (Lindskog, 2009) followed by either a denuder (length 400 mm, diameter center net-tube: 10 mm, diameter outer tube 31 mm) or a packed bed of activated carbon (length: 100 mm, diameter: 25 mm). The model aerosol was heated to 200 ^{o}C, which was sufficient to keep the DOS in vapor phase, and diluted in the probe at the same temperature. By allowing the temperature to slowly decrease in the denuder/packed bed the volatile material could be captured by the activated carbon.

The performance of the setup was evaluated by comparing particle size distributions (Figure 1), obtained with a Scanning Mobility Particle Sizer (SMPS), after the dilution setup. In addition to the SMPS, an Aerosol particle mass analyzer (APM), coupled with a DMA and a heater (DMA-heater-APM), was used during soot measurements. Two particle sizes where selected with the DMA, 87 and 150 nm. By measuring with and without the heater the fraction of volatile material, condensed on the soot particles, could be determined.

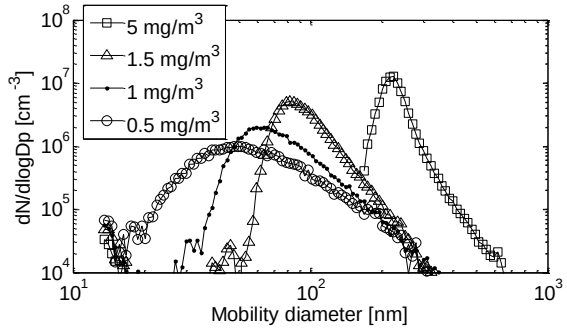

Figure 1. Effect on particle size distribution by allowing different amounts of DOS and constant amount of KCl (0.5 mg/m^3) enter the denuder at 1 lpm.

When a denuder flow rate of 3 lpm was used measurements with KCl showed that the denuder was able to handle 6 mg/m^3 of DOS, compared to 0.5 mg/m^3 when using a flow rate of 1 lpm. Concentrations below 6 mg/m^3 did not render changed particle size distributions compared to the distribution for pure salt.

Despite that the soot particle size distributions did not indicate any condensation, due to the agglomerated structure of the soot particles, mass measurements with the DMA-heater-APM revealed that at a DOS level of 12 mg/m^3 the denuder was unable to prevent obvious condensation on the soot (Figure 2). In order to enhance the removal efficiency of organics, a packed bed of activated carbon was used as a replacement to the denuder. DOS concentrations as high as 17 mgm^{-3} could enter the packed bed without any significant condensation on the soot particles.

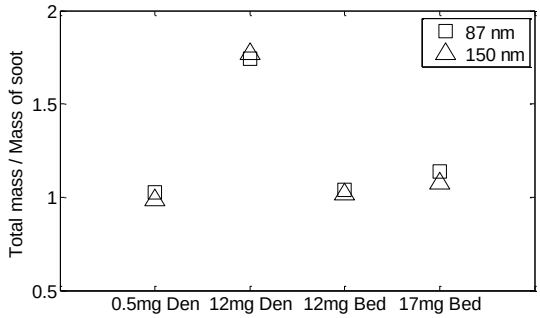

Figure 2. Ratio between obtained total mass and mass of soot core using different inlet DOS concentration for denuder (Den) and packed bed (Bed)

A sampling probe was designed and optimized to collect fine particles in flue gas model aerosols at laboratory conditions. In future measurements it will also be used in field to evaluate cleaning devices operating at the slipstream from a biomass gasifier.

Polychlorinated Dibenzo-*p*-dioxins and Dibenzofurans (PCDD/Fs) have drawn much attention in Taiwan, not only for their adverse health effects, but also for their wide distribution in the atmosphere (Kao *et al*., 2006; Lee *et al*., 2008). Municipal Solid Waste Incinerators (MSWIs) had been identified as the largest contributors to the environmental levels of PCDD/Fs, particularly in Europe.

The objectives of the present study were to develop the concentrations of PCDD/Fs, the gas-particle partitioning of PCDD/Fs and dry deposition fluxes of PCDD/Fs in the ambient air of three MSWIs in northern Taiwan. The results of this study will provide important database to assist the decision makers for formulating policies to alleviate dioxin concern.

In the ambient air of three MSWIs (A, B and C), sampling was conducted at 7 different sites for two seasons. Each ambient air sample was collected using a polyurethane foam (PUF) sampler according to the revised U.S. EPA Compendium Method TO-9A. Each sample was collected continuously on three consecutive days yielding a sampling volume of 972 m^3. The PUF sampler was equipped with quartz-fiber filter for sampling particle-phase PCDD/Fs, and followed by a glass cartridge containing PUF for sampling gas-phase PCDD/Fs, respectively. A known amount of surrogate standard was spiked to the PUF in the laboratory before the field sampling was conducted.

Table 1. PCDD/F concentrations in the ambient air of three MSWIs in northern Taiwan.

	MSWI-A	MSWI-B	MSWI-C
Total PCDD/Fs (pg/Nm^3)	0.360	0.449	0.575
Total TEQ (pg I-TEQ/Nm^3)	0.0207	0.0272	0.0297

Analyses of PCDD/Fs were performed according to the US EPA Reference Method TO9A. Each sample was extracted for 24 h, the extract was then concentrated, treated with concentrated sulphuric acid, and followed by a series of cleanup and fractionation procedures. The elute was concentrated to approximately 1 mL and transferred to a vial. The concentrate was further concentrated to near dryness, using a stream of nitrogen. A high-resolution gas chromatograph/high-resolution mass spectrometer (HRGC/HGMS) was used for PCDD/F analyses. Helium was used as the carrier gas. The analyzer mode of the selected ion monitoring with a resolving power at 10,000 was used.

As Table 1 listed, the mean PCDD/F I-TEQ concentrations in the ambient air at the vicinity of three MSWIs in northern Taiwan were 0.0207, 0.0272 and 0.0297 pg I-TEQ/Nm^3, respectively. They were all much lower than the air quality standard in Japan (0.6pg I-TEQ/Nm^3). The comparisons of PCDD/F congener profiles indicated that, they closely resemble each other and OCDD, 1,2,3,4,6,7,8-HpCDD, 1,2,3,4,6,7,8-HpCDF and OCDF are the top four dominant species in all cases (Figure 1).

According to the percentage of gas-particle partitioning in the ambient air, the PCDD/Fs in the atmosphere were mainly in particle phase. For dry depositions, the dominant mechanism of the dry deposition was the particle-phase deposition. The PCDD/F dry deposition fluxes in the vicinity of three MSWIs in the atmosphere were 131, 196 and 217 pg/m^2-day, respectively.

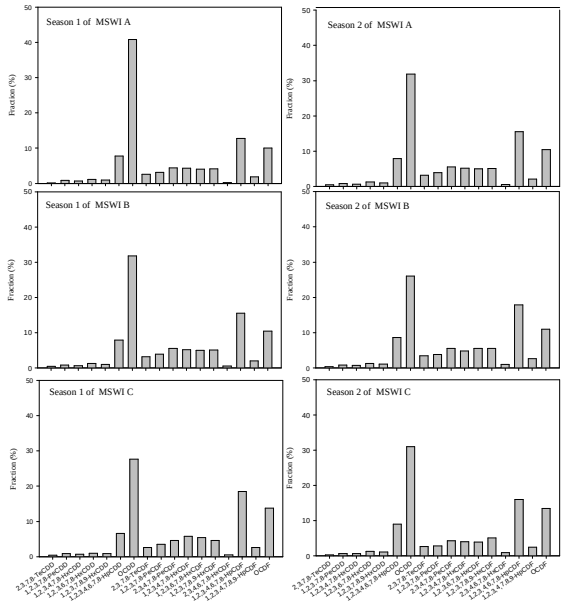

Figure 1. PCDD/F congener profiles in the ambient air of three MSWIs

Keywords: co-combustion, low rank fuels, camera-based process control, load flexibility, fuel flexibility

The growth of the world population is associated with an increase of the specific energy consumption per person, particularly in developing countries. This poses the challenging task to a sustainable management of fossil fuel ressources at increasing energy demand. In Germany, 80 % of the primary energy is provided by use of fossil fuels today. Modern power plants, operated with hard coal, have efficiencies up to 46 % (electric). Very high conversion efficiencies can be achieved with low rank fuels (LRF), e.g. rice husk and wood char, also by the co-combustion technology, which is already applied in some European countries. Together with a carbon capture and storage technology (CCS), co-combustion supports the reduction of CO_2 emissions and favours reduced investment and operation costs.

At the Karlsruhe Institute for Technology (KIT), a load-flexible multi-fuel burner is under development. The multi-fuel burner is tested at a 2 MW combustion chamber (BRENDA). Fig. 1 gives an overview of the experimental arrangement. The flame stability is controlled and improved by an optical camera system (Keller et al., 2007). Measurements of temperature, gas composition and dust properties are performed at several locations upstream and downstream of the burner, as indicated in Fig. 1. Here we report dust measurements performed at the first location downstream of the burner, which corresponds to a residence time around 1.5 sec. The dust samples were taken from the center of the combustion chamber with a non-cooled heat resistant nozzle using isokinetic conditions. The particles were collected on quartz fiber filters free of organic binder. Probe sampling intervals of only 15 minutes could be used, so multiple samples were obtained with high time resolution. The particle mass concentration was determined gravimetrically. Some filters were used for elemental analysis, performed by ICP-OES, and others for carbon analysis to determine the carbon burnout and hence the combustion behaviour.

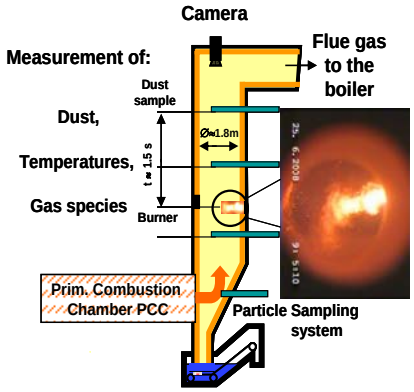

Figure 1. Experimental arrangement at the BRENDA combustion chamber.

Fig. 2 shows the final carbon concentrations measured in the dust samples which are in the range 0.5 – 3.4 wt.-%. The operation conditions of the different co-combustion experiments were similar. The rice husk particles burnt out worse than the hard coal because of bad mixing with the main flow, while the wood char had a very high initial carbon content. In future experiments, it will be investigated, how the carbon burnout of different co-combustion materials depends on specific operation conditions at various sampling points.

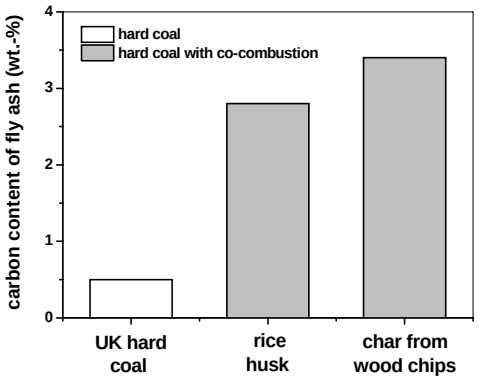

Figure 2. Final particulate carbon concentrations for different fuel mixtures.

Wood combustion emissions in Switzerland and associated impact assessments

Meyer, Nickolas K.[1], Heck, Thomas[1]
[1]Laboratory for Energy Systems Analysis, Paul Scherrer Institute, Switzerland
Keywords: wood combustion emissions, life cycle analysis, sustainability, external costs

Woody biomass combustion produces 5% of Swiss heating energy and 20 - 50 % of airborne, organic and particulate emissions during winter. Further, future energy scenarios suggest that wood consumption could sustainably increase by a factor of two [1], likely leading to increased emissions. On this basis, an inventory describing combustion emissions produced by 25 in-use residential, commercial, and industrial biomass combustion appliance classes was developed for Switzerland. This inventory is used to assess current and historical emissions, to identify those appliance classes contributing most to emissions, to assess future emissions based on sustainable scenarios and finally, to quantify external costs associated with wood combustion in Switzerland.

The inventory incorporates over 200 direct and indirect (life cycle) emission species. Of these species, particulate matter (PM), carbon monoxide (CO), particle bound black carbon (BC), particle bound organic matter (POM) and total organic carbon (TOC), nitrogen oxides (NO_x) and greenhouse gases form a set of core species [2,3]. PM data utilised in this inventory was size classified to represent, total particulate emissions (TPE), and particulate matter having diameters less than 10, 2.5 and 1 μm respectively (PM_{10}, $PM_{2.5}$ and PM_1).

Direct emission factors for core species were collected for average, high and low emission scenarios (based on appliance operating characteristics). Non-core species have so far been considered only for average operating cases. Using these emission factors, annual emissions were determined for each species (for the period 1990 – 2009, with a base year of 2009), and in some cases used to determine future emission scenarios. For the average current emission scenario, annual TPE was calculated to be 6520 tonnes. Analysis of the size dependency of TPE was made (Fig. 1), as was the size dependent contribution of BC and POM to PM (not shown).

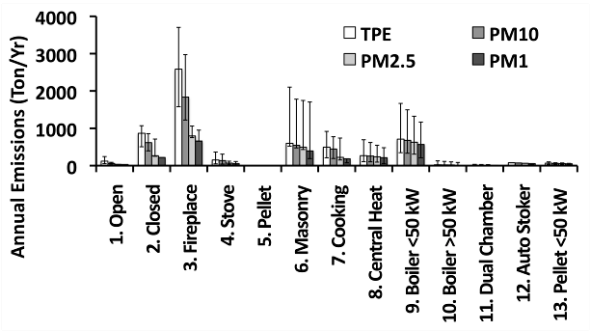

Fig. 1. Annual particulate matter emissions for 13 residential wood combustion appliances in Switzerland, 2009.

In addition to the emission inventory, direct and indirect global warming potentials (GWPs) were calculated for representative systems (Fig. 2). These preliminary GWP calculations highlight variances in potential climate impacts between biomass and fossil systems (particulates are excluded from prelim. GWP)

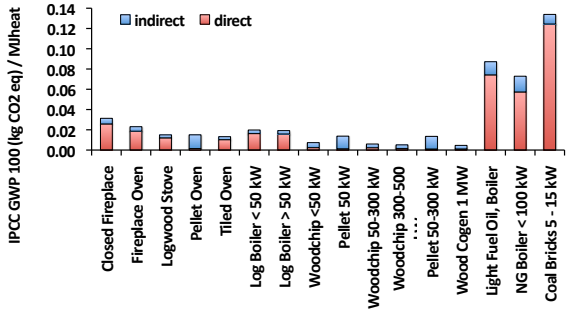

Fig. 2. Direct and indirect global warming potentials for selected combustion systems

As a method of valuing impacts associated with the combustion of wood, external costs methods were employed [3]. Using both direct and indirect emissions, estimates of external costs attributable to wood combustion in Switzerland were made. Further comparison with fossil fuel systems and wood combustion systems incorporating emission reduction devices were also made. Currently, cost estimates exclude aerosol induced climate effects - these should be included within the coming year. Estimates presented here show costs per MJ of useful heat for selected combustion systems (Fig. 3) [3]. Life cycle impact assessment results will be included as well.

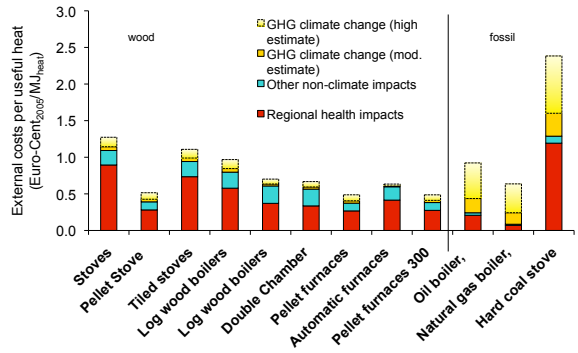

Fig 3. External costs per MJ useful heat for wood and fossil fuel systems in Switzerland.[3]

This work was conducted as part of the research project IMBALANCE and funded by the Competence Center Environment and Sustainability of the ETH Domain (CCES).

Presenting author email: patelks_55@hotmail.com

Biomass (i.e. wood, crop waste and animal dung) is primary cooking fuel for a large majority of households in developing countries. There are an estimated 1.6 million deaths per year due to toxic indoor air pollution (*Smith & Mehta, 2003*). Exposure to these smokes has also been linked to several health effects (i.e. increased prevalence rate of chronic bronchitis in women and acute respiratory infections in children) especially for women who cook with these fuels and in young children. The smoke is a complex mixture of particulate matters (PM) including organic carbon (OC), black carbon (BC), silica, elements, various salts, etc. The OC represent a large variety of organic compounds which can be classified into general compounds such as aliphatic, aromatic compounds, acids and numerous unidentified compounds. Black Carbon is one of the unique pollutants that have a large direct negative impact on human health, indoor and outdoor air quality, temperature, cloudiness, precipitation, mountain glaciers, sea ice, and snow packs (*Ramanathan & Carmichael, 2008*). Black-carbon particulate matter is also damaging to human health (*Rich et al. 2005*). The BC concentration in the indoor environment of some countries was reported (*Fromme et al. 2005; Kwangsam & Crocker 2005; Moloi et al.2002*). The commercial cooking is a surprisingly large source of a range of air pollutants that could pose risks to human health and the environment in India. Therefore, in the present work, the concentration of BC and OC, BC/OC ratio and their fraction in the PM in the Kitchen environment are described.

Thirty five kitchens cooking with fuels i.e. LPG, kerosene, coal, cow dung, biomass and agricultural residue were selected for the present investigation in November, 2008. The Partisol Model 2300 (Thermo Sci. USA) samplers were used for collection of the fine ($PM_{2.5}$) and coarse particulate material (PM_{10}) in the microenvironment. The PM was collected by using Partisol sampler on 47-mm quartz fiber filters (Whatmann, QMA) housed in the molded filter cassettes. The loaded filters were dismounted, brought to laboratory, and heated up to 50 ^{o}C for 6 hrs to remove the moisture contents. The filters were transferred into the desicator, and finally weighted to measure the particulate mass load. A standard thermal method was used for analysis of OC and BC.

The ratio of the $PM_{2.5}/PM_{10}$ is found to be > 95%. It means all PM during the burning processes lie in fine and ultrafine modes. The BC and OC concentration ranged from 31 – 3068 and 121 – 17786 μg m^{-3} with mean value of 1535 and 6648 μg m^{-3}, respectively. The OC/EC ratio is ranged from 0.2 – 11.3 with mean value 4.3±0.7. The mean value of BC, OC and OC/BC ratio for the various fuels are summarized in Table 1. The highest and lowest OC/BC ratio is observed when agricultural residue and kerosene are burnt.

Table 1. Mean BC and OC concentration (μg m^{-3}) in the indoor air with OC/BC ratio

Fuel	BC	OC	OC/BC
LPG(2)	41	126	3.3
Kerosene(2)	1614	312	0.2
Cow dung(2)	734	3139	4.3
Coal(2)	644	2588	4.1
BM(19)	1935	8488	4.3
AR(8)	1362	7387	5.4

BM = Biomass, AR = Agricultural residue

The OC and BC fraction in the PM_{10} is ranged from 8.1 – 72.3% and 2.4 – 53.0% with mean value of 50.1±5.5% and 14.3±3.6%, respectively. Among them, the highest and lowest BC fraction is observed in the kerosene (52.8%) and LPG (3.8%) PM, respectively. The elevated levels of OC and EC are emitted during burning of the fuel. Among these fuels, the kerosene is seemed to be most dirty fuel due to association of high BC fluxes. The fluxes of the PM, BC and OC emitted during burning are described.

Keywords: welding fume, exposure, three-zone model, ship-building industry.
Presenting author email: sakuray66@gmail.com

The whole study was conducted at welding workplaces in a ship-building industry. Samplings were conducted to welders, and the results were compared with model predictive models in order to assess the feasibility of the currently available predictive models.

Results show that the predicted values obtained from the Three-Zone Model has a better prediction to the corresponding measured values than that of Two-Zone Model based on the laboratory data. To measure fume particle sized distributions for the Near field, Lower room zone, and Upper room zone were consistently in a unimode form, and the smallest MMAD were found in that of the Near field. For measured total fume concentrations, we found that big block area> assembly area> small assembly area. The concentrations found in the Near field were much higher that of Lower and Upper room zone, but no significant difference could be found between that of Lower and Upper zones. The main metal contents in welding fumes were Fe and Mn. Using the Three-zone Model to predict welder's exposures, in real workplaces indicates that a systemic bias might exist in the predicted Near field concentrations. The above results might because of the variations of Q and β among different zones. In addition, the stratification of the emitted fume in different zone might not be uniformly distributed and result in different β for the same zone in the practical situation. It is suggested that the use of Three-Zone Model in the field is still required further investigations, particularly in determination of Q and β for the predicative model.

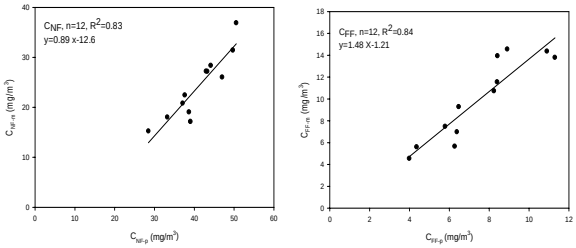

Figure 1. The relationship between predicted value (C_{NF-p} v.s C_{FF-p}) and measured value (C_{NF-m} v.s C_{FF-m}) were obtained by using Two-Zone model in the near and far field.

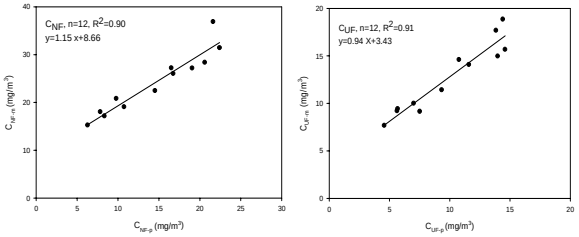

Figure 2. The relationship between predicted value (C_{NF-p} v.s C_{UF-p}) and measured value (C_{NF-m} v.s C_{UF-m}) were obtained by using Three-Zone model in the near field and upper room zone.

Table 1. Mass-based size distributions(μm） obtained from the selected work area.

	small assembly area		assembly area		big block area	
	MMAD	GSD	MMAD	GSD	MMAD	GSD
Near Field	0.69	3.77	0.80	2.98	0.82	3.06
Lower Zone	1.47	2.69	1.64	2.63	0.93	2.97
Upper Zone	1.40	2.66	1.27	2.79	0.91	2.97

Table 2. The relationship between predicted value (C_p、C_p) and measurement value (C_m) ($\mu g/m^3$) obtained from different exposure zone and different work area.

Study of local aerosol combustion concentration with a differential white light opacimeter.

A. Bellivier, R. Delorme, S. Dupont, P. Benhaiem, Y. Chen, P. Le Bars and H. Bazin
Department of Physical Measure and Fire Sciences , Laboratoire Central de la Préfecture de Police
39bis rue de Dantzig, 75015 Paris, France
Keywords: soot particules, concentration, light-extinction, measurements.
Presenting author email: axel.bellivier@interieur.gouv.fr

A differential white light opacimeter is been developing in order to measure smoke concentration directly into the flow over the time. It will allows local measures simultaneously in different parts of the area studied. It is tested in a smoke chamber equipped with a photometer. Concentrations are calculated from the measure of light-extinction, such as Mulholland and al (2000). Six samples of wood are burned : 10; 20; 30; 40; 50 and 60 mm width (respectively 1.49; 3.17; 4.73; 6.07; 8.81 and 10.53 g). The sample is exposed to a heat flux of $2.5W.cm^{-2}$.

Theorical

Following the Beer-Lambert law, the concentration of soot is obtained from measuring the output voltage and maximum voltage of the prototype :

$$C_s = \alpha \frac{-ln(1-\frac{U_{out}}{U_{max}})}{\sigma_s L_{prototype}}$$

with C_s soot concentration $[g.m^{-3}]$; α the calibration coefficient [-]; U_{out} the output voltage [V]; U_{max} value of the max (= 5) $[V]$; σ_s specific extinction coefficient (= 4.4) $[m^2.g^{-1}]$; $L_{prototype}$ opacimeter the optical path of the device (= 0.05) $[m]$.

As above, the concentration of soot is obtained from the Optical Density (OD) measured by the smoke box's photometer (French norme NF X 10-702-1) :

$$C_s = \frac{ln(10^{\frac{OD}{132}})}{\sigma_s L_{photometer}}$$

with C_s soot concentration $[g.m^{-3}]$; 132 chamber's constant; OD optical density provided by the smoke chamber [-]; σ_s specific extinction coefficient (= 4.4) $[m^2.g^{-1}]$; $L_{photometer}$ the optical path of the device (= 0.914) $[m]$.

The prototype is calibrated using Wratten Gelatin Filters. The Fig. 1 present the reference optical density of filters versus optical density obtained with the smoke box's photometer (thin line) and the prototype (bold line). A calibration correction is necessary (dashed bold), $\alpha = 1.4$.

Results

The measurements are presented in Fig. 2. The prototypes measurements are consistent with the photometrics ones. For a given sample, prototype concentrations are lower then the photometers one in case of the difference

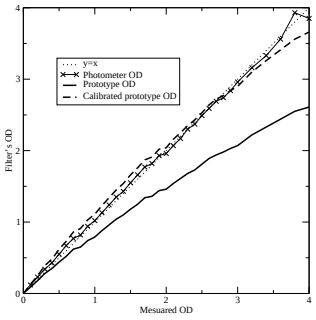

Figure 1: Filter's OD vs Measured's OD.

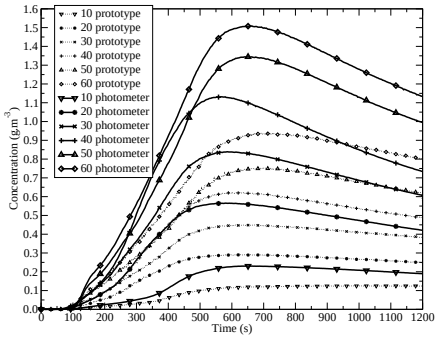

Figure 2: Results for tests with the photometer.

of optical path length. Other position of prototype would be explored to characterize the whole concentration field of the chamber.

Conclusion

A prototype of differential white light opacimeter is been developing. A light-extinction measurement based on the Beer-Lambert' law is made in a smoke chamber. The first measures done with the prototype are very satisfactory. Future works will mainly consist in the comparison of our measurements with non light-extinction devices and look at the fouling problem following Putorti (1999).

Aircraft engine emissions are regulated by two international committees of experts: CAEP (Committee on Aviation Environmental Protection): regulatory, and SAE (Society of Automotive Engineers): measurement methodology. The existing visibility metric for certification of an aircraft engine is based on the Smoke Number filter method. New measurement metrics are required because the quantity and characteristics of emitted particulate matter, mainly consisting of soot, need to be considered due to the affect of soot on the global radiative budget (Lee *et al.*, 2010) and the impact on local air quality and thus on the human health (Ferry *et al.*, 2011).

Real-time particulate measurements are starting to be used to investigate engine emissions but the interpretation of the signals often requires assumptions about the physical particle properties, which are still poorly known. This work aims to enlarge the knowledge of soot particles by determining their physical and chemical characteristics according to aircraft combustor chamber conditions to improve the accuracy of their description.

The experimental setup used in SAMPLE (Petzold *et al.*, 2009) allowed the investigation of three combustion settings representing low smoke/low organic (LS/LO), low smoke/high organic (LS/HO) and high smoke/low organic (HS/LO) conditions. SAMPLE II (Marsh *et al.*, 2010) allowed a more accurate investigation with five different combustion settings. For each condition, the soot morphology, structure and size are determined by Transmission Electron Microscopy (TEM) and size distribution measurements obtained by a Differential Mobility Spectrometer (DMS). In addition, measurements are obtained on the relative carbon composition using a thermal method.

Results show that the geometric mean diameter d_p of soot primary particles which constitute the aggregates, and the geometric mean gyration diameter d_g of these latter vary between the combustion conditions (Table 1). The evolution of these characteristics is more precisely defined with the analysis of aggregates sampled during this work.

The measurements allow comparisons to be made between two equivalent diameters (gyration and electric mobility, d_m) at various combustion conditions. This is performed by combining results from both DMS and TEM analysis. The β parameter that links the two sizes usually ranges between 0.77 and 1.4 (Gwaze *et al.*, 2006) and is evaluated in this study.

Soot acts in the atmosphere as the most efficient absorber of visible radiation. As the light-absorbing and light-scattering properties of soot aggregates change with the size of primary spheres and fractal characteristics, our results can be used to model these properties according to combustor conditions and be applied within atmospheric radiation modelling.

	d_p (nm) (TEM)		d_g (nm) (TEM)		d_m (nm) (DMS)	
	GMD	*GSD*	GMD	*GSD*	GMD	*GSD*
LS/HO	3.6	*1.88*	58	*1.34*	45.5	*1.31*
LS/LO	3.7	*1.93*	39	*1.92*	53.1	*1.39*
HS/LO	3.2	*1.73*	38	*1.97*	58.1	*1.46*

In order to avoid further increase of CO_2 in the atmosphere from the use of fossil fuels the use of renewable energy should be increased. This includes the use of biomass in residential heat production. However, the increase of other harmful compounds, such as fine particles, soot, CO and organic gaseous compounds (OGC) including PAH, should be minimized. The batch wise operated residential scale combustion appliances are troublesome with their high emissions of the incompletely oxidized compounds. Therefore, there is a need to investigate the options to reduce the emissions from biomass combustion.

Batch-wise fired appliances using pellets as fuel may provide an option to significantly decrease emissions. In these appliances a single batch of pellets in burned for heating the stove. In this study a hybrid masonry heater was used where the grate used for combustion of wood logs could be replaced with a specially designed pellet burner. Primary and secondary airs were applied to the fuel bed and additional tertiary air above the fuel bed.

Comprehensive measurement equipment was used. Gaseous compounds CO, CO_2 and O_2 were measured straight from the stack with FTIR, and OGC with FID. A sample of total suspended particles (TSP) was also collected from the hot undiluted flue gas. The sample gas was diluted with porous tube diluter and ejector diluter for the collection of PM_1 and particle mass size distribution (DLPI) samples. PM_1 samples were collected separately from ignition, steady firing and burn out phases and the mass size distribution sample from the total combustion. The organic (OC) and elemental carbon (EC) contents were analyzed from PM_1. Time-weighted average values $PM_{1,ave}$, OC_{ave} and EC_{ave} were calculated for total combustion from the samples of different combustion phases. The flue gas was further diluted with another ejector diluter for online measurement of particle number size distribution (ELPI and FMPS), total particle number (CPC) and mass (TEOM) concentrations. In addition, the combustion air flow rates were measured from air supply ducts separately for primary air and combined for secondary and tertiary air.

For comparison, the hybrid masonry heater was also operated with wood logs, and the same measurements were performed. When operated with logs, only primary combustion air was used.

Compared to the conventional technology of wood log combustion the pellet combustion resulted in clearly lower emissions. OGC and CO concentrations were 24-fold and 8-fold, respectively, lower in the pellet combustion. TSP was 1.7-fold and PM_{10} 2-fold lower in the pellet combustion, whereas $PM_{1,ave}$ was 3.4-fold lower in the pellet combustion. The difference of OC_{ave} was greater than of EC_{ave}, the OC_{ave} being 12.3-fold lower and EC_{ave} 2-fold lower in the pellet combustion. In the pellet combustion the OC_{ave}/EC_{ave} ratio was 1:7.2, whereas in wood log combustion the ratio was 1:1.15. In the different phases of pellet combustion, the PM_1 emission from the ignition phase was clearly higher than from the two other phases, especially EC was high, the PM_1 constituting 78% of EC and 9% of OC. During the steady firing PM_1 was the lowest, below 10 mg/MJ. No significant differences in total number concentrations were observed between the different fuels. The geometric mean diameter was 75 nm and 110 nm in pellet and wood log combustion, respectively. The mass mean diameters were 250 nm and 320 nm, respectively.

The emissions from the pellet combustion were clearly lower than from the wood log combustion, and well comparable to what has previously been measured from modern masonry heaters (Tissari et al., 2009).

It is known that the physico-chemical properties of combustion emissions have effects on health and the environment. However, the formation mechanisms of fine particles and their relationships with toxicological properties and effects on climate are poorly understood. In this study the physico-chemical properties of wood chip originated fine particles from three different combustion conditions were characterized. Of specific interest were to 1) find out the effect of combustion conditions on the particle morphology and composition, 2) verify whether the elemental carbon (soot) is internally or externally mixed with the fine particle fly ash, and 3) investigate the appearance of volatile metals in the complex mixture of elements present in the fine particle fraction.

A novel grate combustion reactor with a nominal output of 40 kW as well as adjustable air flows and staging of the combustion air was used to produce efficient (low CO and organics), intermediate (elevated CO) and smoldering (high CO and organics) wood chip combustion conditions. The dilution for on and off-line measurements was done with dry pressurized air using a porous tube diluter and two ejector diluters in series.

The emissions were characterized using ELPI (Dekati), SMPS (TSI) and FMPS (TSI) for number size distributions, TEOM (Thermo Scientific) and CPC (TSI) for particle mass and number concentrations, NSAM (TSI) for particle surface area, APM (Kanomax) for single particle mass measurements, as well as FTIR (Gasmet) and single gas analyzers (ABB) for measurement of gaseous compounds. Samples for chemical characterization were collected using quartz filters for OC/EC, silver filters for XRD and polycarbonate DLPI impaction plates for SEM/EDX and PIXE analyses. PM1 filter samples were collected for analysis with ICP-MS, ion chromatography (IC) and with thermal-optical carbon analyser.

Two types of electron microscopy samples were collected on holey carbon Cu-grids. First, the diluted exhaust aerosol was sampled directly. Second, the aerosol was size classified with a DMA (TSI) before sampling. The mobility diameters of 37, 40, 80, 100, 150, 220 and 250 nm were selected on the basis of the *in-situ* measurements. The electron microscope analyses were done using TEM (JEM 2100F, JEOL Ltd.) and STEM/EDS (NS7, Thermo Scientific).

Figure 1 shows the particle number size distribution for the three different conditions. Two particle phases, containing mainly of elemental carbon (soot) agglomerates (150-2000 nm) and ash (10-200 nm), were observed using TEM. The separation of soot and ash phases agrees with the study of Tissari et al. (2008). The PM1 inorganic fraction analyzed with ICP-MS and IC contained mostly K, S and Cl but also PO_4, Zn, Pb, Na, Fe, Ca and Al. Preliminary results on STEM/EDS point analyses (spot 0.5 nm) for unclassified samples suggest that the large particle fraction contained mainly C, O, K and traces of Fe, Si, S and Cl. On the other hand, Zn, Ca, P and Cr were found only in the smaller particle fraction. The size classified samples will be analysed in the near future to clarify the actual locations of the ash-forming elements.

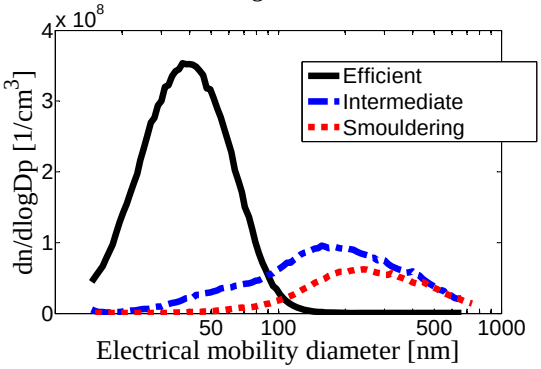

Figure 1. Averaged number size distributions from the different combustion conditions, measured with SMPS.

The combustion reactor was found to be suitable for generating different combustion conditions. Particles from efficient combustion were mainly formed of ash-forming elements and the particles had a closed structure, in agreement with Sippula et al. (2009). In contrast, in smouldering combustion large amount of chain-like agglomerates containing a large fraction of carbonaceous material was present. Furthermore, presence of trace metals was found to vary with the particle morphology.

The research on combustion emissions and development of effective and low emission technologies requires a laboratory-scale biomass combustion device to model full scale combustion in large-scale plants. The aim of this work was to design and construct a laboratory setup for versatile combustion research. This includes different air staging and temperature controlling possibilities which allow wide-ranging combustion conditions. In addition, different additives can be supplied into the furnace to study ash-related problems.

The novel modular combustion setup includes a fully logic-controlled fuel feeding system, a solid-fuel burner (40 kW), a liquid fuel burner, a ceramic insulated combustion chamber, an electrically heated drop tube furnace, a boiler, a stack, and a cooling circuit. The drop tube furnace was equipped with high-temperature sampling ports for the studies on aerosol formation and ash deposition. The moving step-grate burner is designed for solid biomass e.g. wood chips, pellets, peat and is also suited to melt forming fuels. Ash melting on a grate usually causes air feed clogging and therefore the grate has three moving steps to remove melted ash layers and make fuel mixing more effective. The conditions in the reactor can be adjusted to simulate conditions in large-scale boilers, with similar temperatures (max. 1200 °C), residence times (2 s.) and turbulent flue gas flows (max. 14 m/s, Re=2000-8000). Primary and secondary air can be supplied through the burner air fans and the tertiary air through alternative points in the upper part of the chamber.

The influence of air staging on PM1 and gaseous emissions

The influences of different primary, secondary and tertiary air settings on combustion behavior and especially for PM1 and gaseous emissions were studied. The aim was also to find settings to produce different combustion conditions for a study on aerosol physico-chemical properties. Primary, secondary and tertiary air was supplied by the frequency controlled fans and the flows were measured by the air flow sensors (Schmidt). Based on the measured flow rates, lambda values (air-to-fuel ratios) for primary, secondary and tertiary combustion were determined.

The settings 1-4 were operated with total lambdas of 2.0-2.3 and primary lambdas of 0.7-1.6, respectively. The setting 5 was operated with total lambda of 1,5 leading to very low combustion efficiency and high emissions.

The flue gas composition was analyzed with a FTIR (Gasmet) and single gas analyzers (ABB). The sample for particle measurements was diluted by porous tube & ejector combination with a total dilution ratio of 36-45. The particle number concentration was measured using CPC (TSI, 3775) and particle size distributions using ELPI (Dekati) and DLPI (Dekati). PM1 samples were collected for gravimetrical and chemical analyses including thermal-optical carbon analysis (Sunset laboratories), ICP-MS and ion chromatography. The release of the fuel ash forming elements into the flue gas was evaluated on the basis of the bottom ash analysis and PM1 emissions.

PM1 emissions were between 11 mg/MJ and 22 mg/MJ and they were found to correlate with the primary lambda (Figure 1). This agrees with the study of Lamberg et al. (2009). CO emissions increased while the secondary lambda was higher, but similar correlation was not found with the primary lambda.

The new combustion reactor was found to be suitable for generating different combustion conditions. The experimental results show that air staging has a significant effect on emissions and temperature profiles on the fuel bed.

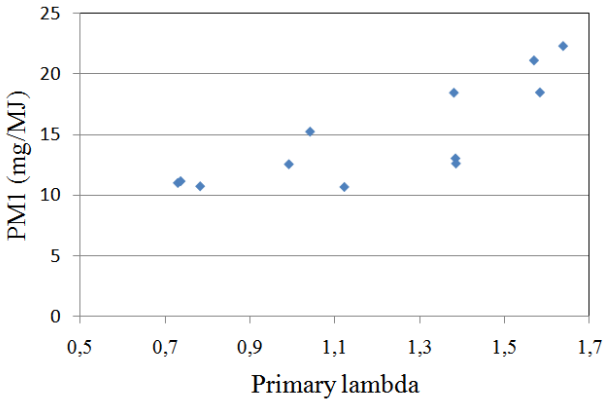

Figure 1. PM1 emission as a function of primary lambda.

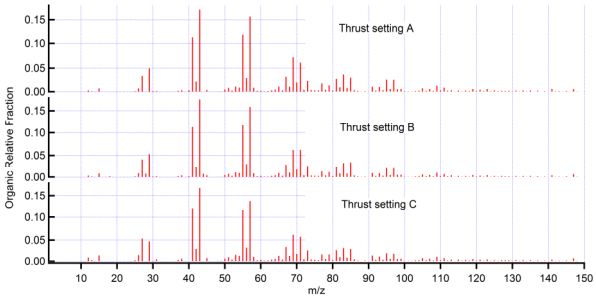
Emissions from aircraft engines impact both on local air quality at regional airports and climate change globally. All new engines manufactured have to pass certain emissions standards before they are certified to fly. Historically, the metric for particle emissions is the smoke number which is a measure of visibility. This metric was defined in the 1960's when inefficient combustion was causing significant air pollution around airports. As newer, more efficient engines are produced and as the concern of the impact of engine emissions shifts, a new metric is need. The main regulatory bodies in the Northern Hemisphere (CAA, EASA, FAA, EPA and FOCA) have all agreed that this new metric should be none volatile number and mass.

Work presented here is from the SAMPLE I + II studies (Study on sampling and measurement of aircraft particulate emissions) which is being used to help define the protocols and metrology of the new standard. Although none volatile particles were the focus of these studies, the volatile and semi volatile composition was also measured.

Particle measurements were made from an aircraft combustor attached to a Hot End Simulator (HES), which replicates the temperature and pressure changes of the turbines of a real engine, at the Gas Turbine Research Centre at Port Talbort. Being only the combustor section of the engine, there are no moving parts, therefore no lubrication oil. Measurements were also made on a current, modern engine at a test bed.

The chemical composition of the volatile and semi volatile particles (VP and SVP) was measured using the Aerodyne Aerosol Mass Spectrometer: for SAMPLE I the High Resolution AMS (Decarlo *et al.*, 2006); For SAMPLE II the HR and the Compact AMS.

Figure 1. Normalised organic MS for three different thrust settings from the modern engine.



The composition of the VP and SVP was dominated by organic material with small amounts of sulphate. It was found that the organics varied between the two combustion sources. However, for the modern engine, the form of the organics did not change with changing engine conditions (thrust, see Figure 1)

The sulphate concentration was sensitive to the ambient conditions. When the inlet was switched between ambient and the combustor/HES with instances of high local loadings (>10 µg m-3), the sulphate mass remained unchanged, although the mean Dp decreased from ~450nm to ~100nm, presumably from the evaporation and re-condensation as the sulphate passed through the combustor/HES.

The results were compared with data from unprocessed engine lubrication oil. These clearly show that unprocessed lubrication oil is not the major component in the condensed organics for the modern engine (combustor/HES is lubrication oil free)

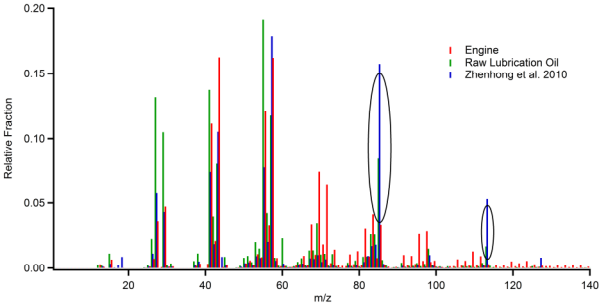


Figure 2. Comparison of organic MS for an engine, its lubrication oil and Zhenhong *et al.*, 2010.

The impact of the aviation commercial activities on the global warming and on the air quality is still a topic of needed investigations. Indeed, the actual official certification on particulate matter measurement called Smoke Number consists on the coloration of a filter. This way of the evaluation of the amount of particulate is not adapted to the new clean engine technology and to the nanoscale of the soot emitted because it does not measure mass and distinguish sizes. The French government funded a project lead by ONERA that includes a campaign of measurements behind a modern civil engine manufactured by Snecma in order to support the international effort on a better taking account of the particulate matter (SAE, 2002; SAE, 2004; SAE, 2009).

During this campaign, ICAO engine set-up test points are applied on the turboreactor. Sampling is performed through a mobile arm that allows sampling at few centimetres at a well defined location behind engine exit. Then aerosol is drive into a sampling line that follows the in place certification to measure the smoke number. From this line, a second line has been built in accordance within the Aerospace Recommended Practice (ARP) of the SAE E-31 to measure mass, number and size of the soot particles behind aircraft engine. Moreover, other properties are investigated by collection of sample on various supports like transmission Electron microscopy grids or filters. Table 1 recaps the set of instruments used.

Main results expected will be in one hand fine traverse measurements, radial and angular profiles, in term of CO2, NOx, Smoke Number, Emission Indices (number and mass) and size distribution profiles. In other hand, this campaign will contribute to the design of the final ARP with some sensibility investigation on the sampling line set-up.

Acronym	Equipment	measurements	
SN	Smoke Number	Certification reference

Day after day, new applications using nanoparticles appear in industry increasing the probability to find these particles in the workplace as well as in ambient air and thus their potential adverse effects on health of exposed workers and general population. Both assessments of these risks, preventive actions, and remediation, when needed, will rely on the measurements and characterization of nanoparticles. Consequently, it is necessary to improve our knowledge in this field to assess the potential toxicology risks; it is particularly important to characterize aerosols emitted by different sources of emission; like for example, during the combustion of composites filled with nanoparticles.

The present work is the continuation of the study led in the framework of the NANOFEU project supported by the French Research Agency (ANR). For this project, several partners (INERIS, LNE, Ecole des mines d'Alès, ISMANS and PlasticsEurope France) collaborated to characterize the fire behaviour of polymers filled with suitable nanoparticles (Chivas *et al.*, 2010).

An experimental setup has been developed to measure the count size distribution of the emitted aerosol produced during the combustion of different formulations of polymers containing nanocomposites. This setup is composed of a Differential Mobility Spectrometer (DMS500 / Cambustion) and a Scanning Mobility Particle Sizer (DMA 3080L + CNC 3022 / TSI) coupled with a cone calorimeter according to standard ISO 5660-1. The sampling flow rates of the DMS 500 and the CNC used are respectively equal to 8.0 l/min and 1.2 l/min. The cone calorimeter main duct is modified in order to minimize the deposition of soot on the 90° angle of the exhaust duct, and also to allow aerosol sampling at a point where the effluent can be considered as homogeneous. The heat flux is fixed at 50 kW/m², with the standard ventilation rate of 24 l/s. The sampling probe diameter has been selected to respect isokinetic conditions.

A Diluter FPS-4000 (DEKATI) coupled at the equipments has been used. This diluter is well adapted for fire effluent dilution because of its two-stages dilution setup. The first dilution stage is heated, and the second operates at ambient temperature. This system allows aerosol dilution, avoids condensation and particle perturbation compared to a simple cold dilution. The dilution ratio used is equal to 28:1. The samples of polymers containing nanocomposites are sized to 50x50x4 mm³ (corresponding to around 12 g of material, depending of the polymer matrix).

The evolution of the characteristics of the aerosol emitted during the combustion of the different polymers is very important. The advantage of the DMS 500 compared to SMPS is to provide real-time measurement (10Hz) on a large scale (5 to 1000 nm) which allows comparison between kinetics of aerosol production according to the kinds of polymers which are burned in different tests. First experiments were carried out with the DMS in a way to point out the mode diameters of the particles produced during the combustion. The Figure 1 presents the count size distribution of the aerosol obtained for Polyamide-6 filled with carbon nanotubes (CNT) measured by DMS 500.

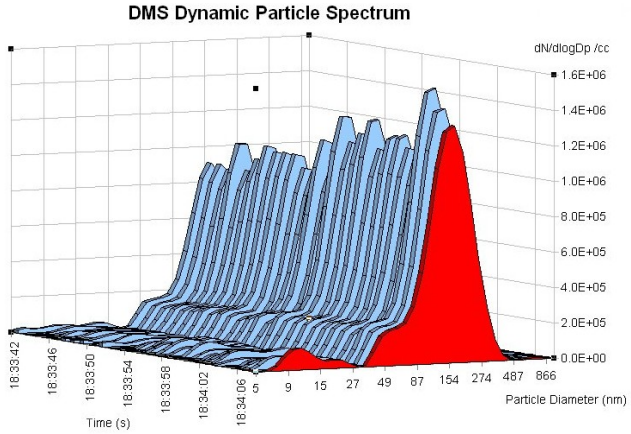

Figure 1. Count size distribution of the aerosol obtained in the case of combustion of PA-6 filled with CNT

Further measurements of kinetic of the particles concentration were performed with the CNC at the DMS 500 mode electrical mobility diameters observed fixed on the DMA (13.3, 23.7 and 200 nm). Several polymers (PMMA–, PA-6) containing another nanofillers (silica and alumina) were investigated.

Structure and reactivity of laboratory-produced soot containing iron

H. Bladt[1], J. Schmid[1], E. Kireeva[2], O. Popovicheva[2], R. Niessner[1] and N. P. Ivleva[1]

[1]Chair for Analytical Chemistry, Technical University Munich, Munich, 81377, Germany
[2]Institute of Nuclear Physics, Moscow State University, Moscow, 119991, Russia
Keywords: combustion aerosols, iron oxides, Raman spectroscopy.
Presenting author email: bladt@tum.de

It is widely accepted that Black carbon (BC), produced by incomplete combustion of fossil fuel, has a major influence on climate and human health (Dockery, 1994). Therefore, it is necessary to evaluate the effect of transport emission on the environment and to define the resultant limitations by determination of the specific characteristics of particle emission of different vehicles and different fuels. The objective is to develop methods for characterization of soot composition, structure and reactivity in accordance with the current requirements.

Among others, metal contaminations of multicomponent aerosols produced by diesel and gas turbine engines due to fuel additives, oil contaminations, or corrosion may be accumulated on the surface of the particles or inside them. Those impurities can cause significant changes in the physical and thermo-chemical properties of soot as they may catalyze the oxidation of soot particles in a thermite-analogue reaction. Especially heavy fuel used by large marine engines exhibits a high amount of inorganic impurities of transition, earth and alkaline metals (Popovicheva *et al*, 2009).

In-depth investigations of composition, structure and reactivity of soot aerosols internally mixed with metal compounds are performed. Therefore, Raman-Microspectroscopy (RM) is applied for structural characterization of the carbonaceous soot fraction as shown by Schmid *et al* (accepted 2011) as well as for identification of metal contaminations in soot. Further comprehensive characterization is performed by scanning electron microscopy (SEM), FTIR spectroscopy, Temperature-Programmed-Desorption (TPD) and -Oxidation (TPO) as well as by conventional thermal methods used for measuring elemental (EC), organic (OC) and total carbon (TC) contents in soot samples in order to evaluate the impact of elemental composition, surface chemistry, nanostructure, organic fraction (OC) and metal compound content on the soot oxidation behavior.

In present experiments emphasis is placed on soot internally mixed with iron compounds. Iron is a relevant metal component that can be found for example in soot emission of shipping. Two different laboratory approaches for the production of iron-containing soot are conducted. The first approach is a test-bench including a diffusion burner unit. Propane as fuel gas is burned in an oxygen stream. The flame is fed with a nitrogen stream charged with iron pentacarbonyl and soot is sampled on quartz fiber filters. RM at λ_0 of 633 nm reveales signals in the lower shift range from 200 to 800 cm^{-1} in addition to the characteristic disordered (D) and graphitic (G) bands of soot at 1350 and 1600 cm^{-1}, respectively (Figure 1). Burning of the filter samples in an oxygen stream revealed an orange residue. Two different iron oxide species could be characterized on the thermally treated filter by RM. Species 1 could be identified to be hematite due to significant Raman bands at 225, 292, 411, 498, 610, 657 and 1318 cm^{-1}. Species 2 to can be assigned to be a mixture of hematite and magnetite due to the observation of significant bands for hematite and additional bands for magnetite at 540 and 665 cm^{-1}.

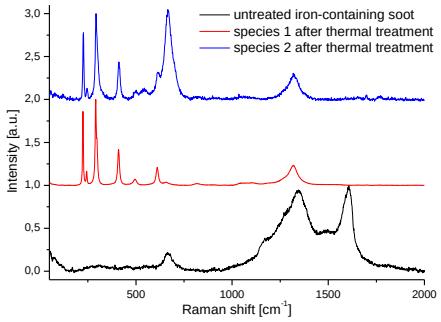

Figure 1. Raman spectrum of iron-containing soot untreated and thermally treated.

The other laboratory approach for the production of iron-containing soot was undertaken by burning diesel fuel mixed with ferrocene with an oil lamp. SEM images reveal the specific morphology of those soot particles containing 10 wt% of iron (Figure 2).

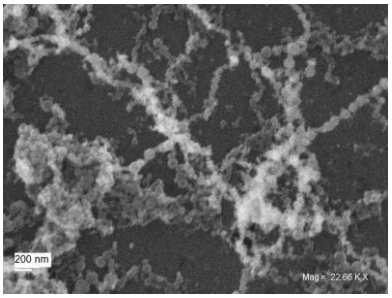

Figure 2. SEM image of soot produced by burning diesel fuel mixed with ferrocene.

This novel approach shall be applied to investigate different soot aerosols from different sources. In particular, the characterization of ship engine exhaust residuals by heavy fuel burning is planned.

Presenting author email: yuanchung.lin@gmail.com

Diesel engines have higher fuel efficiency, power output, fuel economy, and lower emissions of traditional pollutants such as hydrocarbons (HCs) and carbon monoxide (CO) than gasoline-powered engines. The alternative fuels such as biodiesels are being widely discussed in many countries because they used as alternative fuels in diesel engines can reduce HCs and CO emissions (Lin *et al.*, 2006; Yuan *et al.*, 2007). Carbonyl emissions are a part of the exhaust of diesel engines, the main goal of the present study is to analyze CBCs emission factor and emissions of CBCs from HDDEs (heavy-duty diesel engine), especially for formaldehyde and acetaldehyde.

The fuel specifications of the five test fuels are D100, P100, P20, PF80P20, and PF95P05. The total CBC emission factors of them in the exhaust of the HDDE are shown in Tables 1, the total CBC emission factors of D100, P100, P20, PF80P20, and PF95P05 were 1360, 1440, 1370, 1070, and 966 mg L^{-1}, respectively. Using P100 and P20 instead of D100 in the HDDE increased CBC emissions by 80.0 and 10.0 mg per liter-fuel, respectively. However, using PF80P20 and PF95P05 instead of D100 in HDDEs decreased CBC emissions by 290 and 394 mg per liter-fuel, respectively.

Table 1. CBC emission factor (mg L^{-1}) in the exhaust of the HDDE fueled with various biodiesel blends.

CBCs	D100	P100	P20	PF80 P20	PF95 P05
Formaldehyde	988	1086	1036	782	679
Acetaldehyde	32.6	52	42.8	31.6	25.4
Acrolein	47.3	59.2	51.3	38.2	44.9
Acetone	30.5	47	37.6	20.1	25.8

The emission factor and concentrations of regulated harmful matters (traditional pollutants) in the exhaust of the HDDE are shown in Table 2. The emissions of PM, THC, and CO for D100 were mostly higher than those for other test fuels, indicating palm-biodiesel is an oxygenated fuel that improves combustion efficiency. The added fraction of palm-biodiesel should be restricted to be less than 20 vol%. P20, PF80P20, and PF95P05 can reduce the emissions of THC, CO, CO_2, NO_x, and PM as compared to D100. From the results of emission factor, using P20 instead of D100 in the HDDE reduced THC by 22.9%, CO by 4.91%, CO_2 by 3.65%, NO_x by 6.00%, and PM by 9.64%. Using PF95P05 and PF80P20 instead of D100 in the HDDE reduced THC by 39.0–46.46%, CO by 34.0%, CO2 by 1.37–7.60%, NO_x by 12.2–24.3%, and PM by 11.1–11.8%. Similar results were found for emission concentrations.

Table 2. Emission factor (EF) and emission concentrations (EC) of regulated harmful matters (traditional pollutants) in the exhaust of the HDDE fueled with various biodiesel blends.

CBCs	Regulated harmful matters	D100	P100	P20	PF80 P20	PF95 P05
EF	CO (g BHP^{-1} h^{-1})	2.85	2.88	2.71	1.88	1.88
	CO_2 (g BHP^{-1} h^{-1})	658	654	634	649	608
	THC (g BHP^{-1} h^{-1})	0.608	0.515	0.469	0.326	0.371
	NO_x (g BHP^{-1} h^{-1})	6.5	6.13	6.11	5.71	4.92
	PM (g BHP^{-1} h^{-1})	0.289	0.35	0.261	0.255	0.257
EC	CO (ppm)	40.2	40	38.2	26.5	26.5
	CO_2 (ppm)	5880	5780	5690	5810	5450
	THC (ppm)	17.4	14.5	13.4	9.3	10.6
	NO_x (ppm)	55.9	51.8	52.4	48.9	42.2
	PM (mg m^{-3})	4.73	5.63	4.26	4.16	4.19

These analytical results indicate that PF95P05 and PF80P20 are feasible for traveling diesel vehicles (TDVs). Replacing D100 with PF95P05 significantly decreased total CBC (30.3%), PM (11.1%), THC (39.0%), CO (34.0%), NO_x (24.3%), and CO2 (7.60%) emissions. The wide usage of paraffinic–palmbiodiesel blends as alternative fuels could protect the environment.

Keywords: Municipal solid waste incinerators, brominated flame retardants, persistent organic pollutants.
Presenting author email: huangkl@mail.npust.edu.tw

Persistent organic pollutants (POPs), such as chlorinated and brominated aromatics, have been of great concern because of their persistence in the global environment. POPs are lipophilic and may bioaccumulate in the food chain, posing a potential threat to human health (Jones and de Voogt, 1999). Many such compounds (such as polychlorinated dibenzo-*p*-dioxins and dibenzofurans [PCDD/Fs], polybrominated dibenzo-*p*-dioxins and dibenzofurans [PBDD/Fs], polybrominated diphenyl ethers [PBDEs], polychlorinated biphenyls [PCBs], and polybrominated biphenyls [PBBs]) are considered to act as environmental hormones, which disrupt the reproductive cycles of humans and wildlife (Lohmann et al., 2001; Kim et al., 2004; Mari et al., 2008). With the extensive usage of PBDEs as brominated flame retardants (BFRs), they have been found in the emission of municipal solid waste incinerators (MSWIs). However, little attention has been paid to the study of closely related brominated compounds emitted from MSWIs, partially due to the lack of standard methods for sampling and analyzing these compounds.

In this study, the characteristics of five target compounds (2,3,7,8-substituted PCDD/Fs and PBDD/Fs, PBDEs, PCBs, and PBBs) in the stack flue gases of a large-scale continuous MSWI (capacity: 1350 tons/day) were investigated. The stack flue gas sampling procedures were collected isokinetically following U.S. EPA Modified Method 23 using U.S. EPA Modified Method 5 samplings train (USEPA, 2001). ^{13}C-labeled internal standards (ISs) (PCDD/Fs, PBDD/Fs, PBDEs, and PCBs) were added to samples that were then extracted for 24 h in *Soxhlet* extractors with toluene. The extract was concentrated by rotary evaporation in an N_2 gas stream, and then transferred to a vial. The concentrated extract was then treated by a series of simultaneous sample cleanup and fraction procedures, including the use of silica gel, alumina, and active carbon columns. A higher solution gas chromatograph/high-resolution mass spectrometer (HRGC/HRMS) was used for PCDD/Fs, PBDD/Fs, PCBs, PBDEs, and PBBs analyses.

The mean PCDD/F, PBDD/F, PCB, PBDE, and PBB concentrations in stack gases of an MSWI were 0.0719 ng WHO-TEQ/Nm^3, 0.00169 ng WHO-TEQ/Nm^3, 0.00546 ng WHO-TEQ/Nm^3, 20.7 ng/Nm^3, and 0.958 ng/Nm^3, respectively (Fig. 1). Although the dioxin-like PCBs and PBDD/Fs represented only 6.9% and 2.1%, respectively, of the total WHO-TEQ (the sum of PCDD/Fs, PBDD/Fs, and dioxin-like PCBs), the MSWI is regarded as a potential source that may emit dioxin-like compounds.

The emission factors of PCDD/Fs, PBDD/Fs, PCBs, PBDEs, and PBBs were 0.300 µg WHO-TEQ/ton-waste, 0.00667 µg WHO-TEQ/ton-waste, 0.0207 µg WHO-TEQ/ton-waste, 84.5 µg/ton-waste, and 1.05 µg/ton-waste, respectively, in flue gases of the MSWI (Fig. 2). Therefore, in addition to PCDD/Fs, the emissions from MSWIs of other dioxin-like compounds (such as BFRs) should also be concerned.

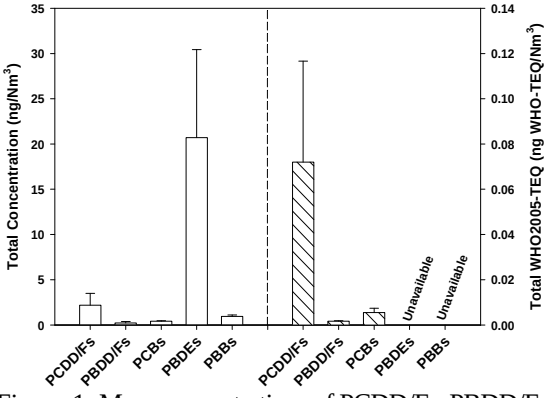

Figure 1. Mean concentrations of PCDD/Fs, PBDD/Fs, PCBs, PBDEs, and PBBs in stack flue gases of the MSWI.

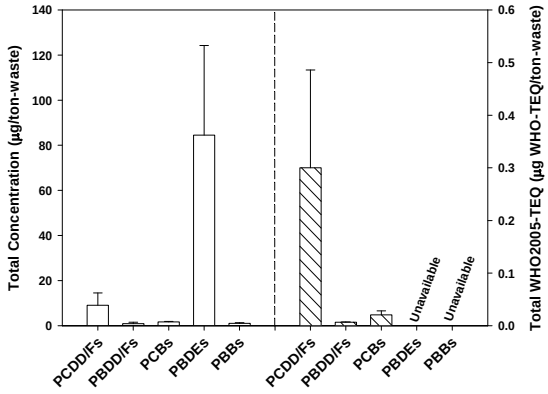

Figure 2. Mean emission factors of PCDD/Fs, PBDD/Fs, PCBs, PBDEs, and PBBs in stack flue gases of the MSWI.

In the foundry industry, the emissions to air arise from the storage, handling, pre-treatment and pyro-metallurgical stages. With the purpose to obtain a data base of emissions from ferrous and non-ferrous metal foundries in Spain, a measurement program was planned and is being carried out. One of the data to be assessed is the size distribution of the particulate matter PM: PM10, PM2.5 and PM1, as well as the size distribution of metals that could accompany it in these emissions.

To carry out this aim, seven steel foundries have participated in the study. Cast steel is normally melted in electric arc furnaces (EAF) or in coreless induction furnaces (IF). Once melted, the liquid metal can be refined and deoxidised, depending on the base material and the quality requirement of the finished product. PM is emitted from metal melting, sand moulding, casting and finishing. A series of campaigns was made to sample, to evaluate the dust fractionation and to analyze the metallic traces in emissions coming from melting stage.

Sampling and measurement was carried out in accordance with US EPA 201A and VDI 2066/5 procedures using three types of cascade impactors: Mark III with eight collection stages and DEKATI 30LPM or KS207 Kalman System GMBH with three stages. The samples of collection substrates were chemically analyzed according to method EPA IO-3.1 as previous step to the determination by ICP-OES and/or ICP-MS and FAAS.

Four ranges of particle aerodynamic diameter have been analyzed, dp (in microns): dp>10, 10>dp>2.5; 2.5>dp>1; dp<1.

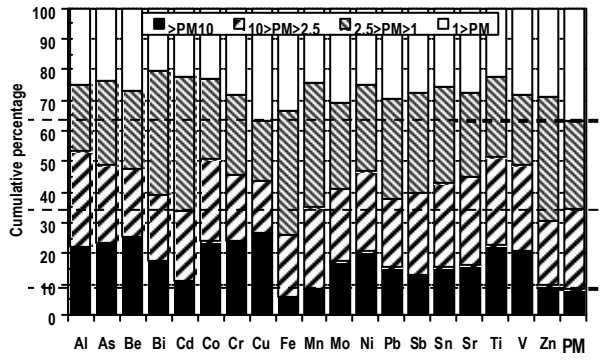

Figure 1. Distribution of metals and particulate matter, PM by size

The total concentrations of particles, PM and metals in the emissions varied in more than one order of magnitude. Also, it was observed significant dispersions in the metals distribution data by particle size.

The distribution of metallic traces by size not always agrees with the distribution of total mass of particles. This means that an enrichment of trace metal occurs for certain particle size ranges.

The predominant interval is the submicron range (36 % of the emitted total mass). Only eight percent of PM corresponds to particles bigger than ten micron. Al, Cu, Fe, Mn, Pb, Sb and Zn were found to be the main metals by mass in PM (higher than 102 $\mu g/Nm^3$). All of the metals except Fe and Mn enrich the fraction of particles larger than 10 microns.

Most of these effects have its origin in the heterogeneity into the furnace bed and the differences in the emission gas cleaning systems. The first one is mainly due to selection and pre-treatment of raw material used (scrap containing impurities and other secondary materials, also the addiction of fused salt and recovered from slag and other additives used to bind the sand) with diversity of shapes and chemical composition. The second one is due to the different cooling system technologies (air injection, heat exchanger, etc.) and separators (cyclone, sedimentation chamber, bag filter…) used in each foundry.

Session 4P: Poster Session A:
Atmospheric Aerosols - Aerosol Processes and Properties

How accurate are the nucleation event analysis tools?

According to current knowledge, atmospheric nucleation events initiate at a particle diameter of ~1.5 nm. However, until very recently, most field instruments measuring the aerosol size distribution have had a low-end cut-off at ~3 nm. Therefore, several mathematical approaches have been developed in order to quantify nucleation rates at the initial cluster size as well as nucleation mechanisms from the measured distribution data (e.g., Sihto et al., 2006; Kuang et al., 2008).

We have evaluated these analysis tools with over 1200 numerical nucleation events for which the nucleation mechanism and formation rates are known exactly. We have tested the performance of different formulations of the tools as well as the sensitivity of the results to the various assumptions that have to be made in the analysis. In order to resemble the atmospheric measurement data as closely as possible, the model output was regridded into typical size channels of a DMPS instrument with 10-minute time intervals.

We find that calculating the growth rate of sub-3 nm clusters from the time delay between the diurnal curves of H_2SO_4 and 3-6 nm particle concentration can overestimate the growth rate during strong nucleation events. This is because of coagulation scavenging of the clusters to the earlier formed nucleation mode, which can under some conditions lead to apparent negative time delays. However, the cases in which the time delay remains positive but is shortened compared to time delay corresponding to the actual growth rate are more problematic for the analysis.

In general, the particle formation rate at 3 nm (J_3) is captured reasonably well by the analysis tools with 43-97% of the events falling within a factor-of-two accuracy from the actual simulated value. However, the accuracy of the analysed values show clear sensitivity to the specific form of the analysis equations used and assumptions made about the initial size of nucleating clusters. On the other hand, the estimates of the actual nucleation rate at 1.5 nm were clearly less accurate with only 37-59% of the events within a factor-of-two accuracy. The main reason for the large errors is that the analysis methods do not take into account the size-dependence of particle growth rates below 3 nm. Moreover, the results are also sensitive to the assumption made about initial cluster size.

The poor estimates of $J_{1.5}$ can lead to fairly large uncertainties in the nucleation prefactors (i.e. constant P in nucleation equation $J_{1.5} = P \times [H_2SO_4]^k$). However, all the analysis set-ups tested in this study resulted to an order-of-magnitude accuracy for almost 90% of the simulated events. This can be considered reasonable since the coefficients derived from atmospheric data typically exhibit a variation of 1-3 orders of magnitude. This indicates that the high variation of observed nucleation prefactors is not a consequence of inaccuracies in the analysis methods, but a real phenomenon caused by (so far unknown) environmental factors.

Large uncertainties were found also when the analysis tools were used to determine the nucleation mechanism in terms of the number of H_2SO_4 molecules in a critical cluster (i.e. exponent k in previous equation). Although our results suggest that in general the analysis tools tend to overestimate the number of H_2SO_4 molecules in the critical cluster, also significant underestimation was found in up to 41% of the cases. This indicates that one cannot automatically rule out more than 2 sulphuric acid molecules in a critical cluster even if field data shows nucleation exponents in the range 1-2. Our analysis also suggests that combining data from several new particle formation events to scatter plots of H_2SO_4 vs formation rates ($J_{1.5}$ or J_3) and determining the slope of the regression line may not give reliable information about the nucleation mechanism.

Keywords: nucleation events, number size distribution, SMPS, classification

Thessaloniki is one of the most densely populated urban centers of Greece suffering from high concentrations of atmospheric particulate matter (PM). The physical and chemical properties of PM as well as the size distributions of ultrafine aerosol particles (i.e., particles having diameter smaller than 1 μm) in the atmosphere over the city have been determined by a number of previous studies (e.g., Voutsa *et al*., 2002; Manoli *et al.,* 2002; Samara *et al*., 2003; Terzi *et al*., 2010; Siakavaras *et al*., 2008).

In the present study we report particle nucleation and growth events observed at a kerbside and an urban background monitoring station in Thessaloniki during the summer period. The two monitoring stations (Venizelou – kerbside site, and Eptapyrgio – urban background site) exhibit the maximum and minimum levels of PM_{10} and $PM_{2.5}$ in Thessaloniki (Petrakakis *et al*., 2007). Two identical Scanning Mobility Particle Sizers (TSI Model 3034) have been employed to measure simultaneously the size distributions of the particles having diameters in the range 10-487 nm at the two sites. Gaseous pollutants (CO, NO_x, SO_2 and O_3) and meteorological parameters (wind speed, wind direction, temperature and relative humidity) were also recorded during the measurements. The experiments were conducted during two summer periods (June to September 2007 and June to October 2009).

Nucleation events were observed at 27% of the days at Venizelou (kerbside site) and at 29% of the days at Eptapyrgio (urban background site). Regional growth events when the increase in particle number concentration having diameters less than 20 nm, N_{20}, lasted for several hours occurred at 20% and 23% of the nucleations at Venizelou and Eptapyrgiou, respectively. The rest of the events were short-lived and did not exhibit growth of the nucleation mode particles to larger sizes.

Depending on the net rate of increase in N_{20} during the first hour of the event (dN_{20}/dt) we further classified the events as weak and strong (Figure 1). In all cases the observed nucleation events started in the morning and were more frequent during July at Venizelou and during July and September at Eptapyrgio. The observations of the events correlated well with high concentrations of SO_2 and NO_x.

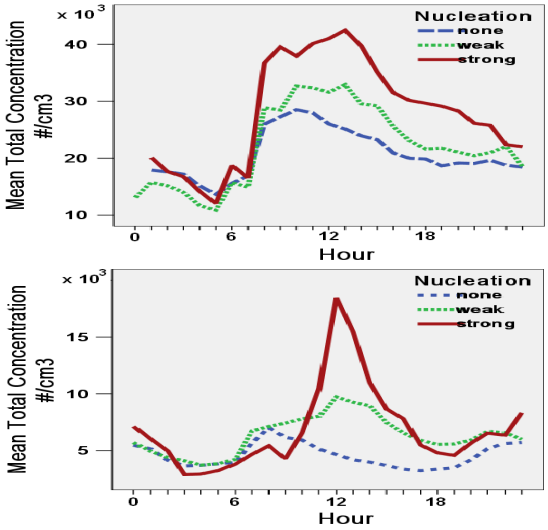

Figure 1. Diurnal particle number concentration vs time for days that exhibit no, weak and strong nucleation events at Venizelou (upper part) and Eptapyrgio (lower part)

Time-frequency analysis of aerosol number concentrations in Europe – 28 day period in nucleation and the (lack of) weekly cycle in CCN-sized particles

A. Asmi
Department of Physiucs, University of Helsinki, Helsinki, FI-00014 UHEL, Finland
Keywords: wavelets, CCN, nucleation, field study.
Presenting author email: ari.asmi@helsinki.fi

Two aerosol-climate interactions are directly connected to cyclicity of aerosol particles. The potential of cosmic-ray or sun-mediated variation in new particle formation, has been under extensive scientific interest. Similarily, a correlation between potentially anthropogenic weekly cycle of particle concentrations and several meteorological parameters has been proposed.

We follow the work of Asmi *et al* (2011), where the EUSAAR measurements did not show any weekly cycle in the CCN-sized aerosol number concentrations. By using long-period measurements from 3 stations in Europe (SMEAR II and Pallas in Finland, Melpitz in Germany), we can extract the time-frequency variations of both nucleation and CCN-sized particles to detect any weekly or monthly cycles in the aerosol concentrations. We used all of the available data from the stations and thus have at longest almost 14 years of continuous dataset. The method used is discrete wavelet analysis, which provides us time-frequency spectra of the concentrations (Torrence and Compo, 1998).

We see no clear signal in weekly or weekly-type (e.g. 5 or 2 days) variation of CCN-sized aerosol in the stations (Fig 1A). This suggests that the number concentration of CCN-sized aerosols are not strongly varying with anthropogenic work week, at least in regional background. The low signal of weekly-type variations do not support indirect aerosol effect based weekday or weekend cycles in European boundary layer regional background.

The nucleation mode results show that the 28 days cycle can be seen in the nucleation mode aerosol concentrations in *almost every spring* at SMEAR II station and visible in all stations (Fig 1B). This period is the same as solar rotation period and related parameters, such as neutron counts on surface and hemispheric energetic particle deposition (Fig 1B bottom). More support on this potential hypothesis comes from the fact that the month-like periodicities of solar-related parameters also are strongest in spring and autumn. The mechanism how this periodicity would actually influence the nucleation rates is not, however, easily defined. To study this phenomena closer, we separated the times of opposite phases of the periodic oscillation in nucleation. By analysing re-analysis weather information during these periods, we noticed that the oscillation was connected to periodic oscillation between of high and low pressure systems around North sea and Barents sea, already discovered by Rinne and Järvenoja (1995). This suggests that the observed 28 day periodicity in nucleation is more likely of meteorological origin, and the underlying reason for the oscillation is periodic Arctic air outbreaks to Scandinavia.

Atmospheric new particle formation (NPF) has been observed all around the world, often by using continuous particle size distribution measurements at a fixed location. In Class I NPF event a new mode of particle is observed in small size classes, and the mode grows to larger sizes when time passes on (Dal Maso *et al*., 2005). As air mass passes over the measurement site, the measurements at different time points do not represent the same air parcel. The fact that the growth of the mode can be observed at a fixed location is usually explained by assuming that new particles are formed over a large area simultaneously.

The duration of a Class I event can be calculated from the time the new mode appears and the latest time the same mode can be observed (figure 1). This also tells us how long the last observed particles have been in the air. When air mass trajectories are available, this information can be used to determine where the new particles were formed. The last observed particles are the ones formed furthest (along the trajectory) from the station. Later in this abstract this point referred as the event-start-location of the NPF event.

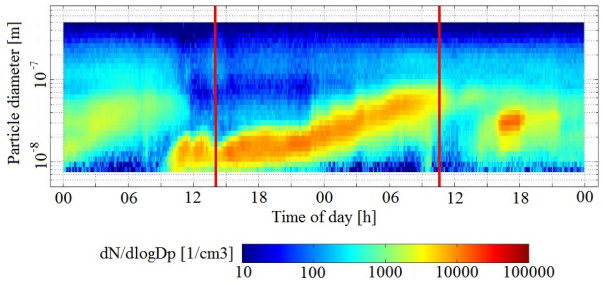

Figure 1. A Class I new particle formation event observed at Pallas April 22-23, 2002. The vertical red lines show the starting time and ending time of the event.

10 years of DPMS data from Pallas Global Atmosphere Watch (GAW) station in northern Finland was analysed (Asmi *et al*., 2011). FLEXTRA trajectories (Stohl *et al*, 1995) were used to calculate the arriving path and speed of the air mass. Total of 68 Class I NPF events were found. Most of these events were associated with air masses arriving to the site from North-Atlantic or Arctic Ocean, and very few Class I events were observed in air masses originating from south or south-east.

Some of the event-start-locations were traced to be far on the ocean while some were clearly inland. Yet 65% of the event-start-locations were within 150 km from the Atlantic- or Arctic Ocean coastline, and 52% within 100 km (figure 2). The 100 km distance from the shoreline is well within the uncertainty of the trajectories and the uncertainty caused by the estimation of the start- and end times of the events.

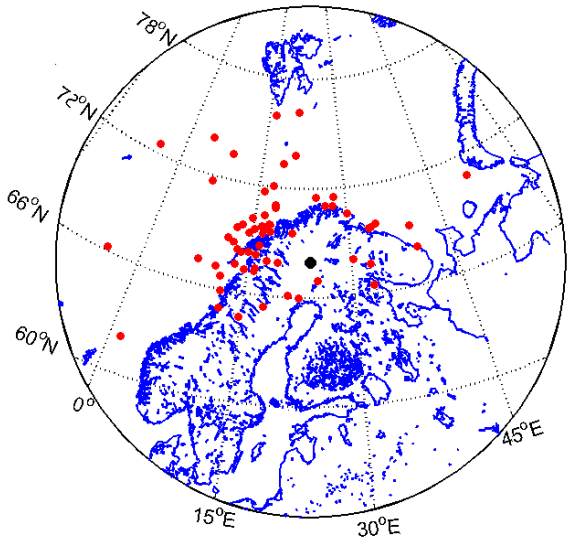

Figure 2. The event-start-locations of the 68 observed Class I new particle formation events (red). The black dot is the location of Pallas measurement site.

Future work will include more detailed analysis of the NPF events in order to separate those cases where the observed end of the growing mode is caused by clear air mass change or meteorological change. Also data from other stations in Northern Scandinavia will be analysed in order to see whether they give similar results on the regional extent of new particle formation. One of the main goals of this investigation is to resolve whether the commonly used assumption of the spatial homogeneity of the new particle formation events over the same air mass is well justified around the Pallas site.

Secondary new particle formation (NPF) has been recognised as an important source of atmospheric aerosol particles worldwide (Kulmala *et al*. 2004). Yet, there are numerous open questions on how this process proceeds or what its climatic importance at different geographic regions is. These questions relate to e.g. particle formation mechanisms, compounds involved in the process, environmental boundaries required as well as the ability of freshly formed tiny particles to grow up to the sizes of climatic relevance. To contribute for answering these questions, we analysed nearly 11-years (April 2000 – December 2010) of continuous measurement data from Finnish sub-Arctic GAW (Global Atmospheric Watch) station Pallas with the focus on NPF events. We classified the days into NPF event, undefined and non-event days following Dal Maso *et al.* (2005), determined the particle formation and growth rates, examined which factors (air mass properties, local meteorology, condensation sink, sulphuric acid concentration, etc.) promote or hinder particle formation, analysed the long-term trends, and in addition, the probability of particles to grow up to the CCN (Cloud Condensation Nuclei) sizes.

The analysis of NPF relied on Differential Mobility Particle Sizer (DMPS) measurements on particle number size distributions (Komppula *et al*. 2003). From the measured distributions, we determined the particle formation and growth rates following the procedure presented in Komppula *et al.* (2003). Auxiliary data on local meteorological variables, as well as on air mass backward trajectories, calculated with FLEXTRA (Stohl *et al.* 1995), were used. Sulphuric acid has been suggested to be a key parameter in atmospheric NPF, and while lacking the direct measurement of H_2SO_4, we used a proxy based on global radiation, condensation sink (CS) and SO_2 (Petäjä *et al.* 2009).

Seasonal variation of NPF events was congruent with previous studies, showing a spring maximum and a winter minimum (Komppula et al 2003). Equally, NPF was found to be favoured by clean Arctic air masses and bright, sunny weather. The observed seasonal trend was by a large part explained by inter-annual changes in climatic and meteorological conditions. Monthly median growth rates varied within the limits of 1.9 and 4.6 nm h^{-1}, being highest in summer months, and as such providing evidence of the significance of organic vapours for the particle growth.

The inter-annual trend of NPF days versus non-event days suggests a decrease in the beginning of the decade and vice versa, increases in the end of the decade (Fig. 1). As the external climatic and meteorological quantities seemed to predict the NPF occurrence fairly well, we developed a proxy for NPF based on air mass origin, visibility and global radiation. It however turned out that this proxy was insufficient for predicting the inter-annual trend and thus other non-specified factors played a role in particle formation, our best guess of these being the quantity of nucleating or condensable vapours.

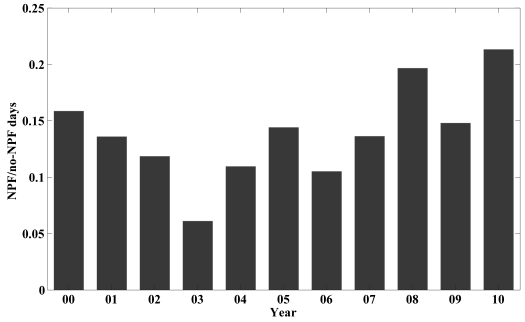

Figure 1. NPF days vs. non-event days – 11 year trend.

Finally, the climatic impact of NPF was examined by separating the events with the growing mode exceeding 80 nm size, previously found to be a good approximation of CCN size limit in Pallas (Komppula et al 2005). In 34% of the class I (for definition, see Dal Maso *et al.* 2005) events this limit was reached with the maximum probability of CCN_{80} formation in summer season. This is in agreement with the higher growth rates observed in summer. We may conclude on the climatic importance of NPF that while the observable CCN_{80} formation from NPF was infrequent, its impact on CCN number was large; the average increase in CCN_{80} number by NPF was 211 %.

Keywords: Nucleation, Aerosol formation, Emission sources, Particle formation and growth.

The new aerosol particles formed by atmospheric nucleation is a global phenomenon proven to take place in different atmospheric environments (Kulmala et al., 2004). A direct chemical analysis of particles < 5 nm in diameter is not technically feasible at the moment; therefore, knowledge on the atmospheric nucleation and particle growth mechanism and its governing circumstances has only been gathered indirectly, for instance by time series analysis of the number concentration of freshly formed particles, gas phase precursor, and meteorological variables. A comparison of sufficiently long atmospheric data sets in different environments is expected to reveal useful information on how different sources and transformation processes modify properties of aerosol particles.

Here, we study, for the first time, the new particle formation (NPF) at the Puijo tower research station. The station is on the top of the Puijo tower; 62° 54′ 32″ N, 27° 39′ 31″ E, and 306 m a.s.l and 224 m above the surrounding lake and located about 2 km northwest of the center of Kuopio city, Eastern Finland. Details of the station can be found in Leskinen et al. (2009).

The quantification of aerosol nucleation in the Puijo research station took place from June 2006 to November 2009. The Puijo data set is unique in the sense that the surroundings of the station are different in each side. There are distinct sectors for cleaner and more polluted air, which give us a good opportunity to investigate the effects of local emission sources on aerosol particle formation. Our analysis uses the measured particle number size distribution (measurements were carried out using a twin DMPS system (Differential Mobility Particle Sizers) at the Puijo site, with particle size ranges of 7-800 nm), trace gas concentrations (SO_2, NO_x, O_3) and basic meteorological variables (T, RH , P, wind speed and wind direction).

In the process of the NPF analysis from Puijo research station, the particle formation events were identified and classified into three different categories according to the local emission sources; Class 1 includes normal NPF days (similar to what has been observed in different environments) with very high number particle concentrations and clear growth of the newly formed particles that last for many hours; Class 2 includes clean NPF days (with relatively low growth rates and low amount of SO_2 concentrations); and Class 3 includes polluted NPF days caused by local sources (with high amount of SO_2 concentrations when the wind comes from N, NE directions, see Fig. 1).

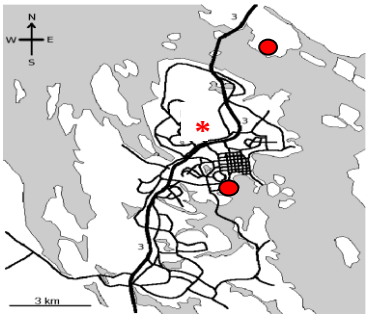

Figure1. The location of Puijo measurement station in Kuopio, Finland, marked by red star, red circles show the location of point sources nearby. The lake is in gray. The highway is marked by number 3.

The number of NPF days were the highest when the wind comes from north and northeast where there is a pulp mill located ~5km from the site (Fig.1). This facility is considered a potential source of high concentrations of SO_2, NO_x and particles, but not soot. We observed moderate numbers of NPF days in which the wind is from the clean biogenically dominated sector to the west. Emissions from a nearby freeway and also the city center of Kuopio, located southeast of Puijo, are associated with higher levels of SO_2, NO_x and particles (especially soot) and showed high number of NPF events. Fewer NPF days of were observed when the wind was from the east, another relatively clean sector.

This pre-study emphasizes the diversity of sources that exist in the Kuopio region, and the interplay between NPF events and local emissions motivates the ongoing comprehensive analysis.

Vegetation is the major source of biogenic volatile organic compounds (BVOC) in the troposphere. These BVOC impact atmospheric oxidation capacity and serve as precursors for secondary organic aerosols (SOA). In regions with low pre-existing particulate matter, BVOC oxidation by OH, ozone, and NO_3 can produce low volatile products which are involved in SOA formation.

Isoprene and monoterpene emissions from vegetation are well known. However, during and after stress situations plants emit many other BVOC. Sesquiterpenes (SQT) such as α- and β-farnesene, C_6-aldehydes and -alcohols produced within the octa-decanoid pathway (green leaf volatiles, GLV), or many different aromatic compounds originating from the phenylpropanoid pathway are typical BVOC emitted during biotic and abiotic stress.

In this study we measured the formation of secondary organic aerosols (SOA) from stress-induced BVOC emissions emitted from grey poplar seedlings (*Populus x canescens*). The experiments were conducted in the Jülich Plant Atmosphere Chamber (JPAC, Mentel *et al*., 2009). This system consists of two temperature controlled chambers, one housing the plants (plant chamber) and the second one was used for photochemical SOA production (reaction chamber). BVOC emitted from the poplar plants in the plant chamber were transferred into the reaction chamber where they were oxidized by ozone and by OH radicals. OH was produced by photolysis of ozone in presence of H_2O. OH concentrations were typically in the range of 3-8×10^7 cm^{-3}. Ambient conditions such as temperature, relative humidity, photosynthetic active radiation (PAR), CO_2, O_3, and NO_x levels were controlled.

We used 4-month-old wild type (WT) poplar plants that emit high amounts of isoprene and transgenic poplar lines down-regulated in isoprene emission (R-lines, Behnke *et al.*, 2007). Comparing particle formation from BVOC emitted from these plants enabled the characterization of the impact of isoprene on the SOA formation from plant emissions. Unstressed poplar plants emitted nearly exclusively isoprene whereby the emissions from the down regulated R-lines were more than an order of magnitude lower than those from the wild type. Using unstressed plants as BVOC sources for particle formation we found inefficient SOA formation with nucleation rates far below 1 cm^{-3} s^{-1}.

All lines showed strong additional emissions of sesquiterpenes and aromatic compounds after stressing the plants by short ozone pulses. Their emission rates and therefore the BVOC emission pattern changed on a time scale of several days after stress application, allowing to study SOA formation under nearly steady state conditions. Feeding BVOC mixes into the reaction chamber resulted in very strong SOA formation events with nucleation rates exceeding 3000 cm^{-3} s^{-1}. Normalized to the BVOC turnover the nucleation rates were generally lower for the isoprene emitting WT poplars compared to non-emitting mutants. This observation confirmed former findings of suppression of nucleation by isoprene (Kindler-Scharr *et al*., 2009).

Rapid variations of PAR in the plant chamber resulted in fast changes of isoprene emissions whereas the emissions of the other BVOC responded on a much longer time scale. Hence, switching off the lamps in the plant chamber allowed removing isoprene very fast while keeping the level of other BVOC concentrations high. Conducting this procedure during a particle formation event caused a fast decrease of isoprene concentration and a strong increase of OH concentrations in the reaction chamber followed by increases in particle number and mass. This also shows that suppression of OH concentrations by isoprene is the major reason for suppression of nucleation from non-isoprene BVOC.

Using a low isoprene emitting poplar plant as BVOC source and adding deuterated isoprene from a diffusion source we estimated isoprenes' contribution to the SOA mass formed from the BVOC emitted from poplar. While isoprene contributed to about 7% [C/C] to the BVOC in the gas phase the contribution to the particulate phase was only 1 %. Thus isoprene oxidation products partitioning into the SOA can not compete with that of oxidation products from the other BVOCs. However the SOA mass produced by isoprene oxidation products does not compensate the decrease of other BVOC particle precursors caused by the decrease of OH concentrations in the presence of isoprene.

Sulfuric acid measurements with CI-TOF-MS

T. B. A. Jokinen[1], M. Sipilä[1], T. Petäjä[1], M. Kulmala[1], D. R. Worsnop[1], and H. Junninen[1]

Keywords: sulfuric acid, chemical ionization, mass spectrometry.
Presenting author email: tuija.jokinen@helsinki.fi

Sulfuric acid is a key compound in atmospheric nucleation (Sipilä et al., 2010). In atmosphere sulfuric acid is produced mainly photochemically via reaction of OH with SO_2. Concentration of sulfuric acid is typically very low, rarely exceeding 10^8 molecules cm^{-3} (e.g. Paasonen et al., 2010). The low concentrations set certain requirements for the detector to be used for quantitative measurements. Method for measuring gas phase sulphuric acid by means of chemical ionization mass spectrometer were developed by Eisele and Tanner (1993). They used nitrate ion, NO_3^-, and its clusters with nitric acid, HNO_3, for selective chemical ionization of H_2SO_4 via $NO_3^-\cdot(HNO_3)_n + H_2SO_4 \rightarrow n(HNO_3) + (HNO_3)\cdot HSO_4^-$. Resulting $(HNO_3)\cdot HSO_4^-$ clusters together with remaining $NO_3^-\cdot(HNO_3)_n$ were dissociated and HSO_4^- and NO_3^- were detected with a quadrupole mass spectrometer.

Here we present a measurement system in which the atmospheric pressure chemical ionization inlet, with geometry similar to Eisele and Tanner (1993), is combined with a high resolution atmospheric pressure interface time-of-flight mass spectrometer (Tofwerk Ag., Junninen et al., 2010). In the present setup, clusters are not broken on purpose, instead the high resolution and mass range of the TOF allows separation and summing of different clusters. Advantage of the method is that it allows one to seek for neutral sulphuric acid containing clusters formed by nucleation in the atmosphere (Kuang et al., 2008) or in laboratory systems (Sipilä et al., 2010).

In this laboratory experiment we generated reagent ions by mixing a small amount of nitric acid to nitrogen flow and exposed it to a radioactive source (^{241}Am). Sulfuric acid vapour is produced by leading synthetic air through a saturator containing pure 95-97% H_2SO_4. Sulfuric acid vapour was then introduced to the CI inlet with multiple different flow rates and diluted with laboratory air to create a constant sample flow of 10 lpm. The mixing with the reagent ions is done by applying voltage between a set of ion lenses.

The sample is guided to the TOF for mass per charge (m/Q) determination. Pressure is reduced to 10^{-6} mbar and by three separately pumped chambers. Ions are guided to TOF using two quadrupoles and an ion lens assembly. We operated TOF in negative ion mode to monitor sulfuric acid and its dimer, trimer and tetramer at m/Q 97, 195, 293, 391 and nitric acid monomer, dimer and trimer at m/Q 62, 125 and 188.

Figure 1 shows increase in deprotonated sulfuric acid concentration when flow rate trough the saturator is elevated from 0.1 lpm to 9,5 lpm. With flow rates under 1 lpm we only detect sulfuric acid monomer and dimer but at elevated flow rates, < 2 lpm, we can detect bigger clusters forming also. Nitric acid is been neutralized during ionization process which can be seen in descending signals of NO_3^-, its dimer and trimer.

The aim is to use CI-TOF-MS to measure aerosol clusters in ambient air and coupling CI with TOF-MS now offers an effective and selective way of ionizing and detecting ambient neutral sulfuric acid and its clusters.

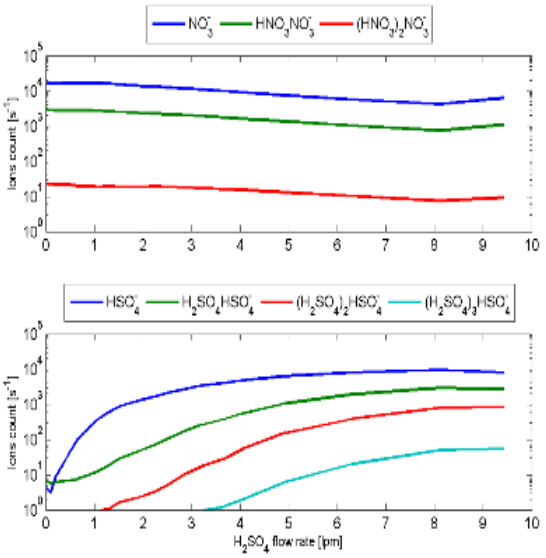

Figure 1. Sulfuric acid and reagent ion concentrations in CI-TOF-MS spectrum.

Presenting author email: becsi.zsuzsanna@gmail.com

New particle formation events can be observed all over the world both in polluted and background air and have been studied for a long time because of the climatic and health effects of the fine particles. Data on new particle formation in Hungarian background air is rather sparse. However, a DMPS (Differential Mobility Particle Sizer) installed in 2007 operates at the Hungarian background air monitoring station and provides aerosol data in order to study the particle formation and growth. The study of the size distribution, the diurnal and seasonal variation in the occurrence of the maximum number concentrations helps to get more information on the parameters, reasons and processes which lead to new particle formation events.

In this work we summarize our results on the particle formation at K-puszta station between Nov. 2008 and Nov. 2009. The time resolution of the DMPS measurements makes the study of the particle formation and growth possible. The size distribution of the particles between 3-800 nm is evaluated. On the basis of DMPS spectra the classification of particle formation events was carried out according to the recommendations of Yli-Juuti *et al* (2009). The event classification was studied with respect to the seasonal variation and the frequency of the particle formation event types (event, non-event and unclassified) was also discussed.

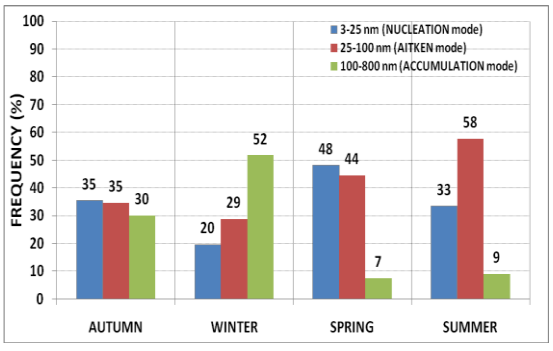

Figure 1. The seasonal frequency of the maximum concentrations in different particle modes.

In new particle formation (NPF) winter was the most inactive period. In winter the total number concentration and the number of NPF events were the lowest during the year due to the unfavourable ambient conditions (lowest solar radiation, weak or lack of photochemical processes and aerosol precursors). The number of NPF events was found to be the highest in spring while a second peak occurred in autumn.

On the basis of the data the frequency of the daily maximum concentrations with respect to the particle size mode was also calculated (Figure 1). The frequency of the nucleation mode (3-25 nm) was the highest during spring and autumn. On the other hand, in winter the accumulation mode (100-800 nm) showed the highest, while in spring and summer the lowest frequency. In autumn all the three modes were evenly distributed.

The growth rate of the freshly formed particles can also be calculated (Hirsikko *et al* (2005), Yli-Juuti *et al* (2009). Our preliminary results show that at K-puszta the particle growth rate is highly variable, it can reach even the 14 $nmhr^{-1}$.

It is well-known that meteorological parameters play an important role in new particle formation. In this work the relationship between new particle formation and meteorological parameters like temperature, wind speed and direction, relative humidity, precipitation, global radiation was also studied.

Keywords: nucleation, nano particles, DEG CPC, working fluid, CLOUD experiment

The physical as well as the chemical properties of nano particles are of special interest in various scientific fields, e.g. when atmospheric nucleation events are studied or within the wide field of nano-technology and its applications. Especially for nucleation studies it is crucial to achieve the lowest cut-off diameter possible in order to derive accurate numbers for the nucleation rates (Sipilä et al., 2010). Standard commercial condensation particle counters rely on the activation of aerosol particles using butanol as the condensation fluid and achieve lower cut-off diameters around 2.5 nm. However, using diethyleneglycol (DEG) as the condensation liquid cut-offs well below 2 nm have been realized (Iida et al., 2010). Due to the low vapour pressure of DEG, particles only grow to sizes ~100nm and are therefore too small to be directly detected with the optical systems usually used. This means, whenever using DEG as working liquid a second CPC (the so-called 'booster') is needed to grow the already activate particles further to count them optically.

For the work presented here we modified a standard TSI 3776 ultrafine butanol CPC. The modifications that were necessary are the following. (1) The wick which is used for the butanol version cannot be wetted by DEG therefore it was replaced by a cellulose filter. This filter was wrapped around a perforated stainless steel tube housed in the saturator part of the CPC. (2) Since the TSI software does not allow for controlling the saturator temperature to values larger than 50°C, an additional temperature control was established. It consists of a Pt1000 installed in a bore inside the saturator block and a Watlow PID heat control. (3) The optics part of the CPC was removed and instead an adapter piece was attached to the outlet of the condenser in order to connect it to the second booster CPC. Test measurements were performed to determine the highest saturatuor temperature where no homogeneous nucleation occurs while having the condenser at a fixed temperature of 10°C. This saturator temperature was found to be 52°C.

Detailed calibration measurements were carried out where the DEG CPC was compared to different TSI CPCs and a particle size magnifier (PSM, Vanhanen et al. 2011). The cut-off curves were determined for these CPCs using a high resolution DMA (Herrmann DMA, Hermann et al., 2000) for classifying the particles. Several different methods were used to generate test aerosol particles. These include an electrospray source providing different mobility standards, a Grimm WO_x generator (model nr.: 7.860), a tube furnace for NaCl particles and H_2SO_4 particle generator. Due to its special design the high resolution DMA cannot classify particles bigger than 4nm in mobility diameter. Therefore to provide bigger particles a Grimm nano-DMA (model nr.: 5.710) was used. The CPC concentrations were normalized by the concentrations obtained from two different electrometers (models 5.705 and 3068B). A cut-off curve for the DEG-CPC is shown in Figure 1.

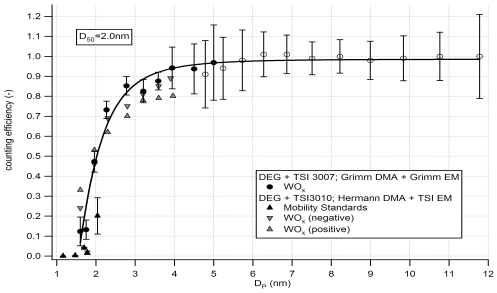

Figure 1 Cut-off curve of the DEG CPC using different types of particles.

During these measurements a TSI 3010 was used as the booster CPC. The cut-off diameter (the size where 50 % of the particles are being detected) of the DEG CPC is 2nm in mobility diameter for this measurement.

The instrument described in this work has also shown to work reliably during a long time period. It was operated during the CLOUD 2010 fall campaign at CERN.

Further tests with the CPC will be performed using a particle generator providing sulphuric acid particles. In addition we would like to test the performance of the CPC in a cool chamber where we can both set and control the temperature well below 0°C, since the temperatures in the CLOUD chamber should be decreased further (down to -90°C)

We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. This research has received funding from the EC's Seventh Framework Programme under grant agreement number 215072 (Marie Curie Initial Training Network "CLOUD - ITN"), from the German Federal Ministry of Education and Research (project number 01LK0902A), from the Swiss National Science Foundation and from the Academy of Finland Center of Excellence program (project number 1118615).
We would also like to thank TSI Inc., especially Oliver Bischof for providing us important equipment.

Nanoparticle formation in the boundary layer is a frequent phenomenon (Kulmala *et al.*, 2004). Sulfuric acid has been identified as a plausible candidate to participate in the nucleation (Weber et al. 1996). Ion-induced nucleation is one of the possible pathways for new particle formation in the atmosphere, but it is still unclear how important the contribution of ions is with respect to neutral pathways. Ion concentration and their size distribution are key quantities to understand ion-induced nucleation processes and dynamics.

During the CLOUD (Cosmics Leaving OUtdoor Droplets) 2010 fall campaign, several experiments of sulfuric acid-water neutral and ion-induced nucleation were performed in an aerosol chamber. In this experiment, Galactic Cosmic Rays (GCR) and the Proton Syncrotron (PS) accelerator at CERN were used as sources to generate ions in the 26.1 m^3 CLOUD aerosol chamber under precisely controlled conditions. Both GCR and the PS pion beam were constantly monitored by a GCR counter and by a hodoscope, respectively.

The ion concentration in the CLOUD chamber was measured with a Neutral cluster and Air Ion Spectrometer, (NAIS, Kulmala *et al.*, 2007). The NAIS is able to measure air ion number size distributions in the mobility equivalent diameter range of 0.8 to 40 nm and correspondingly neutral particle number size distributions from ~2 to 40 nm mobility diameter.

It was also possible to use a PSM (Particle Size Magnifier; Vanhanen e*t al. 2011*), a scanning CPC with a cut off varying from 1 to 2 nm, to retrieve the size distribution of the atmospheric ions created in the chamber and compare it to the NAIS in absence of neutral particles in the chamber (Figure 1).

Based on the measured GCR and beam intensities we were able to calculate the expected ion concentrations in the chamber as a function of beam intensity. The calculated ion concentrations were then compared with the measured values in the NAIS, therefore we retrieved the ion-ion recombination coefficient, performing a dedicated set of experiments at different conditions: in sulfuric acid free ($[H_2SO_4]$<5e5 cm^{-3}) and in sulfuric acid rich environment ($[H_2SO_4]$~3e6 cm^{-3}).

The ratio of formation rates of charged and total particles give information about the contribution of ion-induced nucleation. Charged nucleation rates were retrieved from the NAIS ion mode and from two CPCs one of which was equipped with a switchable ion trap both results will be compared.

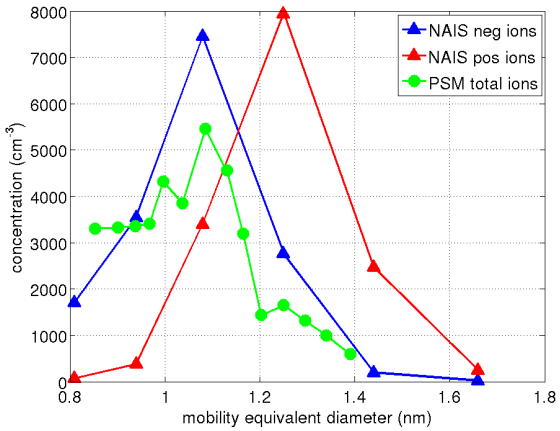

Figure 1. Comparison of number size distribution of ions from NAIS (blue for negative ions red for positive) and from PSM (green).

We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. New particle formation from trace vapours may be responsible for up to one-half of global cloud condensation nuclei, CCN. Sulphuric acid, produced by the photooxidation of sulphur dioxide, is thought to be the primary vapour responsible for the nucleation of new particles in the atmosphere. A mechanism which has been proposed to enhance nucleation rates is ternary nucleation involving ammonia. This process is thought to be effective already at ppt levels of ammonia. In the framework of the EU-ITN project CLOUD (Cosmics Leaving OUtdoor Droplets) this mechanism was investigated in a large simulation chamber at CERN.

We describe here the development of an instrument to measure ammonia at low ppt levels (Figure 1). This is very challenging and hardly reached by any instrument. Furthermore, the inlet of the sampling line plays also a crucial role as ammonia is a rather sticky compound and may adsorb on the walls of the inlet. Therefore, our instrument consists of a specifically designed sampling system to minimize losses of ammonia. Ammonia is stripped from the gas phase into the water phase at the tip of the sampling line. This sample solution is then derivatised by the Berthelot reaction (Patton and Crouch, 1977), which is a reaction between ammonia, hypochlorite and phenol. A blue indophenol is formed which is detected by a long-path absorption spectrometer (Schwab *et al.,* 2007). The latter consists of a liquid core waveguide (LCW) with an effective path length of 5 m. The light source is a red power LED (Luxeon) coupled via a glass fiber to the LCW. Absorbance is measured by a spectrophotometer (Ocean Optics, SD 2000).

The instrument was calibrated with a solution of NH_4^+. We assumed a stripping efficiency of the sampling line of 100% due to the high solubility of ammonia and the very short inlet line of 5 mm without water. The detection limit reached was about 10 nM which corresponds to a gas phase mixing ratio of 40 ppt.

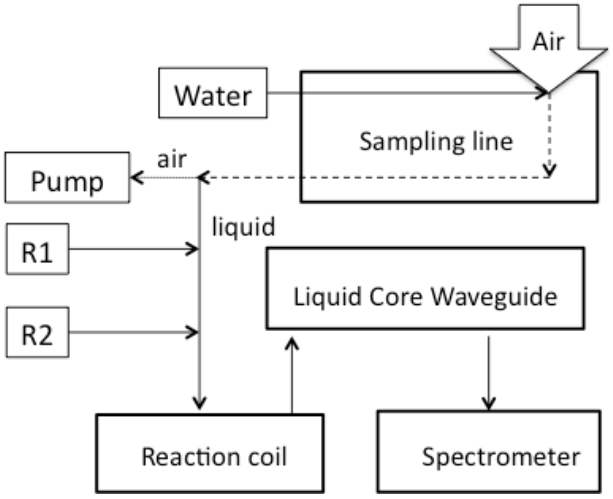

Figure 1. Scheme of the instrument. R1 and R2 denote the reagents phenol and hypochlorite.

We will present the ammonia measurements taken during two CLOUD campaigns. Based on these measurements it was possible to determine the nucleation rate of the system H_2SO_4, /H_2O/NH_3 as a function of different concentrations of ammonia inside the CLOUD chamber.

Acknowledgments: We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. Reduction of Iodate (IO_3^-) to Iodide (I^-) in seawater and recycling of Iodine (I_2) to the atmosphere by the uptake of Ozone (O_3): Links to new particles formation

Ravi Kumar[1,2], Samantha MacDonald[1], Russell W. Saunders[1], Benjamin J. Murray[2], and John M.C. Plane[1]

Iodine exists in open seawaters mainly in the inorganic forms iodate (IO_3^-) and iodide (I^-) (Wong and Zhang, 2008). While the concentration of IO_3^- predominates in deep water, I^- concentrations increase toward the surface. The primary precursor for iodine oxide particle (IOP) formation in the coastal marine boundary layer (MBL) is iodine (I_2) (Saiz-Lopez and Plane, 2006) originating from algae, but recent field measurements suggest that such biogenic iodine emissions cannot account for the observed levels of gas-phase iodine species (Read *et al.*, 2008). Recently, it has also been reported that oxidation of iodide (I^-) at the sea surface resulting from uptake of ozone (O_3) could enhance the emission of I_2 into the MBL (Sakamoto *et al.*, 2009). Thus, these studies indicate additional, non-biogenic global sources of I_2 from oceans which may contribute to IOP formation in the remote MBL.

We have conducted a series of experiments to investigate three potentially important processes likely to participate in the recycling of I_2 from seawater in the presence of sunlight: (i) the role of dissolved organic materials (i.e. humic acid), (ii) the effect of salinity (Cl^- concentration) and (iii) deposition and uptake of O_3.

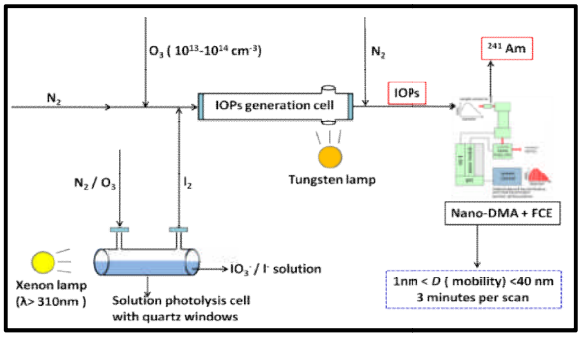

Figure 1. Schematic of experimental set-up used to study the reduction of IO_3^- to I^- and subsequent emission of I_2.

The experiments involved the initial photolysis of IO_3^- solutions with either humic acid or Cl^- added, or of an I^- solution with a flow of O_3 passing through the cell (see Fig. 1). The formation of I^- in solution (due to IO_3^- reduction) was detected using time-resolved UV-Vis spectroscopy. I_2 formation and release to the gas-phase was determined indirectly by its photo-oxidation in a second cell, leading to IOP formation and detection using a coupled differential mobility analyser (DMA) and Faraday cup electrometer (FCE) system.

Fig. 2 shows a series of UV-Vis spectra taken from a photolysed IO_3^- solution (photolysis time indicated in hours) to which humic acid had been added. The appearance of an absorption feature due to I^- at ~ 230 nm is evident.

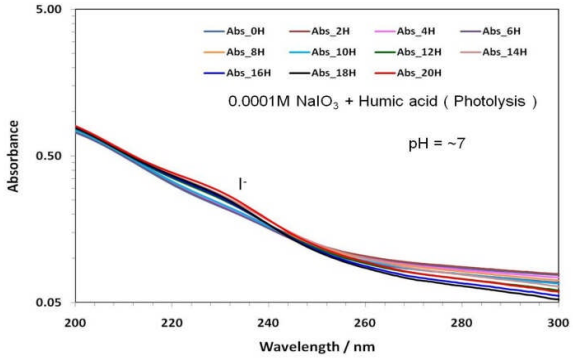

Figure 2.UV-visible spectra of a photolysed 10^{-4}M $NaIO_3$ solution (+ Humic acid).

The addition of Cl^- ions to the IO_3^- solution was found to enhance the formation of I_2 (deduced from increased IOP formation).

Finally, Fig. 3 shows the effect of O_3 uptake on a photolysed I^- solution, with increased I_2/IOP formation occurring as the O_3 concentration is increased.

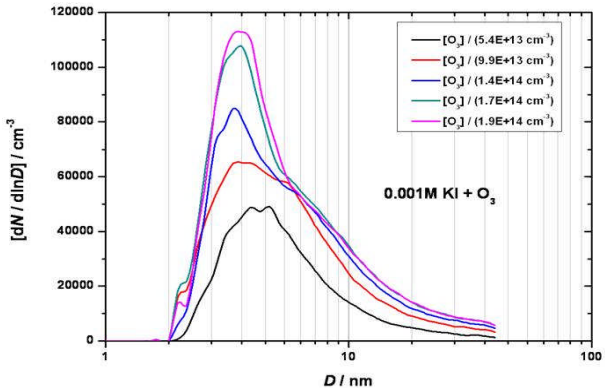

Figure 3. Iodine oxide particle (IOP) formation due to the uptake of O_3 by an I^- solution.

Coastal nucleation events: relation to atomic and molecular iodine concentration

Sorribas, M.[1], Mahajan, A.[2], Gómez-Martín, J.C.[2], MacDonald, S.M.[3], Gil, M.[1], Plane, J.M.C[3], Saiz-López, A.[2]

Bursts of ultrafine particles formed from gas-to-particle processes that grow to detectable sizes are called nucleation events. It has been observed at different environments (Kulmala et al., 2004), included the coastal areas around the world. When the new particles grow into CCN (cloud condensation nuclei) sizes by condensation and coagulation processes, they are able to influence over the direct and the indirect aerosol effects to the incoming solar radiation. Though many nucleation events have been observed, the key questions, such as what precursor gases form the particles and what produces the nucleation and the growth are unresolved.

Seaweeds, in particular the *Laminaria macroalgae*, have been directly related to new particle formation in coastal locations. When macroalgae is exposed to the solar radiation at low tide molecular iodine (I_2) is emitted to the atmosphere (Saiz-Lopez and Plane, 2004), subsequent photolysis and reaction of atmospheric ozone leads to the formation of iodine oxide (IO), which in turn reacts with itself to nucleate new particles (Saiz-Lopez et al., 2006).

In this work, we present the first observations of the ultrafine particles in the Northwest of Spain and the relationship of these observations with concurrent measurements of atomic iodine (I) and I_2.

Methods

Measurements were made at O' Grove, Galicia (42.50º N, 8.87ªW) on the Northwest coast of Spain as part of the "Laminariae Emissions in Galicia: Observation by fLuorescence and Absorption Spectroscopy" (LEGOLAS) field campaign, from 30th Abril to 7th May 2010 (Mahajan et al., 2010).

Continuous particle size measurements were simultaneously carried out by two subsystems monitoring different size ranges of dry particles. Particle number size distribution in the 9-407 nm range was measured using a Scanning Mobility Particle Sizer (SMPS) with 5 min time resolution. Total concentration for particles larger than 3 nm was measured by a second UCPC (TSI Model 3776). Although the lower size limits for the UCPC are not well defined, the difference in total particle number concentration between the UCPC and SMPS system is attributed to particles in the size range between 3 and 9 nm.

Concurrent measurements of I_2 and I were performed using a newly developed instrument based on the detection of molecular and atomic resonance and off-resonance ultraviolet fluorescence excited by lamp emission (Gómez Martín et al., 2011).

Conclusions

A correlation between I_2, I and ultrafine particles concentrations, and the tide was observed (see Figure 1) but the source of each one was not at the same location. Bursts in the number concentration between 3-9 nm were observed only during daytime and low tide on 5 days. The background concentration for ultrafine particles was 1700 cm^{-3} and the highest values were achieved with 18000 cm^{-3} on 2nd May during a nucleation event.

Sub-arctic nucleation events: Observation at ALOMAR Station, Norway

Sorribas, M.[1], López, J.F.[1] Fernández-Léon, M.[1], De la Morena, B.A.[1]

[1] 'El Arenosillo' Atmospheric Sounding Station, Atmospheric Research and Instrumentation Branch, National Institute for Aerospace Technology (INTA), Mazagón, Huelva, 21130, Spain
Keywords: atmospheric aerosol, climate, homogeneous nucleation, coastal particles
Presenting author email: sorribasmm@inta.es

Atmospheric particulates contribute to light absorption and scattering solar radiation, cloud formation and they are a key in the global climate system. Important contributions to atmospheric particle number concentration are made by homogeneous nucleation of supersaturated vapours. The feedback of this size range on global climate is highly uncertain, although potentially large and opposite of the warming effect of greenhouse gases.

Climate change is proceeding fastest at the high latitudes of the Arctic region because it is an extremely clean area. Its impact can be able to produce serious worldwide consequences and then, it is a region where a better understanding of the processes leading to climate change is the most urgently needed. POLARCAT (*Polar Study using Aircraft, Remote Sensing, Surface Measurements and Models, of Climate, Chemistry, Aerosol, and Transport*) is a coordinated international programme of measurements and modelling to quantify the impact of the diverse atmospheric components over the Arctic, to study the pollutant deposition and climate change in the region. In this framework, an intercomparison and an intensive measurement campaign for aerosol characterization were carried out during summer 2008. The aim of this work is to show the first results and conclusions about different aerosol parameters at ground level surface, during some nucleation events.

Methods

The ALOMAR Station is situated in And∅ya Island (69º16'N, 16º00', 380 m.a.s.l), on the North Atlantic coast of Norway. From June to July the sun is 24 hr above the horizon and the climate is very warm during the entire year because this area is influenced by the Gulf Stream.

Sampling aerosol system was designed by INTA following the general recommendations for the Reynolds Number and the system geometry. Thus, in-situ aerosol measurements were carried out 1 m above the top of the main building with a flow rate of 87 $lmin^{-1}$ and *Re* 6240, using a vertical stainless steel tube (19 cm inner diameter and 300 cm length). A splitter was situated in the end with three different outs which had different diameters to provide aerosol flow with laminar conditions to the different instruments. Sampling system efficiency was calculated, resulting in an efficiency of about 50% for 7.0 μm particle and 98% for 16 nm particle. Sampling effects were corrected for data processing. A heating around the principal tube was situated in order to control the relative humidity of the sample aerosol below 40%.

Dry ambient particle number size distributions within the size range (3 – 10000) nm were monitored with a UCPC (TSI – Model 3776), a SMPS spectrometer (TSI - Model 3936) and an APS spectrometer (TSI – Model 3321). Finally, an integrated nephelometer (TSI – 3563) with three wavelengths measured the scattering and backscattering aerosol coefficients.

Conclusions

Number concentration was calculated for (0.003-10) μm size range with 2340 cm^{-3} and mean modal concentration were 1400 cm^{-3}, 300 cm^{-3}, 670 cm^{-3} and 330 cm^{-3} for the nucleation 1, nucleation 2, Aitken and accumulation modes respectively. The concentration for nucleation modes presented high variability due to the very frequent nucleation mechanisms. There were 13 observations that show new particle formation over the Andøya Island which had a long life until 14 hours, increasing the concentration for Aitken mode as well as for accumulation mode during the last hours. Some new particle formation happened even when the previous event was not finished. Then, new particles became optically actives and its influence over the scattering mechanism will be presented.

Particle formation rates were evaluated by dividing an increase of the number concentration for nucleation mode, (size ranges: 3-14 nm and 3-30 nm) by the elapse time. They were mostly within the range (1-7) cm^{-3} s^{-1}. Particle growth rate was evaluated considering a closely linear fashion with time. Then, the range of growth rates spanned (3-10) nm h^{-1}. The maximum diameter was ranged from 26 nm to 107 nm.

Nucleation events have been investigated in terms of meteorological parameters, air-mass conditions, different metrics of the particle size distribution and the scattering coefficient.

This work was supported by a Complementary Action (CGL2007-29842-E/ANT) and Research Project (CGL2008-05939-C03-03/CLI) of the Spanish Ministry of Science and Education.

New parametrization of SOA formation from anthropogenic VOCs for the CAMx model

O. Vlček[1], T. Svendby[2] and L. Corbet[1]

[1] Czech Hydrometeorological Institute, Na Šabatce 17, Praha 4 – Komořany, 143 06, Czech Republic
[2] Norwegian Institute for Air Research (NILU), P.O. Box 100, N-2027 Kjeller, Norway
Keywords: SOA (Second. Organic Aerosols), particle formation, m-xylene, CAMx, Europe.
Presenting author email: vlcek@chmi.cz

Formation of the secondary organic aerosols (SOA) from its volatile organic compound (VOC) precursors is a very complex process and different parametrizations are used for its description. The formation is often described in terms of the fractional mass yield, $Y = \Delta M_0 / \Delta VOC$, where ΔM_0 [$\mu g \cdot m^{-3}$] is the mass concentration of SOA produced from the reaction of ΔVOC [$\mu g \cdot m^{-3}$]. Yield Y is very sensitive to the outside temperature, PM concentration and also NOx concentration. Svendby *et al.* (2007) reviewed SOA formation experiments and proposed a new parametrization of the SOA formation among others from m-xylene and toluene, which should be more realistic for the low temperature conditions and which should also reflect high constant yield under the low NOx conditions according to Ng e*t al.* (2007). Parametrization of the anthropogenic SOA formation in the Eulerian photochemical dispersion model CAMx was changed according to the new one (Svendby and Bartonova, 2010). Experiments for the summer 2008 and winter 2008/2009 were performed to assess the effect of the new parametrization.

Model CAMx v5.2 was used for the experiment. Aerosols were modeled in the fine/coarse mode within the chemistry mechanism SAPRC-99. **Modeling domain** consisting of 309 x 277 cells was covering Central and South Europe and also parts of the West and East Europe with horizontal resolution of 9 km. Its vertical extent was 16 levels with the average hight of the first level 15 m AGL and of the last level 8 – 9 km AGL. Input data were supplied with 1 hr time step. **Meteorology** was provided by the NWP model ALADIN/CE (version CY35T1star). Its assimilation cycle consisted of the analysis followed by 6 hr forecast at 0, 6, 12 a 18 hr UTC. **Anthropocentric emissions** corresponding to the year 2006 were prepared by the emission model developed by B. Krüger from Universität für Bodenkultur Wien. They were based on the EMEP inventory with resolution of 50 km. For Austria, the Czech Republic, Hungary, and the Slovak Republic more detailed emissions of ozone precursors were used. EMEP emissions included a group of XYLA = ARO2 – which is a precursor of the anthropogenic SOA (Environ, 2010). Normalized **biogenic emissions** of isoprene and monotermene were based on the merged AFOLU and USGS databases with a resolution of 1km (Zemánková, 2010). They were further processed by the version 3.12 of SMOKE-BEIS3 model.

Increase in the average concentration of the anthropogenic and biogenic SOA was observed mainly during the summer. However for the biogenic SOA it was much more moderate. Modeled gas species remained without any significant change. The results will be compared against station measurements to see if the modified parametrization brought better agreement between the modeled and observed time series.

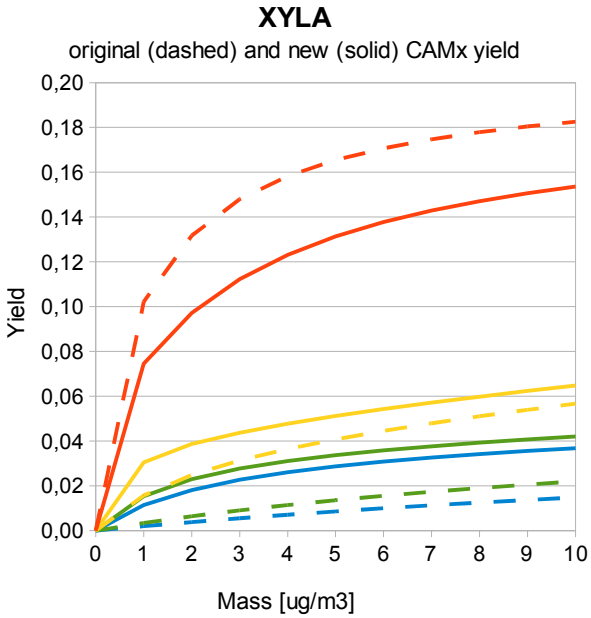

Figure 1. Comparison of the m-xylene yield functions currently used in CAMx 5.2 (dashed) and with a new parametrization (solid). The lowest curve is for 310 K then curves for 303, 283, and 250 K follow. The concentration of already formed aerosols is on the bottom axis.

Atmospheric Aerosols – Specific Aerosol Types

Digital visibility quantification for atmospheric environment with a Harris corner detector

C.-H. Luo[1,*], C.-Y. Wen[2], K.-H. Lin[3] and S.-H. Chiu[3]

[1]Department of Safety, Health and Environmental Engineering, Hungkuang University, Taichung, 43302, Taiwan
[2]Department of Forensic Science, National Central Police University, Taoyuan, 33304, Taiwan
[3]Department of Materials Science and Engineering, National Taiwan University of Science and Technology, Taipei, 10607, Taiwan
Keywords: atmospheric visibility, image processing, visual environment, corner detection.
Presenting author email: andyluo@sunrise.hk.edu.tw

Atmospheric clarity presents the visual quality of the atmospheric environment and is detected by visual range or optical measurements. The regular visibility measurement in a meteorological station is to focus on whether selected targets in a concerned area can be identified by eyes of trained observers. Recently technological improvement in atmospheric visibility measurement is digital image processing applied to real time and on-line visibility detection and confirmed as a useful tool (Luo, et al., 2005; Luo, et al., 2011). The blurred image of a landscape is related with visibility impairment and implies that atmospheric degradation and visual contamination happen, because of adverse meteorological conditions and severe pollution events, such as anthropogenic exhaust, dust storms, and wildfires.

A digital image of atmospheric environment acquired in the field acquisition provides the data for space dimension and digitized brightness which are employed in the $M \times N$ matrix (Petrou and Bosdogianni, 1999). The value in the matrix function is a pixel that presents the digitized brightness at any location of (x, y). The details of the site and equipment setups for this investigation can refer to Luo, et al. (2005). The visibility targets were orientated with GPS. The distance between the targets and site ranges from 3.0 to 14.5 km.

In digital image processing and computer vision, corner can be used in the investigation of shape analysis, pattern recognition, picture matching, data compression, motion analysis and so on. For atmospheric environment, the corners contain important information about the visibility targets. The Harris corner detection algorithm (Harris and Stephens, 1988) is used to detect object corner through the autocorrelation matrix and differential operators which can reflect the gray change of every pixel in any direction. Given a sift (Δx, Δy) around the pixel (x, y), a auto-corelation function is first defined:

$$c(x,y) = \sum_{W} [I(x_i, y_i) - I(x_i + \Delta x, y_i + \Delta y)]^2 \quad (1)$$

The $I(x_i, y_i)$ denotes the intensity on pixel (x_i, y_i). $I(x_i+\Delta x, y_i+\Delta y)$ can be aprrximated using a Taylor expansion. Second, the gradients along x- and y-direction are presnted, respectively. Finally, a 2×2 matrix, **H**, and two eigenvalues of the matrix **H**, λ_1 and λ_2, are evalulated. According to an Harris emprical formula, the corner response (R) is used to solve the eigenvalues of **H**.

The Harris corner detection operator needs to apply a Gaussian smoothing window. A larger Gaussian smoothing window makes the location of the corner have a greater offset. A corner is defined as detectable while eigenvalues of related **H** are large enough. Corner points in an image are defined as the intersections between detected targets and surrounding background.

The corner detection results showed that the number (c) of detectable corners increased when visual range (v) enlarged. A good correspondence (R^2= 0.8129) between c and v is shown in Figure 1. A larger value of the digital index, c, appears for better atmospheric visibility. It was confirmed that the camera-computer system equipped with a Harris corner detecting programs has the potential to record a visibility investigation in real-time.

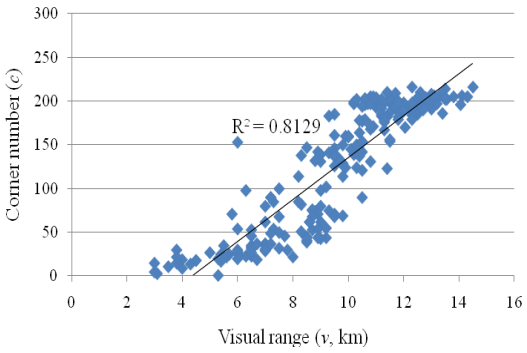

Figure 1. Relationship between the corner number and visual range measured by trained observers.

Abstract
New atmospheric particle formation above coniferous forests has been observed for many years. Nucleation events have been detected predominantly at daytime with maxima during May and August, while night-time events occur less frequent with their maxima shifted towards winter, thus cooler and cleaner periods. A link to biogenically emitted terpenes has been reported at least for the growth process of ultrafine particles to cloud condensation nuclei sizes. However the origin of newly formed particles is intensively discussed, i.e. either sulphuric acid initiated or biogenically initiated. This presentation summarise the current findings at a Central German spruce forest site (Taunus Observatory, 810 m a.s.l.). A potential explanation by a new organic nucleation pathway and its implications for climate feedbacks will be explained and discussed.

Methods
(Experimental) Particle size distributions have been recorded at Taunus Observatory (50°13'25" N, 8°26'56" E) by an SMPS (TSI 3936) since spring 2008 (9.8 nm < D_p < 422 nm). Ambient and emission volatile organic compound (VOC) measurements were performed in October 2010 using a high sensitivity PTR-MS (Ionicon) accompanied by sample GC-MS analysis of individual mono- and sesquiterpene contributions. Meteorological parameters have been measured continuously by the HLUG in 30 min averaged intervals.
(Theoretical) Based on nucleation event classification criteria, non-event and event conditions have been intercompared and correlations with measured trace gases, meteorological parameters and sinks computed.

Findings – A. Nucleation events and correlations
As found earlier by Hyvönen *et al.* (2005) for Hyytiälä (Finland) daytime nucleation is positively correlated with temperature, solar radiation and ozone and negatively correlated with condensation sink, water vapour and sometimes pollution. During night-time the situation is mainly linked to dropping ozone and high NO_2 values and higher temperature.

Nucleation mechanism assumed
Based on laboratory investigations of new particle formation by alkenes and ozone, a new organic nucleation mechanism can be postulated: Sesquiterpenes react with ozone forming a nucleation inducing molecule that is activated by large RO_2 radicals produced by monoterpenes and OH. Subsequently, the partitioning of VOCs causes particles to grow to CCN sizes.

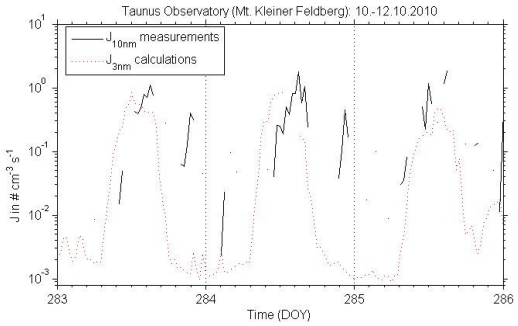

Figure 1. Nucleation rates calculated (dashed line) and measured (solid line) using OH only (day). The observed time shift is caused by different particle sizes and growth time in between.

B. Organic nucleation proposed
Applying the potential organic nucleation mechanism, new particle formation can be explained for October. However, chemical analysis of these particles is currently impossible. It is interesting to note that a change in sesqui- or monoterpene composition with different reactivities for ozone and OH, can remarkably affect the calculated nucleation rates. Moreover, the presence of isoprene can act as nucleation suppressive, since it scavenges OH.

C. Biosphere climate feedbacks
Apart from the changes in biomass, leaf area index and thus albedo and transpiration increase with increasing temperature making the air more humid. However the relative increase in water vapour per Kelvin is very similar to the rise in ozone. Consequently, the emission and the reactions of terpenes are potentially the key to understand particle formation under a future, warmer climate [Bonn *et al*., 2009]. Once particles are formed they partially grow by the uptake of semi-volatile vapours to CCN. Comparing the situation before and after a nucleation event an increase of CCN by a factor between 1.1 and 4 has been observed. This affects the radiation balance at the Earth's surface to compensate about 25% of the warming at maximum partially supporting the biosphere to survive.

Keywords: volcanic particles, elemental composition, aerosol evolution, stratospheric aerosol

Introduction

Major volcanic eruptions inject gases and particles deep into the atmosphere. Measurements of atmospheric aerosols by the CARIBIC (Civil Aircraft for Regular Investigation of the atmosphere Based on an Instrument Container) platform following the Kasatochi (Alaska), Sarychev (Russia) and Eyjafjallajökull (Iceland) eruptions in the period 2008-2010 (all with VEI4) are presented. After the eruption of Kasatochi, analyses of the stratospheric aerosol composition showed enhanced concentrations of sulfur and carbon for several months. On the other hand the ash component, which could clearly be seen in a sample seven days after the eruption, was not detected a month later (Martinsson et al., 2009). To further investigate the composition of the volcanic aerosol three flights trough the volcanic plume of the Eyjafjallajökull eruption were performed. The CARIBIC platform operates on a Lufthansa passenger aircraft usually on inter-continental flights, measuring the atmospheric composition in the UT/LS at 8-12 km altitude once per month (Brenninkmeijer et al., 2007). Instruments on the platform perform aerosol sampling for chemical characterization and particle number concentration measurements. The CARIBIC data set also includes meteorological information and measurements for mixing ratios of a large number of trace gases.

Methods

Specific flights bringing the CARIBIC platform through the volcanic ash cloud from the Eyjafjallajökull eruption were carried out on April 20, May 16 and May 19, 2010. Aerosol samples were collected by an impaction technique with a cut off diameter of 2 µm (Nguyen et al., 2006) and analyzed by quantitative multi-elemental analysis by PIXE (Particle-Induced X-ray Emission) to obtain concentrations of elements with atomic number larger than 13. Also PESA (Particle Elastic Scattering Analysis) was used to obtain elemental concentrations for hydrogen, carbon, nitrogen and oxygen (Nguyen and Martinsson, 2007).

Results and Conclusions

Three samples taken during the special flights to study the Eyjafjallajökull eruption contained unusually high concentrations of elements pointing to crustal origin. The composition of these samples was compared to ash from a fall out sample (Sigmundsson et al., 2010). The ratio of detected elements to iron in both sample types shows good agreement for most of the elements for all three aerosol samples (Fig.1). The deviation in content of potassium (K) and Zirconium (Zr) could be caused by fractioning in concentration between different sizes of aerosol due to degassing of these elements from the magma followed by condensation onto aerosol particles. The composition is compared to earlier stratospheric samples influenced by the Kasatochi and Sarychev eruptions, and the evolution in time of the volcanic influence on aerosol after eruptions is investigated.

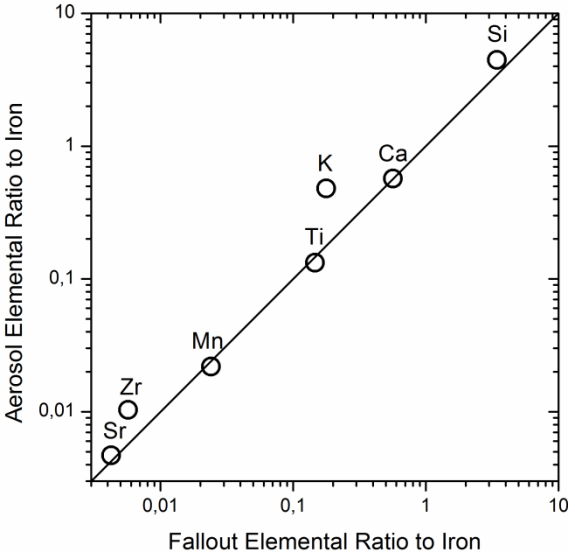

Figure 1. Geometric mean of elemental ratio to iron in aerosol samples collected by the CARIBIC platform vs. fall out sample (SRG 5a, Sigmundsson et al., 2010). The solid line indicates equal ratio.

One of the most important properties of the polar remote aerosols is their size distribution, giving valuable information on the source of these aerosols and on the atmospheric processes modifying their properties during atmospheric transportation. The size distribution and the chemical composition play also a crucial role in the interaction aerosol-solar radiation, in the properties of clouds and how they affect the long-range transport and deposition pattern of anthropogenic pollutants over the polar areas.

We report here the preliminary result on size distribution and bulk chemical composition of Arctic aerosol sampled at Ny Ålesund (Svalbard Islands, Norway) and Thule (North Greenland) in March – September 2010.

Svalbard Islands (Norway), located in the northernmost point yet influenced by the warm West Spitsbergen Current, are an ideal location to study the interaction between the climate changes and the atmosphere, ocean and land variations. In particular, Ny Ålesund (78.6°N, 11.6°E) is a site where international cooperation ensures the continuous study and monitoring of a large number of physical and chemical key-parameters characterizing the Arctic ecosystem. During the 2008-2010 period, two relevant scientific platforms were built in the framework of the CNR CCT-IP (Integrated Project Climate Change Tower) and PRIN07 "Dirigibile Italia" scientific projects: a 34-m high tower, with meteo probes and photometers (up-welling and down-welling radiation) distributed on 5 levels, and an observatory (Gruvebadet) for aerosol measurements and sampling.

During the 2010 campaign, the measurement of physical, optical and radiative properties of snow and aerosol in the PBL were coupled with an intensive sampling of size-segregated aerosol particles, by several kinds of impactors and at different time resolutions. The aerosol particles size distribution was carried out by using SMPS (Scanning Mobility Particle Sizer), working in the range 6 - 500 nm, and APS (Aerodynamic Particle Sizer), able to count the atmospheric particulate in the range 0.5 – 20 um. The two instruments were synchronized in order to obtain a unique spectrum of 106 size-classes in the range 6 nm – 20 um every 10 minutes.

Aerosol sampling was carried out by several collectors: a PM10 sampler (24 h resolution) with Teflon filters, for ions and metal determination; a 4-stage impactor (4-days resolution) with polycarbonate (>10, 10-2.5, 2.5-1 um fractions) and Teflon (< 1 um) filters, for ions and metal size-segregated analysis; a 12-stage impactors (4-days resolution) with polycarbonate filters, for elemental characterization by PIXE analysis; a TSP medium-volume collector with quartz filters, for EC and OC measurements.

Chemical composition have been compared with the high-resolution particle size-distribution, meteo conditions, back-trajectory reconstruction and statistical analysis (Positive Matrix Factorization and Absolute Principal Components Analysis) for source apportionment and to understand changes in source intensity and transport processes during the March-September 2010 period.

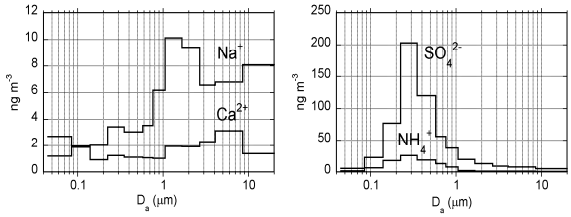

Figure 1. Size distribution of sea salt (Na^+), crustal (Ca^{2+}) and secondary (SO_4^{2-},NH_4^+) markers in an aerosol sample collected in march 2010 at Ny Ålesund.

In parallel with the scientific activity in Ny Ålesund, a PM10 sampling campaign was carried on at Thule (76.5°N 68.8°W), Greenland. In the same site, measurements of optical properties and vertical distribution of atmospheric aerosol (by LIDAR) have been also carried out.

This wide data set will help to clarify origin, transport and deposition of aerosol particles in the Arctic and their relationships with the optical atmospheric properties and the PBL dynamics.

Presenting author email: silvia.becagli@unifi.it

Aerosol studies carried out at internal sites of Antarctica are focused in improving our knowledge on present-day source intensity, transport efficiency and atmospheric pathways (including stratosphere-troposphere interchanges) of atmospheric particles reaching these remotes sites. Understanding the properties and behaviours of Antarctic aerosol is essential in the study regarding the cycles of natural compounds as well as in the interpretation of past climate based on Antarctic ice core data. Chemical aerosol measurements in Antarctica are sparse and mainly confined to coastal areas (e.g. Minikin et al. 1998, Legrand et al. 2001, Jourdain and Legrand 2002), on the contrary very few aerosol data are related to central Antarctic regions.

Size-segregated aerosol and surface snow samples have been collected at Station Concordia (Dome C - East Antarctica, 75°06'S, 123°23'E, 3233 m a.s.l., about 1100 km far from the coastline), in the framework of an Italian PNRA-French IPEV joint program, by using different low- and medium-volume systems, including pre-selected cut-off samplers (PM10, PM2.5 and PM1) and multi-stage impactors.

All-year round aerosol collection for a long period (so far, covering the 2005-2009 period) allowed reconstructing the seasonal trends of the size-distribution and the chemical composition of aerosol particles, as well as investigating their main sources and transport processes. In particular, sea spray, crustal, biogenic and tropospheric (photochemistry) sources were identified by chemical markers. Besides, meteo conditions on synoptic scale and back-trajectory analysis were used in order to understand atmospheric processes leading to abrupt high concentration levels of specific aerosol components.

The chemical analysis of size-segregated aerosol and daily superficial snow samples can contribute to clarify some aspects yet under discussion. In particular: the possible seasonal pattern of sea spray aerosol could be related to sea ice formation timing and/or to changes in zonal wind intensity and atmospheric pathway; the mineralogical analysis of insoluble dust particles can allow the identification of continental sources, by comparison with soils collected in the potential source areas (PSAs); finally, the seasonal pattern of biogenic markers (such as methanesulphonic acid and non-sea-salt sulphate) can be linked to sea surface temperature, sea-ice cover and southern-hemisphere circulation modes (e.g., SOI, AAO or SAM and ACW). Indeed, oxidised sulphur compounds deserve a particular attention because they are assumed to affect the climate system by influencing the Earth's radiative budget, both directly (solar light scattering) and indirectly (acting as cloud condensation nuclei). Methanesulphonic acid (MSA) and H_2SO_4 (from DMS phytoplanktonic emission), are the best tracers of marine productivity. Their use as reliable markers of oceanic biogenic emissions is hindered by poorly known mechanisms (temperature and photochemistry induced) controlling the MSA-H_2SO_4 ratio from DMS. Since DMS in route toward central Antarctica is subjected to lower temperatures and lower humidity and, in summer, to larger atmospheric concentrations of OH (and/or BrO) radical, all conditions promoting the preferential H_2SO_4 formation, non-sea-salt sulphate is the most reliable biogenic marker at Dome C. Depositional and post-depositional processes, able to potentially modify in the time the snow composition, were also investigated. The analysis of chemical markers in aerosol, superficial snow and hoar crystals, sampled contemporaneously, allowed evaluating the contribution of some key-factors (snow acidity, solar irradiation) affecting the preservation of components reversibly fixed in the snow layers (such as, for instance, MSA, nitrate and chloride).

The study of the changes in source intensity, atmospheric processes and transport pathways of the present aerosol at Station Concordia will allow improving our understanding on past climatic and environmental changes, through ice core stratigraphies of aerosols components trapped in the snow layers by atmospheric scavenging processes. These studies will deserve particular relevance for the interpretation of the chemical records along the EDC ice core, drilled in the framework of the EPICA project.

Understanding of the free tropospheric aerosol is important in the investigation of transboundary and interhemispherical contribution to local air pollution. The Global Atmosphere Watch (GAW) station is located on the northern western slopes of Mt Kenya (Fig. 1). It is on the equator at 37^0 E at altitude 3700 m and has free view in all directions thus offering a good site for free troposheric aerosol characterization (Henne et al 2008). Gatari et al (2009) reported high elemental concentrations of Ca, Fe and K in all analyzed $PM_{2.5}$ and PM_{10} samples implying high mineral dust in the aerosol. However the local soil dust influence due to the mountain winds was not assessed. This study was therefore designed to assess the contribution of long-range transported mineral dust and local contribution through mountain winds.

In August 2009 two cyclone samplers (BGI 400 personal samplers) and an Andersen dichotomous impactor were used to sample $PM_{2.5}$ and size segregated PM_{10} respectively. In August 2010 the measurements were repeated and an aerosol monitor (TSI model 8530 DUST TRAK II) fitted with a $PM_{2.5}$ sampling head was included. The measurement reported here were from 10 day field campaign at the GAW station which included random collection of top soil samples from the area.

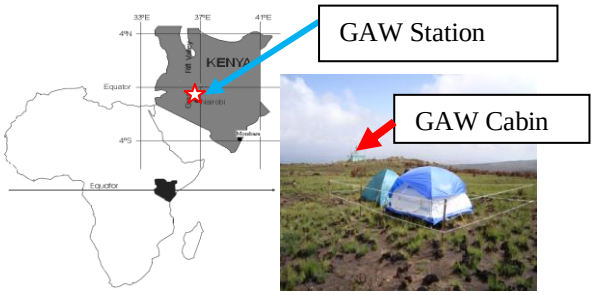

Figure 1. The location of Mt Kenya in Kenya in Africa

Teflon filters (Pall R2PJ037) were used in all the samplers. The monitor gave real time readings and particles on its internal filter. All the filter samples from all the instruments were analyzed for elemental content using EDXRF. The soil samples were analyzed for particle size distribution using a Laser particle diffraction analyzer (LPDA) (Horiba model LA-950V2), and for soluble and insoluble elemental content by TXRF (Bruker model AXS S2 PICOFOX). A digital microbalance (Mettler model MT5) was used for gravimetric determination of the filter collected PM. The LPDA uses Mie theory and its measurements are in equivalent spherical particle diameter (Eshel et al 2004).

The mean $PM_{2.5}$ concentration was 10 µg m^{-3} out of which 22 % was nighttime contribution on average. The elemental concentrations of Ca, Fe, K and Ti were 50 ± 29, 50 ± 12, 31 ± 2, 4 ± 1 g kg^{-1} in the particulate aerosol, respectively and 5 ± 0.005, 42 ± 0.01, 5 ± 0.006, 8 ± 0.005 g kg^{-1} in the top soil. These results and in addition the small available percentage of $PM_{2.5}$ particles in the top soil implied negligible contribution of Ca and K bearing particles to the aerosol while Fe and Ti was substantial. The study also showed high daytime contribution of mineral dust and that which is from long range transport as a major component that needs further investigation besides other aerosol components.

Atmospheric Aerosols - Aerosol Processes and Properties

In-situ aircraft observations on gases and particulate pollutants around Beijing area: distributions and influencing factors

W.J. Zhang[1*], Z.P Bai[1], J.Z. Ma[2], J.H. Chen[1], W. Yang[1], B.H. Yin[1]

[1]Chinese Research Academy of Environmental Sciences, Beijing, 100012, China
[2] Chinese Academy of Meteorological Sciences, Beijing, 100081, China
Keywords: Aircraft measurement, Gaseous pollutants, Particles, Back trajectory
Corresponding author email: zhangwj@craes.org.cn

At present, the air pollution around Beijing area has become a complex problem with a combination of different types of sources: coal smoke, traffic emission, dust re-suspension, and so on. Additionally, the transport of particulates seems to be a large-scale regional pollution. It is of great value to conduct aircraft measurements of pollutants at different altitudes (Wang et al., 2008).

In-situ measurements of gaseous pollutants, including ozone (O_3), sulfur dioxide (SO_2), nitrogen oxides (NO_X = NO + NO_2), carbon monoxide (CO), particle concentration (5.6-560 nm and 0.47-30 μm), and related meteorological information (T, RH, P) were conducted around Beijing area during Sep. 17-Oct. 7 in 2008. A two-engine light aero-transport YUN-12 (made in China) was used. The flight altitude ranged from ground to 4000m with the central point of Gucheng (N39°08′, E115°42′) in Hebei province around 5~15 km range, and the cruising velocity was generally kept at about 180 km h^{-1}. The total effective flight time was 23 h with 6 flights. This measurement was to characterize the regional variation of air pollution during and after the Olympics of 2008, the impacts of different transport direction and possible influencing factors.

Results suggested different characteristics of different gaseous pollutants and particles. (1) The meteorological factors showed significant influences for all the pollutants, as shown different pollutant levels at the ground level for different flights. (2) SO_2, NO_X, and CO showed highest concentration at the ground level, and decreased with the increasing of the height. It suggested the characteristics of major sources from ground emission for these gaseous pollutants. Figure 1 showed the variation of gaseous pollutants on flight Oct. 2 as an example. (3) Two different characterization of O_3 variation was obtained. It includes: ①similar variation with other gases, highest at the lowest altitudes, indicating the effects of ground emission sources; ② lowest concentration at the ground level, and increasing with the increase of altitudes until to 3000 m. For the O_3 variation above 3500 m, it showed similar range of 43~53 ppb at all flights, indicating the regional pollution level at high altitudes. (4) Backward trajectory analysis showed different transport direction of air masses, i.e. the pollutant transport of the southern direction with higher pollutants level; the cleaner long-range transport of the northern or northwestern direction with lower pollutants level; the transport from the eastern direction with characteristics of sea sources, i.e. middle level of gases pollutants and higher particle concentration; the transport of mixing directions, i.e. lower altitudes from the pollutant transport direction or local pollution but higher altitudes from the clean transport direction. (5) Coarser particles (0.47-30 μm) showed peaks of 0.6~0.8 μm, and highest in the ground level, and decreased abruptly with the increasing of heights, as Figure 2 showed. (6) For the ultrafine particles, the size distribution showed bimodal or multiple peaks variation, and concentrated on 10 nm and 20~100 nm. While, no obvious peaks were observed above 200 nm in the 5.6~560 nm range.

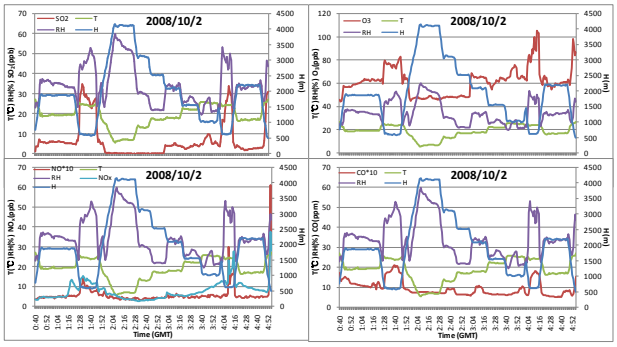

Figure 1. Variation of gaseous pollutants with meteorological factors and height on the flight of Oct. 2.

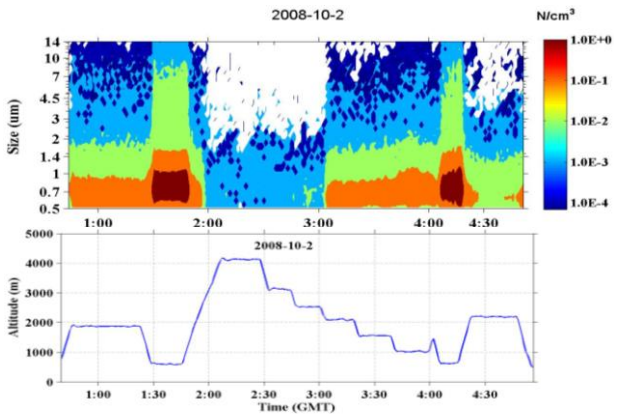

Figure 2. Variation of coarser particles with heights on the flight of Oct. 2.

SMPS spectra under various meteorological conditions

N. Zikova[1.2], V. Zdimal[1], J. Smolik[1]

[1] Department of Aerosol and Laser Studies, Institute of Chemical Process Fundamentals of the AS CR, v.v.i, Prague, 16502, Czech Republic (ICPF)
[2]Department of Meteorology and Environment Protection, Charles University in Prague, Prague, 180 00, Czech Republic
Keywords: atmospheric aerosol, particle size distributions, meteorology
Presenting author email: zikova@icpf.cas.cz

Particle size distributions (PSD) of atmospheric aerosols have been studied extensively due to the confirmed influence of aerosols on global climate, aerosol – clouds interactions, atmospheric visibility, human health etc. (Kerminen *et al* 2005; IPCC, 2007; Wichmann *et al*, 2000). Strong feedback mechanisms of the atmosphere acting on PSD have been found as well (Mikkonen *et al*, 2011). To evaluate these feedbacks, it is necessary to describe a connection between individual meteorological phenomena and atmospheric aerosol.

The variety of measured meteorological variables able to alter or adapt aerosol PSD in its shape or amplitude is wide. But their contributions vary a lot. The most important characteristics, besides temperature, radiation and wind speed, are relative humidity (RH) and precipitation amount (Zikova *et al*, 2010). This work describes first results of categorization of aerosol PSD according to the various meteorological conditions connected to atmospheric humidity.

The data were collected during the first 22 months of measurements from 05/2008 to 02/2010 at Observatory Košetice located in the Czech Highlands (49°35'N, 15°05'E, altitude 534 m). This background station, operated by the Czech Hydrometeorological Institute, specializes on environmental quality monitoring but is also a part of the national professional meteorological measurement network. Recently, the observatory became a part of the EUSAAR network and was equipped by the IfT-SMPS run by ICPF.

SMPS was sampling every 5 minutes over mobility size range from 9 to 900 nm. Data were averaged according to the EUSAAR standards into one hour intervals. Cumulative concentrations up to 30, from 30 to 50 nm, from 50 to 100 and above 100 nm were computed along with total concentrations. Results were compared to the standard meteorological data (RH, precipitation amount and temperature) and professional observer's records taken simultaneously in one hour time resolution describing the character of weather at the station and types of precipitation. Then, typical SMPS spectra were derived.

Bimodal distributions are typical for very dry conditions (Fig. 1). With the growing RH, particles under 50 nm in diameter are most effectively removed or grown into the accumulation mode. Above 60% RH, the accumulation mode particles' concentrations increase, reach maxima around 80 % RH, and then start to drop again.

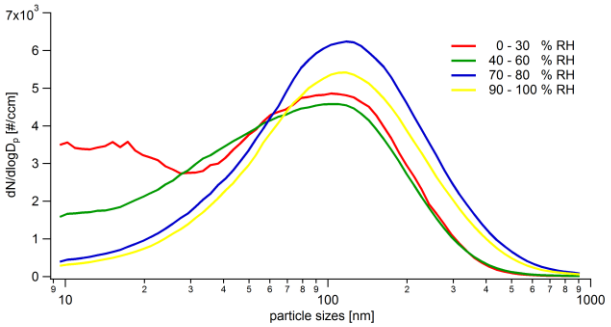

Figure 1. Averaged particle number size distribution for different amounts of atmospheric relative humidity. The fog or precipitation events were removed. (IfT SMPS, Košetice station).

During foggy days, no bimodal distributions had been recorded with concentrations being well below average (Fig. 2).

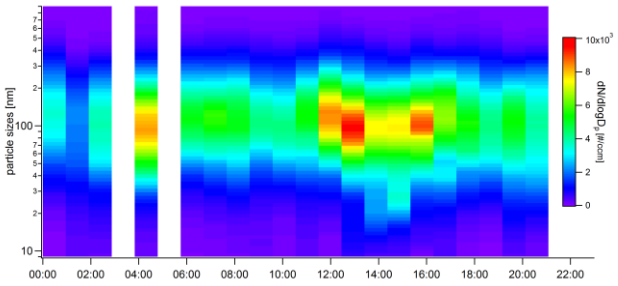

Figure 2. Typical particle number size distribution for a day with a fog recorded in every hour. Averaged from the real measured data in individual hours of the day. (IfT SMPS, Košetice station).

Introduction

Atmospheric aerosols have significant but highly uncertain impacts upon both the climate and human health. The quantification of these impacts requires the development of novel technological applications, owing to the complexity and diversity of atmospheric aerosol components. Both inorganic and organic material can transfer between the gas and particle phase. Inorganic material is restricted to a few well-understood compounds; but the organic component can comprise many thousands, as yet largely unidentified, compounds with a vast range of properties.

Predicting the evolution of aerosol requires calculation of the distribution of all components between the gas and aerosol phase according to equilibrium absorptive partitioning or disequilibrium mass transfer. Either treatment requires knowledge of all component vapour pressures and other thermodynamic properties. Furthermore, the physical properties of aerosol particles that determine their climatic impacts require detailed knowledge of fundamental properties of all components. The many thousands of individual organic aerosol components ensure that explicit manual calculation of these properties is impractical. The emergence of explicit automatic mechanism generation techniques (Aumont, et al., 2005**)** including up to many millions of individual gas phase products as aerosol precursors renders the process impossible and automation is necessary.

In this presentation we present development of a chemical informatics suite that will enable prediction of key properties of components in complex aerosol which can then be used to predict bulk aerosol properties for comparison with atmospheric analytical techniques.

The model system

The software is written in PYTHON. This high-level language is widely used as a scripting language for web applications. It supports both fixed-point and floating-point numeric calculations, string manipulation and facilities for structures and arrays. It is distributed under a permissive free software license and is available for all major operating systems, which will enable our software to be highly portable. Also, a PYTHON interface has been developed for our selected chemical parsing software (OpenBabel)(O'Boyle et al., 2008).

The Automated extraction of molecular substructure information is performed using the SMILES format (**S**implified **M**olecular **I**nput **L**ine **E**ntry **S**ystem) for the target molecule. SMILES is a simplified chemical notation that allows a user to represent a two dimensional chemical structure in linear textual form. The notation is commonly employed in commercial and public software for prediction of chemical properties. It can be imported by most molecule editors for conversion into 2D/3D models and has a wide base of software support and extensive theoretical backing (see www.daylight.com).

The 'OpenBabel' chemical toolbox has the ability to filter and search molecular files using the SMARTS format (created by Daylight Chemical Information Systems, Inc alongside the SMILES format) (figure 1). Prediction of specific properties such as pure component vapour pressures requires development of bespoke SMARTS libraries. For example, SMARTS libraries have been initially designed for a set of vapour pressure models using the 2742 compounds within the master chemical mechanism (MCM; Jenkin et al., 2003).

Example applications

Examples will be given to illustrate how this approach reduces problems associated with currently available parsing tools within the community. Extensions to a wider set of atmospherically relevant compounds will be discussed, as will novel links with commercially available software which enable direct model/measurement comparison for the first time. All of these tools will be made available via a web portal hosted at Manchester University.

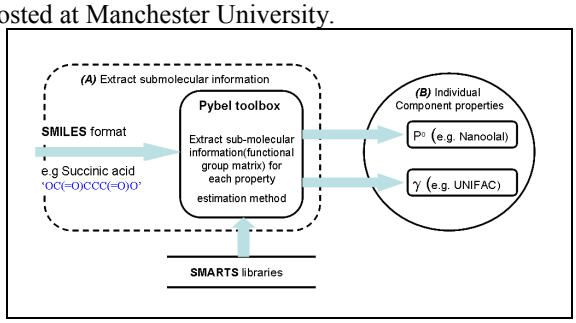

Figure 1. Dataflow diagram highlighting (A) the use of SMILES and SMARTS format with the Pybel toolbox to extract functional group matrices for input into (B) individual component property estimations

D-elements and peptides in aerosols above water: interdependence between size and chemical composition.

M.A. Chichaeva[1], A.V. Syroeshkin[2]

[1]Analytical department, Institute of applied geophysics, Moscow, 129128, Russia
[2]Laboratory of applied hydrochemistry and analytical chemistry, State Oceanographic Institute, 119034, Moscow, Russia
Keywords: aerosol chemistry, biogenic particles, nanoparticles, primary marine aerosols.
Presenting author email: MAChichaeva@gmail.com

Transference and concentration of toxicants from ocean surface to the low atmosphere can cause significant contamination of air in coastal zones (Kolesnikov, 2005). Toxicity of marine aerosols in coastal cities is the main factor of pulmonary and allergic diseases growth (Fleming, 2008; Pierce, 2008).

In experiment White, Baltic, Barents, Kara, Azov seas, south Atlantic and Noth pole area were discovered. Time period of experiment is from 2002 to 2009. Concentrations of heavy metals and biotoxins in the article are averaged and characterize areas in whole.

One of the investigation goals was finding of correlations between concentrations of HM and physical parameters of aerosol, such as mean diametr; total, number and volume concentration. Sought – for correlations were found on all aquatories. In significant number of cases it was linear with correlation coefficient 0.99 – 0.85. Such physical characteristics as volume concentration of particles with diameters 1.5 ($V_{1.5}$); 4.3($V_{4.3}$); 5.5 ($V_{5.5}$) mkm had the most frequency of occurrence. Concerning heavy metals Ni, Zn, Cd, Pb have the most number of linear correlation (see tab.1). These elements have high toxicity and carcinogenicity. Due to association with submikrometer particles that heavy metalls becomes capable to freely enter the body, bypassing the larynx. These toxic particles during the ingalation prosess may caurse canser of nose and throat, lungs.

Table 1. The equations of interdependence between the physical and chemical characteristics of marine aerosol.

HM	Phys. param.	Formula	R	sea
Ni	$V_{4.3}$	Y=3925x-21	0.99	Black
Ni	$V_{1.4}$	Y=1610x-25	0.98	Black
Cu	$V_{1.5}$	Y=44.5+339x	0.97	White
Zn	$V_{1.5}/V_{3.7}$	Y=184=56x	0.99	Black
Cd	$V_{1.5}/V_{5.5}$	Y=49x-2	0.95	Black
Pb	$V_{5.5}$	Y=18.4x-0.3	0.99	White

In specific hydrometeorological conditions marine aerosol can bring a threat to the health of the inhabitants of the coast.

Another investigation goal was to compare mean concentration level of heavy metals within marine aerosols of the seas of Russian coastline, southern Atlantics. Aerosols of North Pole area were considered as the background (see fig.1).

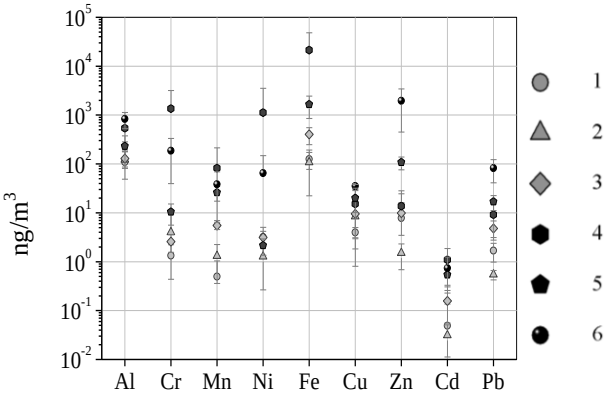

Figure 1. Comparison of concentrations of heavy metals within marine aerosols of southern and northern seas. 1 - South Atlantic Ocean, 2 - high-latitude regions of the Arctic Ocean, 3 - Kara Sea, 4 - Baltic Sea 5 – Azov sea, 6 - Mediterranean

Investigation showed that moving from northernmost seas to areas of southern seas concentrations of heavy metals in marine aerosols increases significantly.

Biogenic nanoparticles (less than 200 nm) were also in focus of the work. Nanoparticles are the basic form of transportation of biotoxins. It is well-known that marine biotoxins, forming during degradation of marine ecosystems, are the menace to human health. Viruses are also belongs to this type of nanoparticles. Sedimentation speed of nanoparticles is negligible. Concentration of biogenic nanoparticles in the lowest layer of atmosphere of southern Atlantics (in 2008) was established. Content was evaluated, using Fabry-Perot interferometer, methods for the quantitative determination of aerosoled DNA of marine heterotrophic bakterioplankton and peptide analysis. Concentration may rise to more 10^{15} m^{-3}. In areas with constraint turbulence diffusion it can reach contagious level.

Mass-based aerosol water uptake measurements, hygroscopicity parameters and solute interaction parameters

E. Mikhailov[1,2], V. Merkulov[2], S. Vlasenko[2] and U.Pöschl[1]

[1]Max Planck Institute for Chemistry, Biogeochemistry Department, 55128 Mainz, Germany
[2]St. Petersburg State University, Atmospheric Physics Department, Institute of Physics, 198904 St. Petersburg, Russia

Keywords: aerosol hygroscopicity, mass-based theory, interaction parameters.
Presenting author email: Eugene.Mikhailov@paloma.spbu.ru

In this study we have presented an expanded version of single hygroscopicity parameter model (Petters and Kreidenweis, 2007) based on mass water uptake by pure and mixed aerosol particles (Mikhailov et al.,2011a). The mass hygroscopicity parameter κ_m describes the particles hygroscopic behavior including early stage of particles growth where all solutes are in solid state and final stage where all solutes are completely dissolved. Non-ideal behavior of the concentrated particle solution is accounted for cross- and self – interaction terms in κ_m.

The hygroscopicity parameter when combined with the Kelvin term into κ_m-Köhler theory determines the equilibrium water vapor saturation ratio, as over partially dissolved particle and over fully dissolved aqueous droplet and can be used to predict the particle critical diameter for activation to a cloud droplet.

If the chemical composition, interaction parameters and solubilities of the multicomponent aerosol particles are known the hygroscopicity κ_m can be determined over the all water activity range. In the absence of information on these characteristics, experimental data for complex particles can be fitted to obtain the mass hygroscopicity parameter.

In this work the experimental mass growth factors, G_m directly obtained from a new filter-based differential hygroscopicity analyzer (FDHA) (Mikhailov et al. 2011b) were used to test the theory approach on example of pure and mixed particles. It was shown that two-parameter model including Rault mass hygrosocopicity and self- interaction term is well-suited to describe hygroscopic behavior of the pure inorganic (NaCl, $(NH_4)_2SO_4$) and organic (LG, OA) particles including highly concentrated droplets are in the metastable state.

For natural aerosols collected in Amazon Basin and in suburb of Saint-Petersburg it was disclosed that upon particle humidification the mixed particles exhibited the three pronounced sections on the κ_m-G_m dependence (Fig.1). The first linear section corresponds to beginning stage of particles growth when all solutes are in solid state (5-64%RH) and the concentration of any water soluble compound is equal to eutonic solubility, the second nonlinear section is responsible for gradual dissolution of the water soluble compounds with different solubility (64-96%RH), and the third section stands for completely dissolved mixed particles, where concentration dependence of κ_m disappears with particle growth (96-99% RH). The κ_m- theory model provides a good fit on the all stages of mixed particle evolution (Fig.1). We suggest that κ_m-model may be useful in describing particle hygroscopicity both in under- and in super-saturated water vapor. The experimental mass hygroscopicity can be converted into standard volume-based hygroscopicity κ throughout the all water activity range.

In the mass hygroscopicity model all components are weighted by their mass fraction. That substantially facilitates its validation and practical application since the commonly used aerosol analytical equipment determine the mass of chemical species in the particle.

The κ_m values can be derived from electrodynamic balance and other technique based on water mass uptake. The further research on quantification cross- and self-interaction hygroscopicity terms for pure and mixed particles is needed.

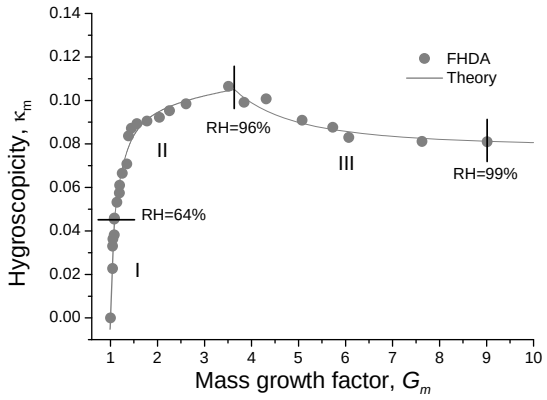

Figure 1. A comparison between theory predicted particle hygroscopicity and experimental data. Explanations are in the text.

Optical, physical and chemical characteristics of sub-urban atmospheric aerosols during very clean and local biomass burning events

Kwang Y. Lee[1], Young J. Kim[1*], T. Batmunkh[1], M.B.G. Cayetano[1], Sung Yong Kim[1], Ju S. Shin[1], and Kwan Chul Kim[1]

[1]Advanced Environmental Monitoring Research Center (ADEMRC), School of Environmental Science and Engineering, Gwangju Institute of Science and Technology (GIST), Gwangju 500-712, Republic of Korea
Keywords: Clean day, Biomass burning, Spectral absorption
yjkim@gist.ac.kr

In order to understand the characteristics of sub-urban aerosols under different atmospheric environmental conditions, chemical, physical and optical properties were continuously measured using PILS-IC, grimm OPC, semi-continuous EC/OC analyzer, 7-wavelength aethalometer and nephelometer (NGN-3) during spring (May. 24 ~ Jun. 10, Figure 1) and fall (Nov. 9 ~ Dec. 9, Figure 2) intensive measurement periods in Gwangju (126˚50'E, 35˚13'N), Korea.

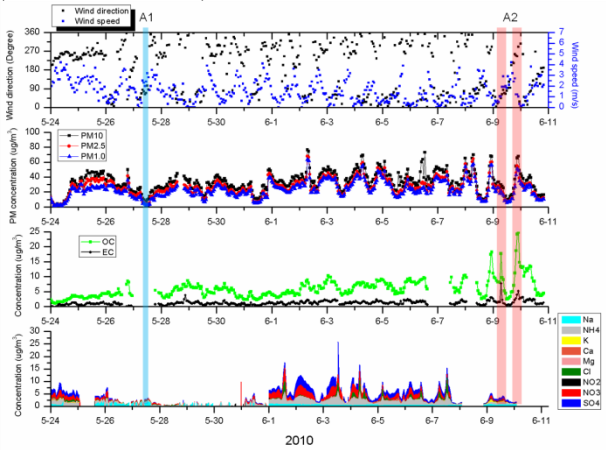

Figure 1. Temporal plots of wind speed, wind direction, PM, OC, EC and ion concentrations during the spring intensive measurement period

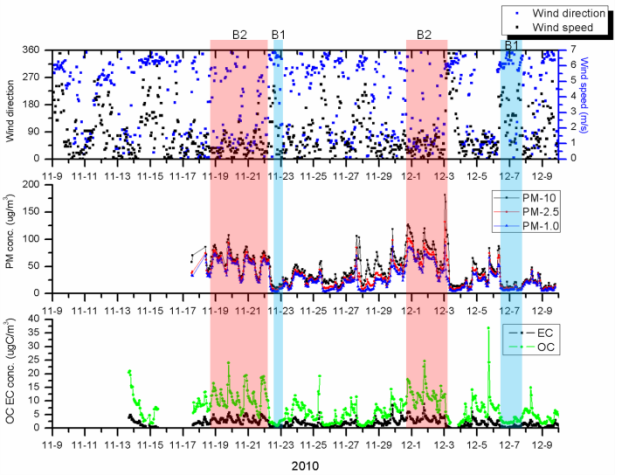

Figure 2. Temporal plots of wind speed, wind direction, PM, OC and EC concentrations during fall intensive measurement period

Average PM_{10} and $PM_{2.5}$ concentrations were measured to be 33.1±13.8㎍/m^3 and 26.1±12.0㎍/m^3 in spring and 44.4±28.4㎍/m^3 and 34.8±23.7㎍/m^3 in fall, respectively.

Several different events including very clean, long range transport of aerosols, and local biomass burnings cases were identified based on aerosol measurements and 4-day Hysplit air mass backward trajectory analyses (Table 1).

Table 1. Average concentrations of PM, OC, EC, σ_{abs} and σ_{scat} during different event periods

	Spring		Fall	
	Clean	BB	Clean	LTP+BB
PM_{10} (㎍/m^3)	8.7±1.5	57.5±14.4	12.4±3.4	83.5±17.4
$PM_{2.5}$ (㎍/m^3)	4.7±1.1	48.0±13.3	9.5±1.9	71.6±11.5
OC (㎍C/m^3)	-	19.4±3.7	2.5±0.5	14.0±4.0
EC (㎍C/m^3)	-	4.0±1.9	0.7±0.2	3.8±1.4
σ_{abs} (Mm^{-1})	5.7±2.2	49.9±15.4	4.4±2.2	78.2±35.6
σ_{scat} (Mm^{-1})	11.4±4.7	126.7±37.5	22.6±4.0	206.3±36.4

The most clean event (A1, excluding rainy days) was observed 9AM ~ 1PM (UTC+9) on May 27. $PM_{2.5}$ was observed as low as 6.6㎍/m^3 when the air mass originated from East Sea. The highest OMC (OMC =1.7[OC]) concentration of 42.2㎍/m^3, consisting of 78.7% of total $PM_{2.5}$ concentration (53.6㎍/m^3) was observed during a biomass burning event (A2). Short wavelength absorption increased under local biomass burning event conditions (A2) while no spectral dependence was observed during clean event period (A1).

Information on spectral absorption coefficient of atmospheric aerosol can be related to chemical composition of atmospheric aerosol.

The volatile fraction of Arctic aerosol particles derived from thermodenuder/mobility spectrometer measurements during ASCOS

A. Held[1], J. Walz[1], D. Orsini[2] and C. Leck[3]

Presenting author email: andreas.held@uni-bayreuth.de

The Arctic Summer Cloud Ocean Study (ASCOS, www.ascos.se) investigates physical and chemical processes controlling cloud formation in the high Arctic Ocean. This work analyzes the volatile fraction of Arctic aerosol particles during summer when the aerosol in the atmospheric boundary layer is typically not affected by long-range pollution. Thus, local processes are expected to dominate aerosol formation and aging. The fraction of volatile compounds in aerosol particles of different sizes yields insight into the formation and aging processes of these particles.

During the 2008 ASCOS expedition, aerosol number size distributions were measured in the diameter range between 3 nm and 800 nm using a twin differential mobility particle sizer (TDMPS) in combination with a thermodenuder TD (Wehner et al., 2002). Measurements were taken onboard the Swedish icebreaker Oden over open water (OW), the marginal ice zone (MIZ), and the pack ice zone (PIZ).

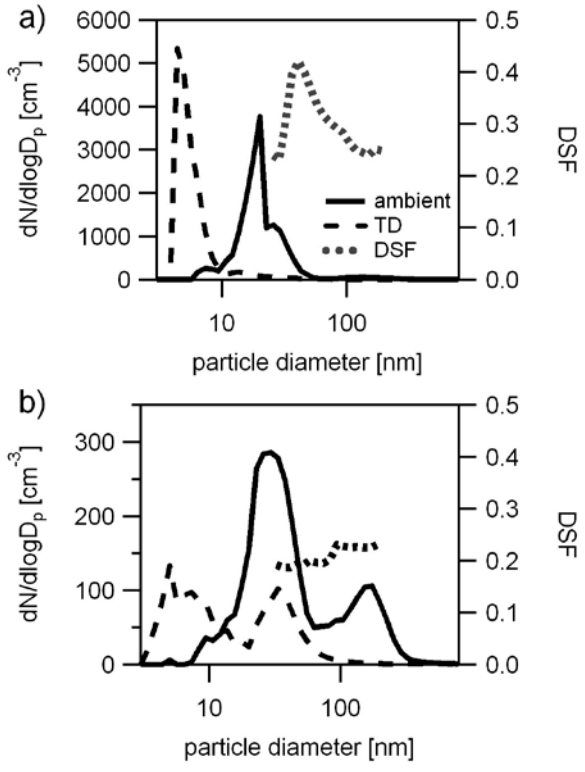

Figure 1. The descriptive shrinking factor DSF, and aerosol number size distributions at ambient temperature and after TD treatment: a) OW and b) PIZ.

The volatile fraction of the aerosol was derived from a comparison of alternating particle size distribution measurements at ambient temperature and after TD treatment (heating to 300 °C). Evaporation of volatile material at 300 °C resulted in a shift of size distributions to smaller diameters. Thus, the volatile aerosol fraction can be expressed as a shrinking factor, i.e. the ratio of the diameter of the heated particle and of the original particle. In this study, size-dependent descriptive shrinking factors (DSF) were obtained using the summation method (cf. Engler et al., 2007).

Typical ambient number size distributions were dominated by Aitken mode particles with maximum particle number concentrations in a diameter range from 20 nm to 33 nm (Fig. 1). OW particle number concentrations were greater than 900 cm^{-3}, nearly four times higher than over the ice. In the MIZ and PIZ, bimodal number size distributions were observed, with a characteristic minimum at a diameter around 70 nm, separating the Aitken mode from the accumulation mode. The number size distributions retain the bimodal shape during and after TD treatment (Fig. 1b).

DSF analysis showed that accumulation mode particles over OW and in the MIZ typically contained more volatile material than Aitken mode particles (Fig. 1a). In contrast, in the PIZ the maximum amount of volatile material was found in the Aitken mode, decreasing with increasing particle size (Fig. 1b). This is indicative of different chemical composition and aging of OW and PIZ aerosol particles.

This work was funded by the Bert Bolin Centre for Climate Research at Stockholm University and by the Knut and Alice Wallenberg Foundation. ASCOS is an IPY project under the AICA-IPY umbrella and is endorsed by the SOLAS program.

Hygroscopic properties of sub-Arctic aerosols: continuous HTDMA measurements from Pallastunturi, Finnish Lapland

A.-P. Hyvärinen[1], K. Neitola[1], E. Asmi[1], and H. Lihavainen[1]

[1]Finnish Meteorological Institute, Erik Palménin aukio 1, Helsinki, P.O. Box 503, FI-00101 FINLAND
Keywords: H-TDMA, hygroscopic growth, Pallastunturi.
Presenting author email: antti.hyvarinen@fmi.fi

Arctic climate has warmed twice as quickly as climate on average during the last century. Despite growing knowledge, climate models give still uncertain predictions for Arctic areas. The uncertainty arises for example from understanding the direct and indirect climate effects of aerosols.

To address the knowledge gap in the properties of Arctic and sub-Arctic aerosols, FMI begun continuous measurements of aerosol hygroscopic growth at the Pallastunturi GAW station in the Finnish Lapland (Hatakka et al. 2003). The measurements were started on December 2008.

The measurements are conducted with a hygroscopicity tandem differential mobility analyser (HTDMA) built in-house FMI. The HTDMA was built according to the EUSAAR recommendations, and fulfils the EUSAAR criteria for continuous measurements. The main HTDMA features include:

- Measurement of hygroscopic growth factor (HGF) at a fixed RH of ~90 %
- Quality assurance with automated dry- and ammonium sulphate checks
- 8 dry diameters from 15 nm to 265 nm (1 cycle takes 1 hour)
- Aerosol humidification from the sample flow using a Gore-Tex humidifier
- DMA's in closed loop arrangement with a dew point analyser as the main humidity sensor

The 2009 annual average growth factors varied from 1.15±0.08 measured for 15 nm dry particles to 1.44±0.11 measured for the 265 nm dry particles. Figure 1 illustrates the corresponding HGF distributions. The growth factors had some seasonal variation, having highest values in the spring and lowest in the autumn (Table 1). However, the seasonal variation was weak and nearly within the standard deviation of the annual data.

Table 1. Average growth factors with standard deviations for representative Aitken and Accumulation mode dry particles

Month	50 nm (Aitken mode)	165 nm (Accumulation mode)
Spring	1.23±0.09	1.43±0.09
Summer	1.18±0.08	1.32±0.10
Autumn	1.13±0.07	1.32±0.11
Winter	1.19±0.08	1.42±0.09

The mean growth factors were used to deduct the hygroscopicity parameter κ-values. These can be derived from the measured HTDMA growth factors (HGF) as follows (Good et al., 2010):

$$\kappa_{HTDMA} = \frac{HGF^3 - 1}{RH}\exp\left(\frac{4\sigma_w M_w}{RT\rho_w D_d HGF}\right) + 1 - HGF^3. \quad (1)$$

The annual average κ-values for 2009 varied from 0.1 for 25 nm dry particles to 0.23 for 265 nm dry particles. Therefore, the Kelvin effect alone does not explain the increasing HGF towards larger dry particles.

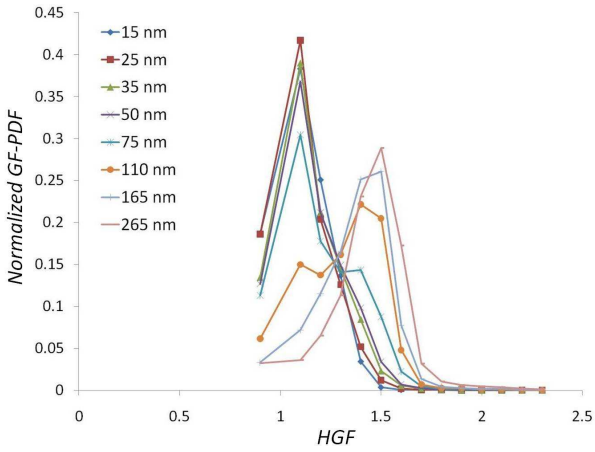

Figure 1. Average growth distributions for Pallastunturi aerosols

The long term measurements of aerosol hygroscopic growth factors in Pallastunturi fill some of the knowledge gaps in aerosol properties in the sub-Arctic. This will be helpful when determining the climate effects of aerosols in the Arctic.

This work was supported by EUSAAR and the Maj & Tor Nessling foundation. Marting Gysel from PSI is acknowledged for providing the IGOR inversion algorithm for the HTDMA data.

The International Arctic Systems for Observing the Atmosphere (IASOA, www.IASOA.org) is an International Polar Year (IPY) Activity (#196) which aims at better understanding of climatically important atmospheric processes. A fundamental part of this activity has been coordination and upgrade of observatories in the Arctic. Tiksi meteorological observatory in northern Siberia (71°40'N, 128°40'E, Fig. 1) has been operating since 1930s. As a part of IPY project funding was obtained to upgrade and expand the existing observatory to serve as a base for long-term climate studies in Russian Arctic region. The project is run in collaboration between National Oceanic and Atmospheric Administration (NOAA) with the support of the National Science Foundation (NSF), Roshydromet (AARI and MGO units), government of the Republic of Sakha (Yakutia) and the Finnish Meteorological Institute (FMI). The research activities of FMI in Tiksi include continuous long-term measurements of aerosol number size distributions as well as the fluxes and concentrations of the most important greenhouse gases (GHGs), carbon dioxide and methane. Quality control and measurement procedures are done by following the Global Atmosphere Watch (GAW) network requirements.

The climatic effects of atmospheric aerosol particles are pronounced in the Arctic - a region specifically vulnerable to changes in climate forcing components and feedbacks (e.g. Walsh and Chapman 1998). The frequently presented clear seasonal cycle in Arctic aerosol concentrations is to a great extent controlled by the winter/spring 'Arctic Haze' season (Barrie 1986; Shaw 1995). Major research questions regarding the Arctic aerosols are their source regions and transportation patterns, chemical and dynamical changes during transport and deposition in the Arctic. The year-round aerosol measurements in Tiksi to a great extent contribute for answering these questions. Here, we concentrate on the seasonal analysis of the Arctic aerosol modal properties, as well as their sources and transportation patterns by using the measured size distribution data from Tiksi together with the calculated backward trajectories given by the FLEXTRA model (Stohl *et al.* 1995).

The aerosol number size distributions in Tiksi are measured with a Differential Mobility Particle Sizer (DMPS) in the size range of 7-500 nm. Bigger, > 500 nm, particles are measured with a TSI Aerodynamic Particle Sizer (APS). The continuous measurements started in the beginning of July 2010 and are currently on-going. Considering the hazardous Arctic environment inflicting many practical difficulties, the measurements have been running amazingly well, with only minor occasional breaks.

Figure 1. Measurement site Tiksi is located in the permafrost zone at the coast of Arctic Ocean.

The results from the first year of measurements are under analysis. We aim in obtaining the general seasonal characteristics of the particle modal concentrations and properties, as well as their dependency of the air mass type and local meteorological conditions. The impact of Arctic Haze season is of our special interest. The yet very preliminary results from this autumn suggest that the particle modal characteristics exhibit large air mass related differences. Increased concentrations of aged accumulation aerosols are observed in air masses originating from the Central Siberia while the smallest particles often originate from Arctic and coastal regions. This feature is to be confirmed by using a full dataset of one year.

Particle number variation due to the disappearance of a thermal inversion

J.F. Nicolás[1], C. Pastor[1], J. Giménez[1], R. Castañer[1], E. Yubero[1] and J. Crespo[1]

[1]Department of Applied Physics, Miguel Hernández University, Avda. Universidad, 03202, Elche, Spain
Keywords: Vertical distribution, Mixing layer, Particle counting, Number concentration.
Presenting author email: j.nicolas@umh.es

The vertical profiles of particle number concentrations and meteorological parameters were obtained using a motorized paraglider. The flight was performed on 22 September 2009 in southeast Spain, near the Mediterranean coast (~20 km). The paraglider took off at 07:45 UTC, reached an altitude of 2500 m, and landed 45 minutes later, at 08:30 UTC. The horizontal displacement from the launch site was almost negligible. The synoptic meteorological conditions during the flight were anticyclonic.

The instrument used to obtain the particle number concentration was a GRIMM 1.109 aerosol spectrometer. This instrument determines particle number concentrations in 31 particle size channels from 0.25 to 32 μm. Its uncertainty in particle counting determination is 5%. A Delta Ohm ultrasonic anemometer, model HD 2003, was used to record the temperature, relative humidity and pressure.

We want to focus on determining the influence of atmospheric stability conditions upon the particle concentrations, above all in the first meters above ground level, and thus advance the research initiated in previous works (Giménez *et al.*, 2010).

Figure 1 (only represents the first 700 m of flight) shows the temperature vertical profile during the ascent (grey continuous line) and descent (black continuous line). We can observe how the initial thermal inversion is disappearing at the same time the temperature increases 4°C at ground level. This circumstance causes a significant effect upon particle number concentrations, above all in the first 200 m above ground level.

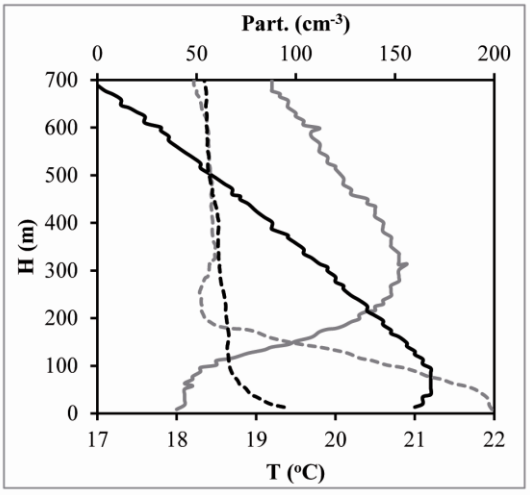

Figure 1. Temperature and particle concentration profiles obtained during the paraglider ascent and descent.

We realize how a ground level concentration of ~ 200 part. (cm^{-3}) (when the paraglider took off, grey dashed line) changes to 95 part. (cm^{-3}) during the landing (black dashed line), 45 minutes later.

Moreover, we see how the particle decay in the two cases is different. With the inversion fully developed, with an SBL (Stable Boundary Layer) height of ~300 m, the particle decay has a less steep slope than when the inversion is disappearing.

In order to quantify the disappearance of the thermal inversion effect, we have calculated (see table 1) the percentage reduction in the particle concentration between the ascent profile and descent profile. We have done this in the first 180 m because this is the height where the two profiles intersect (see figure 1). We have separated the decrease percentage between the coarse mode (size >1 μm) and accumulation mode particles (size <1 μm).

Table 1. Percentage decrease in coarse and accumulation mode particles depending on the height due to the disappearence of the thermal inversion.

Height intervals (m)	Percentage Decrease (%) (Coarse Mode)	Percentage Decrease (%) (Accumulation Mode)
0-15	85.7	52.7
15-30	84.8	55.9
30-45	84.7	59.6
45-60	84.3	60.9
60-75	85.0	59.9
75-90	81.2	58.2
90-105	76.4	55.4
105-120	69.1	51.1
120-135	64.3	46.4
135-150	63.6	38.8
150-165	47.2	26.9
165-180	44.0	10.4

The percentage decrease in coarse particles is between 20-30% higher than in accumulation particles at all heights. In addition, roughly speaking, the percentage reduction in particle numbers due to the disappearance of the thermal inversion increases as we get closer to ground level.

Thanks to Paul Nordstrom and Guillermo Escribano for their support in this work.

Inhibited water diffusion and inhomogeneities in glassy atmospheric aerosol proxies

D.L. Bones[1], H.-J. Tong[1,2] and J.P. Reid[1]
[1]School of Chemistry, University of Bristol, Bristol, BS8 1TS, United Kingdom

A detailed knowledge of the timescales for water uptake on atmospheric aerosol particles is critical to understanding the behaviour of potential cloud condensation nuclei. Atmospheric aerosol particles are typically complex mixtures of organic and inorganic species with correspondingly complex behaviours in changing humidity regimes. Here, we investigate the formation of glassy states and highly viscous solution phases in aqueous sugar aerosols (sucrose, raffinose and levoglucosan) and aerosols of mixtures of these sugars and sodium chloride.

While the efflorescence and deliquescence points of aerosols of purely inorganic compounds like sodium chloride or ammonium sulphate are predictable and well characterised by such models as AIM and ADDEM (Topping, *et al.* 2005), the behaviour of aqueous organic aerosol is poorly understood. Ambient atmospheric aerosol is typically a mixture of inorganic and organic compounds of varying solubility (Reinhardt *et al*. 2007). It has recently been recognised that many aerosols exist as highly viscous solutions or as amorphous glasses, rather than a crystalline state, over a wide range of relative humidities (Virtanen, *et al.* 2010).

We use optical tweezers to trap single aerosol particles, which we can accurately size to a precision of ± 1 nm from the size-dependent resonance patterns exhibited in the Raman spectra of the back scattered light. Resonant modes, often referred to as whispering gallery modes (WGM), can be predicted via the Mie solutions to Maxwell's equations (Mitchem and Reid, 2008). The resonant modes penetrate to varying depths inside the particles and can hence provide insight into the structure of the particle. Also, variations in refractive index as a function of radius generate reproducible shifts in the wavelengths at which certain modes appear.

We can exploit these subtle changes in the Raman spectra to deduce the processes involved in water uptake and evaporation from aqueous organic particles and mixed aqueous organic/inorganic particles. We also extend on previous work to present further evidence for glassy states and non-ergodic behaviour (Tong *et al.* 2011). A statistical treatment of the exponential changes in particle size reveals significantly different kinetics of water uptake and loss above and below the glass transition point. However, because the viscosity of these particles is significant above the glass transition point, they also exhibit very slow diffusion rates in this region (Figure 1). This is confirmed by comparison of measured particle sizes at equilibrium with those predicted by thermodynamic models. Figure 2 illustrates this effect on a sucrose particle subjected to small, step-wise decreases in relative humidity. At low relative humidities, the particle is taking times in excess of 20 000 s (*i.e.*, 6 hours) to reach equilibrium. Predictions of the composition of organic aerosol need to include this inhibited rate of change to accurately represent the processes occurring in atmospheric aerosol.

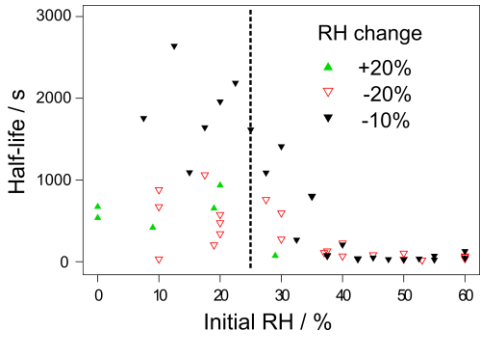

Figure 1. Timescales, represented as half-lives, for equilibration of sucrose particles, for both increasing and decreasing RH steps. The glass transition (~ 25% RH) is represented by the dashed line.

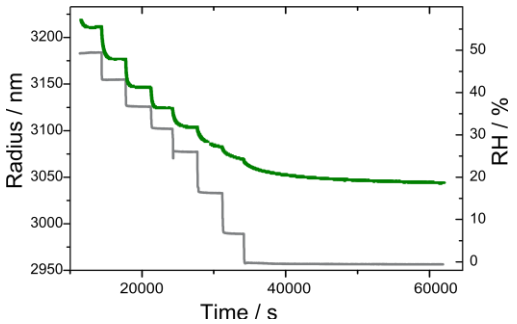

Figure 2. Time dependence of the size of a sucrose droplet (green) with change in RH (grey line, right axis). Adapted from (Tong, *et al.* 2011)

The hygroscopic properties of aerosols have significant effects on the climate change and human health. Using the HTDMA (Hygroscopic Tandem Differential Mobility Analyzer) system, the hygroscopic properties of 7 kinds of laboratory-generated inorganic and organic aerosols were characterized quantitatively for determining the main affecting factors on the hygroscopicity of ambient aerosols.

It was found that the deliquescence points of inorganic compounds NaCl and (NH4)2SO4 were about 75 ± 2% rh. The particle sizes of NaNO3, CaCl2 and synthetic sea salt shifted to the larger sizes when the RHs (relative humidity) gradually increased. While, the sizes of CaSO4, oxalic acid and adipic acid were not observed obvious increase with the increasing of RH.

The hygroscopic properties of aerosols have significant effects on the climate change and human health. The hygroscopicity of ambient aerosols was conducted during December 8-20, 2009 in Beijing, and the influencing factors were also discussed. It was found that the aerosol hygroscopic growth factors were between 1.01 and 1.4 in winter in Beijing, with the property of weak hygroscopicity and nearly hydrophobic characteristics. The major influencing factors included aerosol size distribution, the air pollution situation, different sources such as vehicle exhausts, meteorological conditions and so on. The aerosol growth factors in accumulation mode were higher than those in atiken mode. With the API gradually falling down during monitoring, the environmental aerosol growth factors declined also. For those days with good atmospheric stability, the aerosol hygroscopic growth factors showed a bimodal variation, i.e. two peaks at noon and midnight and two valleys in the morning and evening. While, for those days with poor atmospheric stability, the aerosol growth factors showed a single-peak variation, i.e. a peak at midnight and a valley at noon. In addition, aerosol components with weak hygroscopicity were predominent for “peak” growth factors, and those with nearly hydrophobic characteristics were predominent hfor “valley” growth factors. The result in Beijing in this work supplied the necessary scientific basis for the atmospheric hygroscopic characteristics and related radiative forcing and climate changes.

Sulphuric acid has been shown to be involved in nucleation and growth of newly formed particles (Weber et al., 1997; Laaksonen et al., 2008; Kuang et al., 2008). The problem is that gas phase sulphuric acid concentration is difficult to measure and in many measurement sites no H_2SO_4 data are available. The purpose of this study is to test how well different measured trace gas and meteorological variables can predict the measured sulphuric acid concentration in different datasets and to construct a proxy which could be used to predict the sulphuric acid concentration in places where direct measurements have not been made. Mikkonen et al. (2011) investigated different data sets and provided evidence that high SO_2 and radiation together with low condensation sink (CS) increases the concentration of H_2SO_4 and thus make a significant contribution to particle formation and growth. Petäjä et al. (2009) studied different proxies for EUCAARI 2007 campaign data and our aim is to widen this study for other datasets measured in different environments.

Six campaign datasets and one long term dataset were analyzed for this study. The campaign datasets were measured in Hyytiälä, Finland, in 2003 and 2007, in San Pietro Capofiume (SPC), Italy in 2009, in Melpitz, Germany, in 2008, in Atlanta, USA, in 2002, and in Niwot Ridge (NWR), USA, in 2007. The long term data were measured in Hohenpeissenberg, Germany within years 1998 to 2000 (Birmili et al., 2003).

The main source of sulphuric acid in the atmosphere is the reaction chain induced by SO_2 and OH radical whereas its main sink is condensation to aerosol particles. OH radical concentration is suggested to be strongly correlated with the intensity of ultraviolet radiation (Rohrer and Berresheim, 2006) despite the complex OH chemistry in the atmosphere. UV radiation is highly correlated with global radiation so due to UV-data availability issues we use the measurements of global radiation as a proxy for OH.

A nonlinear fitting procedure was applied to all datasets, with a fit function given by

$$[H_2SO_4] = a \cdot k \cdot Radiation^b \cdot [SO_2]^c \cdot CS^d.$$

where a, b, c and d are parameters calculated from the data, k is temperature depended reaction constant, $[H_2SO_4]$ and $[SO_2]$ have units of molecules cm^{-3}, *Radiation* is global radiation in W m^{-2} and CS has units of 1/second. Only data points with Radiation higher than 10 W m^{-2} and $[SO_2]$ higher than 0.1 ppb were used in the analysis. If the steady state applies without any additional chemistry, then b and c should be unity and d should be -1. However, the fitting procedure results in Table 1 show that the powers vary a lot in the best predictive models and they are quite far from the theoretical values. Probable reason for this is that $[SO_2]$ acts also as an indicator to air pollution, i.e. factors that are sinks for sulphuric acid, and thus reduces the impact of CS.

Table 1. Best fitted values for nonlinear fit function, correlation coefficient *R*, which describes the correlation between observed values and the model predictions and R theory, which is the correlation coefficient if b = c = 1 and d = -1. Values marked with * are not statistically significant and can be considered as zero.

The studying of new particle formation was long limited by the incapability to detect neutral particles below about 3nm. Sipilä *et al.* (2008) showed the applicability of condensation particle counters to measure in the sub-3nm range in field conditions. Since it cannot be resolved by CPC measurements only if the activated seed-particles are large molecules, clusters, or actual particles, it has become customary to call them nano condensation nuclei (nano-CN).

Measurements were conducted at the Hyytiälä SMEAR II station in Finland as a part of HUMPPA-COPEC campaign in late summer 2010, and also during spring 2011. The Airmodus A09 Particle Size Magnifier (PSM) was used to resolve the size distribution of particles below 2nm. The PSM is a dual-stage mixing type CPC using diethylene glycol for activating and initial growth of particles, while further growth and counting is done by an external CPC. The cut-off size of the instruments can be varied between about 1-2nm by altering the mixing ratio of saturator and aerosol flow and thus changing the supersaturation created. The relation between the mixing ratio and activation diameter has been determined in laboratory calibrations using mobility standards and size-selected tungsten oxide and silver ions. The nominal cut-off size of the Particle Size Magnifier at the highest mixing ratio is about 1.5nm (Vanhanen *et al.* 2011).

We found the PSM well suited for long-term field measurements, and the concentrations of nano-CN were in agreement with previous studies using pulse-height CPC (Lehtipalo *et al.* 2009). Figure 1 shows an example day with total particle concentrations measured with PSM at cut-off sizes 1.3 and 2nm, ultrafine water CPC (TSI 3786) at 3nm, and small positive and negative ions measured with A-NAIS ions spectrometer (Mirme *et al.* 2010). During daytime, the PSM showed higher concentrations compared to the ultrafine CPC, while the concentration of small ions remained almost constant. This indicates the presence of neutral nano-CN during that time.

We observed that the fraction of ions from all particles in the size range between 1.3-3nm was diminishing with increasing total concentration, the median charged fraction being close to 1%. Generally, the total nano-CN concentration varied much more than the small ion concentration. Correlation was also found between the concentration of sulphuric acid (as measured with a chemical ionization mass spectrometer) and the concentration of nano-CN.

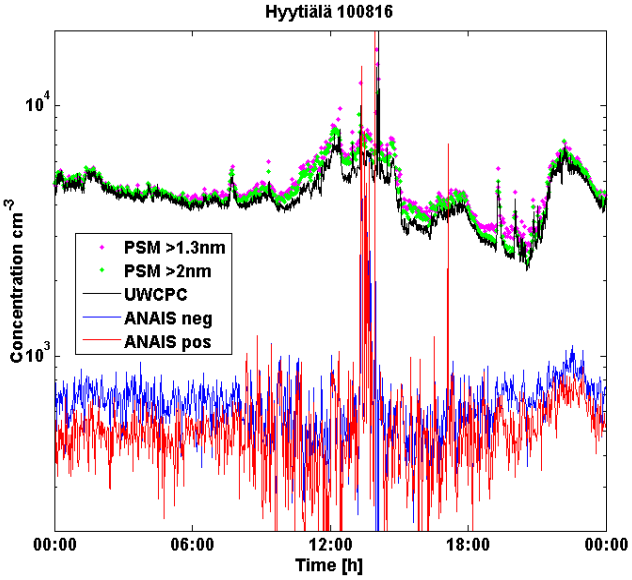

Figure 1. Example of measurements with PSM at cut-off sizes 1.3 and 2nm, compared to TSI 3786 (UWCPC) at 3nm cut-off and small positive and negative ions measured with ANAIS ion spectrometer.

Atmospheric aerosol can act as cloud condensation nuclei (CCN) to affect the amount of cloud on the earth and thus global climate. Such aerosol-cloud interactions comprise the largest uncertainties in our understanding of human-caused climate change. The composition of aerosol plays an important role determining its CCN activity. Thus direct and long-term observations of effects of chemical composition of aerosol on aerosol-cloud interactions are especially welcomed.

An observation station has been established in Kuopio, Finland, for making long-term measurements of aerosol-cloud interactions. The station is located at the top of Puijo tower, 306 m.a.s.l. and 224 m above the surrounding lake level (Leskinen et al., 2009; Portin et al., 2009). Aerosol sources that impact the site include long-range transported aerosol from surrounding continents and oceans, as well as local pollution from traffic, a pulp mill, heating plant and other urban sources. A measurement campaign was carried out during Sep. 21-Oct. 27, 2010 for the observation of cloud events. An Aerodyne high resolution aerosol time-of-flight mass spectrometer (TOF-AMS, DeCarlo et al., 2006) was used to measure the chemical composition of ambient particles. We also applied positive matrix factorization (PMF) analysis to track the aerosol origin (Ulbrich et al., 2009).

On average, the mass loading of non-refractory species quantified with the AMS and black carbon is 2.36 μg m^{-3}. Of this, organic, sulfate, nitrate, ammonia, chloride and black carbon mass contributed to 48.2%, 28.3%, 6.2%, 7.2%, 0.4% and 9.6%, respectively. Sulfate showed the largest variability in terms of mass concentration, from 0.02 μg m^{-3} to 7.28 μg m^{-3}. It is heavily wind direction dependent with aerosol sources from northeast (pulp mill as primary emissions) and from southwest (transported from the European continent) contributing higher fractions of sulfate than other directions. Nitrate concentrations showed similar behaviors as sulfate, which is mainly affected by the primary emissions from pulp mill in the northeast direction. Ammonia showed a close correlation with sulfate and nitrate. Measured ammonia concentration was less than 76% of predicted ammonia, indicating the observed aerosol in this campaign was acidic in nature.

Five organic aerosol (OA) components were identified from AMS spectra using PMF (Fig. 1): chemically-reduced urban primary emissions (hydrocarbon-like OA, HOA), low volatile OA (LV_OOA), semivolatile OA (SV_OOA) and biomass burning OA (BBOA_1 and BBOA_2), which contributed to 5.9%, 54.7%, 22.2%, and 16.7% of OA, respectively in mass loadings. LV_OOA and SV_OOA correlated with SO_4 and NO_3, respectively, with only several exceptions of SO_4 and NO_3 events (primary emissions). BBOA_2 is from freshly emitted biomass burning aerosol, which shows correlation with black carbon. BBOA_1 is contributed from oxidized aerosol, showing a good correlation to levoglucosan. Contributions of HOA might be from the local traffic, which correlated to NO_2.

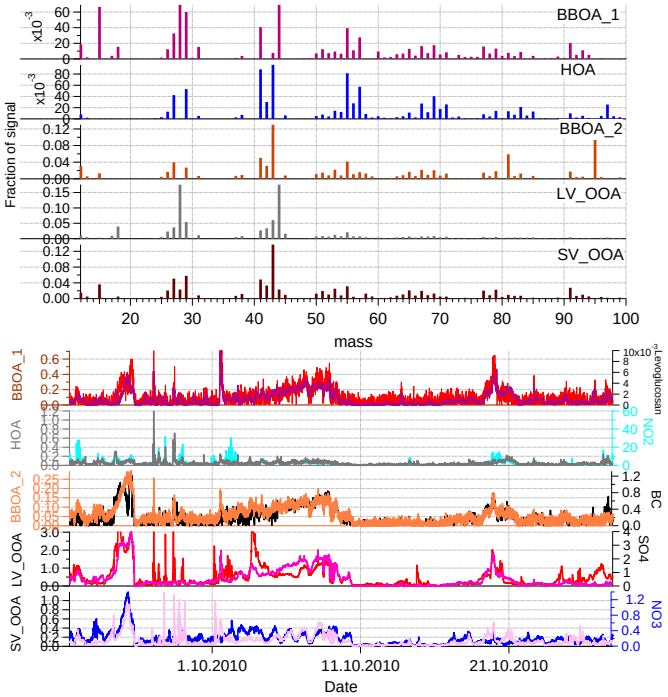

Figure 1 Time series of PMF-AMS sources and corresponding tracers. The bottom panel is in unit of μg/m^3.

Hygroscopic properties of the urban aerosol in Paris in relation to its chemical compositions

K. Kamilli[1], L. Poulain[1], A. Nowak[2], A. Held[3], W. Birmili[1], A. Wiedensohler[1]

[1]Leibniz-Institute for Tropospheric Research, 04318 Leipzig, Germany

Keywords: Hygroscopic growth, Chemical composition, Megacity
Presenting author email: kamilli@tropos.de

Aerosol measurements with the objective to characterize the aerosol particles with regard to their physical and chemical properties were made within two field campaigns as part of the MEGAPOLI project work package 3 “Megacities Plume Case Study” (Megacities: Emissions, urban, regional and Global Atmospheric POLlution and climate effects, and Integrated tools for assessment and mitigation). The measurements took place in Paris from 29th of June 2009 to 1st of August 2009 and 15th of January 2010 to 15th of February 2010, respectively.

Dry size distributions were measured by a Twin Differential Mobility Particle Sizer (TDMPS) in a size range between 3 and 700 nm in summer and up to 800 nm in winter whereas humidified size distributions were obtained from a Humidified Differential Mobility Particle Sizer (HDMPS) from 25 to 800 nm. The combination of these two instruments made it possible to get dry and wet number size distributions in high time resolution. Using the summation method (Birmili et al., 2004), the size-resolved descriptive hygroscopic growth factors (DHGF) were derived in the size range from 25 nm to 350 nm at relative humidities of 30, 55, 75 and 90% (Birmili et al., 2009). Simultaneous measurements with an Aerosol Mass Spectrometer (AMS) and a Multi Angle Absorption Photometer (MAAP) yield the mass concentrations of the sulfate, nitrate, and ammonium ions, as well as organic matter and the total mass concentration of black carbon. Using a simplistic particle growth model that assumes a homogeneous particle mixture (Zdanovskii-Stokes-Robinson mixing rule) supplied hygroscopic growth factors initialized by the experimentally determined chemical composition. This enables to draw a comparison between measured growth factors and the ones calculated by the ZSR relation.

Various periods have been examined under various meteorological conditions. A main result is that temporal variations in the observed mean DHGF could be well explained by changes in the chemical compositions. In addition, good agreement has been observed when sulfate was the predominant inorganic factor, whilst worse results with a clear overestimation of the predicted growth factor have been reached when the influence of nitrate became more obvious.

This is possibly due to the strong temperature dependency of nitrate concentrations in the solid phase and the potential of evaporation losses of NH_4NO_3. Because of the increased nitrate concentration in winter the evaporation losses carry more weight. Therefore, the differences between measured and predicted GF are much higher in winter than in summer.

The research leading to these results has received funding from the European Union's Seventh Framework Programme FP/2007-2011 within the project MEGAPOLI, grant agreement n°21252.

Aerosols physico-chemical and optical properties are fundamental for climate change (IPCC, 2007; Kaufman et al., 2002) as well as for remote sensing applications (Wang et al., 2010; Di Nicolantonio et al., 2009); for the latter their 3D knowledge, especially along the whole atmospheric column is required (Levy et al., 2007; Wang et al., 2010).

For the reasons above, vertical profiles measurements of aerosol properties were conducted in winter 2010 along Italy over the cities of Terni (Central Appenine Valley), Milan (Po Valley) and Merano (Alpine Valley).

A tethered balloon was fitted with an instrumentation package consisting of: 1) a tandem-OPC system (2 OPCs GRIMM *1.107*; 31 size classes between 0.25 to 32 μm: one dried, the other one at ambient RH), 2) a novel micro-Aethalometer (AE51, Magee Scientific), 3) a miniaturized cascade impactor (Sioutas SKC with 2 impaction stages: <1 μm, >1 μm), 4) a metorological station.

OPCs tandem system data allowed us to determine the aerosol humidographs along height following the method reported in Snider et al. (2008) (Figure 1). Hygroscopic growth (Gf) was found to be not uniform along the vertical profiles (Figure 2) evidencing how the use of simple parameterizations of Gf along the atmospheric column in remote sensing applications can be a source of uncertainty in the results.

Micro-Aethalometer data enabled us to estimate black carbon (BC) concentration and absorption coefficient profiles. BC profiles clearly identified the mixing height (MH), which was characterized by a strong vertical concentration gradient. Over Milan BC profiles also showed a shallow layer of increased concentrations close to the ground (+24% compared to the whole MH), due to the proximity of combustion sources. The BC fraction of aerosol volume fell to 50-70% above the MH, compared to ground-level data. This caused a change in the optical absorption properties of the aerosol at different heights. Fairly constant values of absorption coefficient were found above the MH for each location, between 5-20% (2-15 Mm^{-1}) of those measured within the mixing layer.

PM samples collected with the cascade impactor were analysed by ion chromatography (Dionex ICS90 and ICS2000) system. The chemical speciation (Ions and BC) allowed to estimate a aerosol refractive index, and aerosol optical properties along height were calculated from OPC data using a Mie code (Bohren and Huffman, 1983): vertical optical properties were useful to improve the satellite retrieval of particulate matter at ground-level.

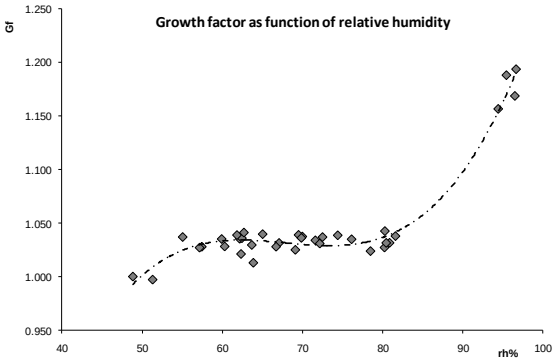

Figure 1. Humidograph along vertical profiles.

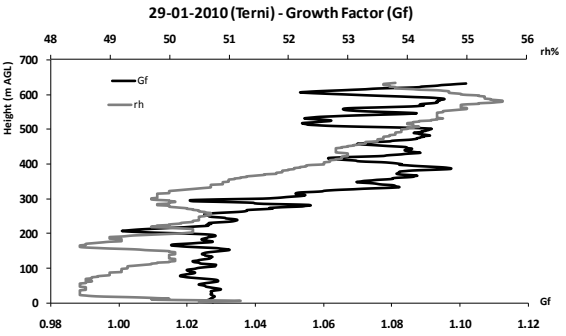

Figure 2. An example of Gf vertical profile.

Aerosols hygroscopicity is fundamental for climate change (IPCC, 2007; Kaufman et al., 2002) as well as for remote sensing applications (Wang et al., 2010; Di Nicolantonio et al., 2009). Aerosol hygroscopicity is also important in local studies involving industrial application, i.e. to prevent corrosion effects in computer centres; the latter topic is normed by ASRHAE (2009).

In this study aerosol hygroscopicity was investigated at a rural site located in the middle of the Po Valley (Sannazaro de' Burgondi, Pavia, North of Italy); this place was chosen as it will be the location of a computer centre.

To study aerosol hygroscopicity PM_x samples ($PM_{2.5}$, PM_1, $PM_{0.4}$) were collected using a FAI-Hydra dual channel low volume sampler with the following time resolutions: $PM_{2.5}$ (4-h filters), PM_1 (8-h filters) and $PM_{0.4}$ (24-h filters). The sampling period was 24 March – 19 April (spring) and 10 June – 2 July 2010 (summer). All the collected filters were extracted in ultra-pure water and analyzed by IC to determine the concentration of water soluble inorganic ions (Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}; F^-, Cl^-, NO_3^-, PO_4^{3-}, SO_4^{2-}) and mono-/dicarboxylic acids (acetic, propionic, formic, glutarric, succinic, malonic, maleic, oxalic acids). Then, a thermodynamic model (*E-AIM*, Clegg et al., 1998; http://www.aim.env.uea.ac.uk/aim/aim.php) was used to determine humidographs for each collected sample. Figure 1 reports daily averaged humidographs for $PM_{2.5}$, PM_1 and $PM_{0.4}$ for the spring campaign. The total amount of water uptake in the reported humidographs depends on the atmospheric concentrations of water soluble inorganic and organic ions available on particulate phase.

At the same time, a tandem-OPC system allowed to estimate (Snider et al., 2008) aerosol hygroscopicity with a time resolution of 1 minute. The system is composed by 2 OPCs GRIMM *1.107* (31 size classes between 0.25 to 32 µm): one OPC measures particle number size distribution under dried conditions (OPC_{dry}), the other one performs the same measurement but at ambient RH (OPC_{wet}).

Humidographs for particle with diameter less than 2.5 µm and 1 µm were derived from collected data and compared to that estimated using the *E-AIM* model.

Figure 2 reports humidograph for $V_{2.5}$ (particle volume obtained by particles with diameter less than 2.5 µm) for the spring campaign, as calculated from tandem-OPC system data. The total amount of water uptake in the reported humidograph was calculated from the volume difference between the OPC_{wet} and the OPC_{dry}.

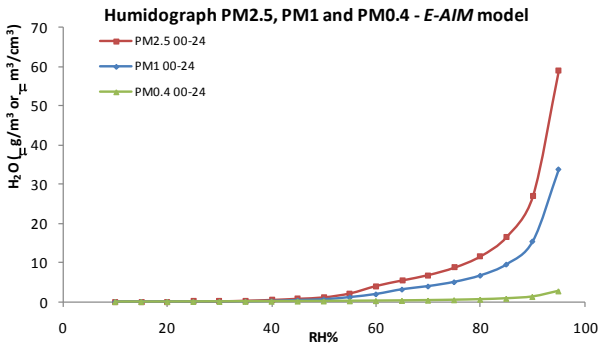

Figure 1. Humidographs calculated from the application of *E-AIM* model to the daily averaged PM_x ionic composition of the spring campaign.

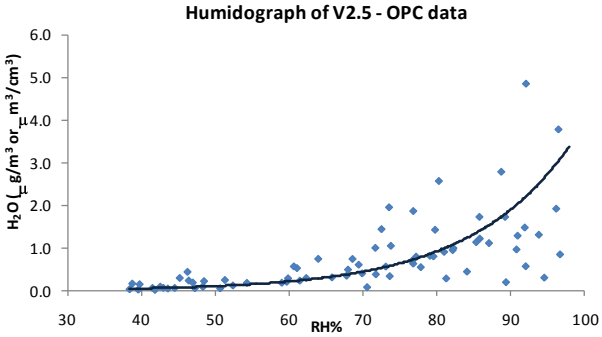

Figure 2. Humidograph for $V_{2.5}$ (particle volume obtained by particles with diameter less than 2.5 µm) for the spring campaign, as calculated from tandem-OPC system data.

Both experimental and modeling data evidenced 65% of relative humidity (RH) as the moisture of the beginning of the hygroscopic growth of particles. Daily cycle of the deliquescence relative humidity will be discussed. As RH in data centres is controlled and kept lower than 60%, these results avoid corrosion hazards due to particle hygroscopicity.

Aerosol particles are ubiquitous in the atmosphere. Their effect on the global climate has not yet been resolved fully. The particles also cause adverse health effects to the human population. These various consequences depend on aerosol particle size as well as their composition. Particle size and hygroscopicity (ie how particles behave as a function of relative humidity, RH) has a crucial role governing their ability to participate in the cloud processes and determine their fate in human airways.

With a Volatility Hygroscopicity Tandem Differential Mobility Analyzer (VH-TDMA) we can study the volatility and hygroscopicity of aerosol particles, as well as the hygroscopicity of the various evaporation stages of particles. This study represents the results of the VH-TDMA measurements in CalNex 2010 campaign.

The operation principle of the VH-TDMA is as follows (e.g. Johnson et al. 2004, Villani et al. 2008). The VH-TDMA developed in this study uses three Vienna type Differential Mobility Analyzers (DMAs), marked as DMA-1, DMA-2a and DMA_2b. A monodisperse fragment is separated from dried aerosol population with DMA1 and led to DMA-2a and DMA-2b operated in parallel. The sample is either passed directly to the second DMAs, or passes through a thermal denuder, using a solenoid valve. DMA-2a measures the dry size and DMA-2b measures the size after the aerosol is humidified. A full measurement cycle for a certain size with a certain denuder temperature and RH consist of a size distribution scan with and without the thermal denuder. TSI CPC-3772 and CPC-3010 are used to detect the particles passing DMA-2a and DMA-2b, respectively.

The VH-TDMA was located in a R/V Atlantis reseach vessel during the CalNex campaign from May 14th to June 8th. R/V Atlantis sailed near the coast of California from San Diego to San Francisco. During the cruise, various types of aerosols were encountered and measured from polluted urban aerosol to clean marine aerosol. Also sea salt particles produced in situ by bubbling seawater with specially constructed raft were measured.

As an example, in figure 1 is presented the hygroscopic and volatility growth factors (HGF and VGF recpectively), and hygroscopic growth factors of particles after passing through the thermal denuder (VHGF). It shows the growth factor distributions of 100 nm particles of polluted urban aerosol at 90% RH. The mode with the HGF around 1.6 are most likely ammonium sulfate particles (HGF >1.6 at RH 90%) with some less hygroscopic contaminants. Ammonium sulfate particles disintegrates at higher temperatures (>150°C); this is clearly visible in the figure. The mode with the HGF around 1.1 is made of either black carbon or fresh organic aerosol particles. Black carbon particles are non-volatile and the volatility of organic particles depends on the composition.

The VH-TDMA has proven to be an especially useful instrument for detecting the external mixing of an aerosol population, which can be seen in figure 1.

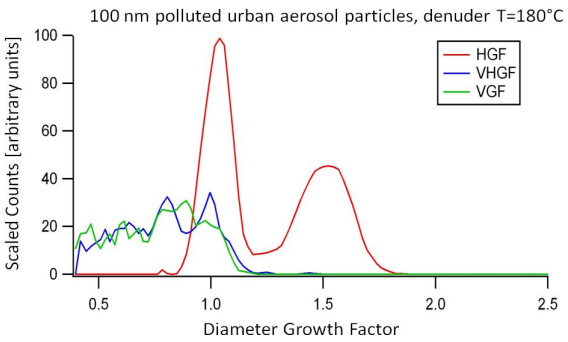

Figure 1. Hygroscopic Growth Factors (HGF), Volatility Growth Factors (VGF) and Hygroscopic Growth Factors of particles after passing through the thermal denuder (VHGF) of polluted urban aerosol at RH of 90%.

The assessment of the climatic impacts and adverse health effects of atmospheric aerosol particles requires detailed information on particle properties. However, very limited information is available on the morphology and phase state of secondary organic aerosol (SOA) particles. The physical state of particles greatly affects particulate-phase chemical reactions, and thus the growth rates of newly formed atmospheric aerosol. Thus verifying the physical phase state of SOA particles gives new and important insight into their formation, subsequent growth, and consequently potential atmospheric impacts.

According to our recent study, biogenic SOA particles produced in laboratory chambers from the oxidation of real plant emissions as well as in ambient boreal forest atmospheres can exist in a solid phase in size range > 30 nm (Virtanen et al., 2010). Here, we extend previously published results to diameters in the range of 17-30 nm. The physical phase of the particles is studied by investigating particle bounce properties utilizing electrical low pressure impactor (ELPI). We also investigate the effect of estimates of particle density on the interpretation of our bounce observations. The observed bounce behavior is also, related to the chemical composition characterized by AMS.

According to the results, particle bounce clearly decreases with decreasing particle size in sub 30 nm size range (Virtanen et al., 2011). The decreasing bounce can be caused by the differences in composition and phase of large (diameters greater than 30 nm) and smaller (diameters between 17 and 30 nm) particles.

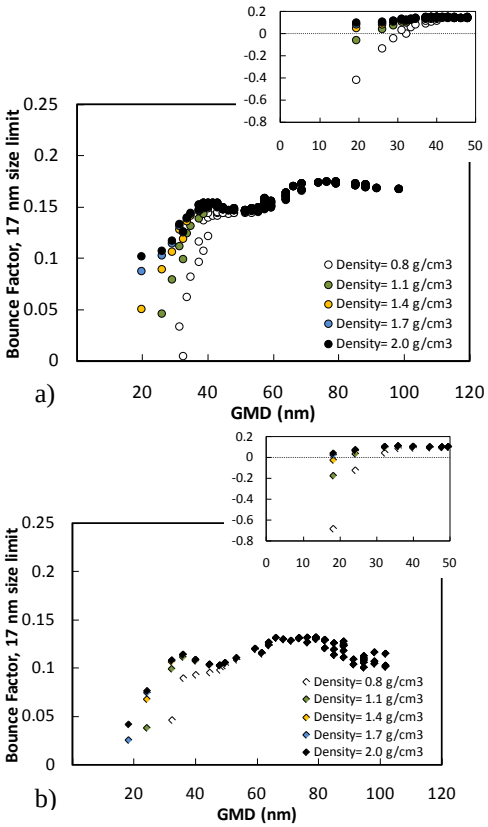

Figure 1. Calculated bounce factors for the 17 nm size limit measured for a) O_3 initiated oxidation and b) OH dominated oxidation in presence of SO_2. Density values 0.8 - 2 g/cm^3 were used in calculations. Insets in the upper right corners of figures a and b show details in bounce factor values for the smallest particles.

Elemental Composition of the Atmospheric Aerosol in the Central Amazon Basin.

Andrea A. Arana[1], Paulo Artaxo[2]

[1] Instituto Nacional de Pesquisas da Amazônia - INPA, CEP 69060-001, Manaus, AM, Brazil
[2] Instituto de Física, Universidade de São Paulo, CEP 05508-900, São Paulo, SP, Brazil.
Keywords: Amazon, Atmospheric aerosol, Atmospheric chemistry
Presenting author email: artaxo@if.usp.br.

The elemental composition of atmospheric aerosols in central Amazon, a remote region with little influence of anthropogenic activities was studied in order to investigate the sources and processes that regulate aerosol concentrations in Amazonia. Aerosols are important because they affect the biogeochemistry cycles and the atmospheric radiation budget, besides having important effects on the formation and development of clouds. Measurements of elemental composition of aerosols were done in Central Amazonia, in two locations: the biological reserve (Rebio) Cuieiras - Manaus and in Balbina. They were compiled and analysed jointly in an attempt to find a regional identity of the biogenic natural aerosol in the central region of the Amazon Basin.

Stacked Filter Unites (SFU) was used to collect PM10 aerosol samples. Fine mode aerosol ($PM_{2.5}$, less than 2.5 μm) and coarse mode (2.5< dp<10 μm) were collected in Nuclepore filters. The filters were analysed for mass, equivalent black carbon (EBC) and trace elements. Particle Induced X-ray Emission (PIXE) were used to measure about 22 trace elements from Na to Pb. Multivariate statistical techniques such as principal factors, absolute principal factors and cluster analysis of the aerosol chemical composition were performed in order to obtain information on sources and processes. A very large data set of more than 6 years continuous sampling was used in this study.

Atmospheric processes that determine the chemical composition of aerosol particles, like the long range transport of Saharan dust and marine aerosol, biogenic emissions during the rainy season and biomass burning emissions most pronounced during the dry season were identified. The Hysplit model was used to calculate back trajectories and confirm the transport of Sahara dust to the Amazon during the rainy season.

Our results show a similar elemental composition for both sites and hence a homogeneous elemental signature, with very low concentrations. During the rainy season the mean concentration of fine particulate matter is 1.60 $\pm$ 0.92 μg/m^3 at Manaus and 3.4 $\pm$ 1.7 μg/m^3 at Balbina, while that of coarse mode is 6.2 $\pm$ 2.0 μg/m^3 at Manaus and 7.8 $\pm$ 3.0 μg/m^3 at Balbina. In the dry season, the mean concentration of particulate matter in the fine mode is 4.8 $\pm$ 2.4 μg/m^3 at Manaus and 5.4 $\pm$ 3.0 μg/m^3 at Balbina, while in the coarse mode is 6.0 $\pm$ 2.5 μg/m^3 at Manaus and 6.7 $\pm$ 2.0 μg/m^3 for Balbina.

Receptor modelling shows that three main factors for the fine mode were identified and can be qualitatively described as: (1) natural biogenic emission associated with biomass burning with high loadings of EBC, and the elements Br, S, Cl, K and Zn; (2) soil dust particles with high loadings of the elements Ti, Fe, Al, Si, Mn and Ca; (3) biogenic natural emission with high loadings for P. The natural biogenic emissions do not occur in the same factor as the biomass burning emissions. A component of SOA is present in the first and third components, with high amount of organic matter.

For the coarse mode, it was possible to identify 3 factors: (1) soil dust due to high loading of the elements Ti, Al, Fe, Si, Mn and Ca; (2) biogenic emission due to high loading of the elements K, Zn, P, S, associated with EBC and (3) a component of long-range transport probably marine aerosol, represented by the high loadings for the element Cl. This third component represent air masses from the tropical Atlantic, after crossing about 2.000 km of pristine forests, carrying particles of sea salt origin, mixed with biogenic aerosols.

Using Absolute Principal Factor Analysis it is possible to calculate the absolute contributions for each element for each factor in the fine and coarse particulate matter. At Manaus the soil dust component presented 52.1 ng/m^3 of Al, 106.4 ng/m^3 of Si, 22.1 ng/m^3 of Fe and 0.56 ng/m^3 of P. For the biogenic component, 4.81 ng/m^3 of Al, 10.8 ng/m^3 of Si, 147 ng/m^3 of FPM and 1.5 ng/m^3 of P were found, while for the biomass burning component it was 145 ng/m^3 of S, 64.0 ng/m^3 of K and 204 ng/m^3 of EBC. For the coarse particulate matter, the soil dust component presented 52.8 ng/m^3 of Al, 113 ng/m^3 of Si and 25.9 ng/m^3 of Fe, while for the biomass burning component it was 56.8 ng/m^3 of S, 49.6 ng/m^3 of BC and 26.2 ng/m^3 of P.

It is important to emphasize that the significant concentrations of Al, Si, Ti, Mn and Fe observed in Central Amazonia from Saharan dust transport episodes occurred despite the large travel distance and strong aerosol deposition processes due to high rainfall rates typical of the Amazon. The composition of aerosols in Manaus and Balbina are quite similar, showing that natural biogenic and biomass burning aerosol have signatures that can be retrieved using long-term sampling programs like this study.

Urban air pollution is due to emission of gases and aerosol in the atmosphere from numerous anthropogenic sources. The pre existing aerosols provide enough surface area for toxic and non toxic pollutant to condense over its surface. In last two decades health-related issues are statistically associated with worsening air quality due to presence of aerosol (Delfino *et al.* 2011). Recent studies (Delfino *et al.* 2011) on exposure to combustion-related (predominantly from traffic) particles and increase in risk of myocardial ischemia, systemic inflammation and blood pressure have revealed the importance of aerosol sources, size and composition in health study.

Aerosol also effect the local air quality and climate. Climate impacts of aerosol include change in energy budget of Earth-Atmosphere system and modification of cloud microstructure leading to alteration of circulation pattern and hydrological cycle.

Recently, the change in energy budget and extremes of precipitation pattern resulting in floods and draughts in Indian region were linked with the size and composition of aerosol (Ramanathan *et al.,* 2005). However, a lot need to be done to establish a clear statistical link between human health, climate, source, size and composition of aerosol.

Water-soluble ions and elements in atmospheric aerosols are reported more commonly for various cities of India. However, very few such efforts (Srivastava *et al.*, 2008) have been made for Delhi city. Delhi the capital of India is one of the dangerously congested and overcrowed (population of Delhi in 2007 was around 17 million) city. Many anthropogenic sources including 3 coal power plants and industries in 13 estates are the threat to air quality of Delhi city and near capital region (NCR). Apart from this, the traffic in Delhi has already been increased to alarming level. The weather of Delhi characterized by hot summer (max. temp. 48 °C) and cold winter (min temp. 2 °C) associated with dust and dense foggy events respectively. The extremes in weather are also believed to play a critical role in aerosol distribution. Therefore, present study has focused on the measurement and characterisation of aerosol for water soluble ions and trace metals during winter and summer season at road site in Delhi. The sources were identified using Positive matrix Factorisation (PMF).

Aerosol mass ($PM_{1.0}$ and $PM_{2.5}$) were collected at two road site near IIT Delhi using impactors developed and calibrated at IIT kanpur (Gupta et. al., 2009). Particles were collected for 10 hrs during day and night time seperately from November 2009 to March 2010. The sampling frequency was 3 days per week including Saturday, Sunday and Monday. Total 39 Samples at Site 1 and 41 samples at Site 2 were collected for both $PM_{1.0}$ and $PM_{2.5}$. Teflon filters with $PM_{1.0}$ mass were subjected to chemical analysis for ions by Ion Chromatography and trace metals by Atomic Absorption Spectroscopy and Inductive Couple Plasma-Optical Emissions Spectrometry. The sources identification and quantification using positive matrix factorisation is in progress.

Average 10 hrs $PM_{2.5}$ concentration on both the sites were significantly maximum in December and January and minimum in March (Table 1). PM1.0 followed the same trend. Night time concentration were always higher than day time. The temperature inversion and atmospheric stable condition above ground resulted in accumulation of aerosol near ground leading to higher concentration during night.

Ions and trace metals contributed ~27 to 57% in various months with expected higher contribution during day time compared to night time. Among anions sulphate, nitrate and chloride are the major contributor. Ammonium and calcium were the major cations obsereved in this study. The presence of calcium, iron and mangnese in significant amount indicated the influence of resuspended dust in aerosol mass. Further identification and quantification of sources will be done using positive matrix factorisation.

In recent years, interest in better understanding the factors affecting the Earth's radiation budget, and hence the global climate has increased considerably. While the effects of greenhouse gases are now fairly well understood, the impact of atmospheric aerosol particles in the radiation budget still has many uncertainties.

The aim of this work is to present 1 year of simultaneous measurements of optical and chemical properties of the aerosol particles obtained in an urban environment in Eastern Spain (Granada, 37.18ºN, 3.58ºW, 680 m a.s.l). The instrumentation used was an integrating nephelometer (TSI, model 3563) to obtain the aerosol scattering coefficient at 450, 550 and 700 nm (σ_{sp}), and an Absorption Photometer (MAAP) operating at 670 nm to derive the aerosol absorption coefficient (σ_{ap}). A detailed description of the instrumentation and experimental site can be found in Lyamani *et al* (2010). Furthermore, two high volume samplers (flow rate 30 m^3 h^{-1}) were used for sampling PM_{10} (CAV-A/MSb) and PM_1 (Digitel DHA-80) using Schleicher and Schuell quartz fibre filters (QF20 150 mm). Once the levels of bulk particulates were obtained, the filters are analyzed in the laboratory for determining the levels of major and trace components following the procedure of Querol *et al* (2001). The sampling period was 24 hours starting at 7:00. There are 47 periods with simultaneous measurements of the four instruments described from March 2006 to February 2007. We have averaged σ_{sp} and σ_{ap} over the sampling periods.

The mass scattering and absorption efficiencies (α_{sp}; α_{ap}) of aerosols are the key parameters used to link aerosol chemical properties and radiation model (Seinfeld and Pandis, 1998). They are determined using concurrent measurements of the aerosol light scattering/absorption coefficient and particle mass.

During the study period, σ_{sp} shows a mean value (± SD) of 61 ± 25 Mm^{-1}, typical of urban areas, and σ_{ap}(550 nm) presents a mean value of 25 ± 10 Mm^{-1}. Both, σ_{sp} and σ_{ap}, exhibit the largest values during winter and the lowest during summer, denoting an increase in the anthropogenic contribution in winter combined with the predominance of mixing layer heights (Lyamani et al, 2010). A very low average value of the single scattering albedo of 0.70 ± 0.07 was calculated, suggesting that urban aerosols in this location contain a large fraction of absorbing material. PM_{10} and PM_1 mass concentrations show a mean value of 43 ± 18 $\mu g/m^3$ and 16 ± 7 $\mu g/m^3$, respectively. The mineral matter (CO_3^{2-}, SiO_2, Al_2O_3, Ca, K, Mg and Fe) is the major constituent in the PM_{10} fraction (more than 40 %). This contribution increases during summer (60 %) when the re-suspension from the ground is higher and the North-African dust outbreaks are more frequent. Organic matter and elemental carbon (OM+EC) contribute the most to the PM_1 fraction (42 %). Levels of OM+EC are mainly due to traffic emissions and domestic heating. The OM+EC levels found in Granada are typical of kerbside stations. Secondary inorganic aerosols -SIA- (NH_4^+, NO_3^- and SO_4^{2-} non marine) account for 18% and 23% of PM_{10} and PM_1 fractions, respectively.

We have estimated α_{sp} and α_{ap} of PM_{10} particles applying the Measurement method (Hand and Malm, 2007) which consists in a simple linear regression of σ_{sp} versus PM_{10} mass concentration. Also, we have performed different approaches of the Multilinear Regression (MLR) method to derive α_{sp} and α_{ap} of fine and coarse particles (FM;CM), and α_{sp} and α_{ap} of the major aerosol constituents (Mineral matter, SIA, Sea salt, OM+EC). This method consists in a multiple linear regression with measured σ_{sp} as the independent variable and the measured mass concentrations for each species as the dependent variables (Hand and Malm, 2007). On the other hand, we have found that the light absorption process is dominated by OM+EC particles so α_{ap} for OM+EC was obtained by the Measurement method. The most important results are shown in Table 1.

Table 1. Mass scattering and absorption efficiencies (m^2g^{-1}).

	PM_{10}	FM	CM	OM+EC	SIA
α_{sp}	1.5±0.5	2.5±0.4	0.5±0.2	2.6±0.3	5.4±0.6
α_{ap}	0.6±0.2	0.8±0.2	0.1±0.1	1.7±0.1	--

Hygroscopicity of aerosol particles at Kosetice background station (Czech Republic) using the HTDMA system

J. Ondráček, P. Vodička, V. Ždímal, J. Schwarz and J. Smolík

Laboratory of Aerosol Chemistry and Physics, Institute of Chemical Process Fundamentals, v.v.i., AS CR, Rozvojová 135, Prague 6, 165 02, Czech Republic
Keywords: HTDMA, hygroscopicity, atmospheric aerosols.
Presenting author email: ondracek@icpf.cas.cz

The ability of submicron aerosol particles to absorb water vapor has a large effect on their physical and chemical properties. The tendency for cloud formation and resulting cloud properties depends on the chemical composition as well as on the size distribution of the aerosol particles. Hygroscopic properties of atmospheric aerosols are of major importance affecting the life cycle of the aerosol and the direct and indirect effects of aerosols on climate (e.g. Swietlicki et al., 2008).

Moreover, water content of atmospheric aerosols affects their optical properties (e.g. the light scattering causing the visibility reduction). Also, the partitioning of semivolatiles between the gas and particulate phase is influenced by the presence of water. Furthermore, the deposition pattern of aerosol particles in the human respiratory tract may significantly change with changing size of aerosol particles, and therefore depends also on hygroscopic properties of aerosol particles.

The hygroscopic growth of aerosol particles can be studied in great detail using the HTDMA (Hygroscopic Tandem Differential Mobility Analyzers) systems (e.g. Swietlicki et al., 2008). The HTDMA system is one of the solutions for the online and in-situ measurements of hygroscopic properties of atmospheric aerosols. Generally, the HTDMA systems are suitable for long time measurements at background sites or at sites with slow and small changes in chemical composition and size distribution of the atmospheric aerosol. The humidification and/or drying system (the conditioning system) is one of the key parts of such instrument.

The conditioning system as well as the drying system in the LACP HTDMA is based on the set of Nafion driers and humidifiers. The aerosol sample reaches the desired humidity using the Nafion humidity exchanger. The conditioning (purge) clean air of the Nafion humidity exchanger comes up from the automatic valve system controlled with PID controller. The valve system controls and combines the amount of the dried and the humidified clean air coming from the lines equipped with Nafion dryer and Nafion humidifier, respectively.

The LACP HTDMA was deployed at Kosetice background station from beginning of May 2008 till the end September 2009 within the frame of EUSAAR project. The instrument was in operation during the whole period with some gaps measuring 7 different dry particle size diameters between 22 nm and 225 nm. One scan for each particle size takes 10 minutes (up and down scan) and 20 seconds (changing the particle size), thus the time resolution for the whole size range is 1 hour, 12 minutes and 20 seconds. The problems leading to the data gaps were usually caused by malfunctioning of the RH conditioning system (not stable RH in DMA2) and/or low Nafion drier efficiency (too high RH in DMA1).

Monthly averages of resulting growth factors for individual particle sizes can be seen from Fig. 1. The figure shows the increasing water uptake with increasing particle sizes. This is most probably caused by increasing content of hydrophilic inorganic salts in larger particles. Furthermore, the particles in accumulation mode are more aged and thus their surface is more oxidized, which leads to higher hygroscopicity. Seasonal variations of growth factors show the increasing hygroscopicity of aerosol particles during the spring season.

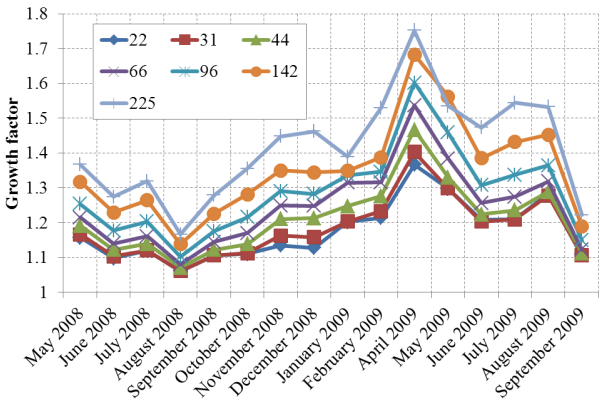

Figure 1. Monthly growth factor for individual particle sizes at Kosetice station.

The impact of atmospheric aerosol particles on the climate and regional air quality depends on e.g. their local and regional source strengths (e.g. O'Dowd, 2001). Coastal new particle formation is occurring frequently (O'Dowd and Hoffmann, 2005, Ehn et al 2010a). The physical and chemical character of the atmospheric ion population reflects the regional environment. The aim of this study was to gain insight into participating compounds in both coastal and marine particle formation events by looking in detail the chemical composition of atmospheric ions at Mace Head during MaCLOUD Inc project in December, 2010. A unique location of Mace Head station with strong costal tides makes it possible to study the various nucleation pathways. We also looked into the role of halogens as well as organic ions in the burst-like new particle events at Mace Head despite the low concentrations.

We quantified the atmospheric ion population both in terms of the chemical composition and their physical character. We used an Atmospheric Pressure interface- time-of-flight mass spectrometer (APi-TOF, Junninen et al. 2010, Ehn et al. 2010b), which can probe the chemical composition of naturally charged ions in atmosphere. The data indicate that the ion composition during the new particle formation bursts was dominated by iodine, iodic acid and their clusters. Also bisulphate ion was present in the ion population.

We also provided a detailed physical characterization of the ion population using an Air ion Spectrometer (AIS, Mirme et al. 2007). Furthermore we deployed a Particle Size Magnifier (PSM, Vanhanen et al. 2010), which reveals the concentration of both charged and neutral particles in sub-3 nm particle size. These instruments provided data in the sub-3 nm particle size, which is the size where the gas-to-particle conversation occurs (Kulmala et al. 2007).

An exemplary plot on the chemical and physical characterization is presented in Figure 1. A more detailed data analysis is currently underway and the results presented in this short report need to be considered as preliminary. However, already the vast amount of data that we gathered during the MaCLOUD experiment will definitely improve our understanding about the marine and coastal aerosol particles and ions.

The next MaCLOUD experiment will be held in May 2011. Furthermore, in collaboration with the NUIG, we operated the AIS instrument at Mace Head during the period in between the campaigns in order to capture the temporal variability of the ion population.

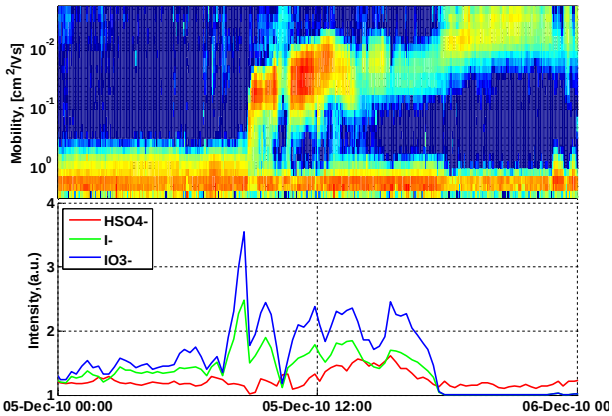

Figure 1. Number size distribution of ambient ions characterized with the AIS during a selected measurement day (top panel) and time traces for ambient selected ambient ions determined with the APi-TOF.

The MEGAPOLI project is an international scientific project to study the interaction between megacities (population > 5 million), emissions, pollution and climate effects. The goal is to link the spatial and temporal scales that connect local emissions, air quality and weather with global atmospheric chemistry and climate. In the four major European Union population areas (Paris, London, Rhine-Ruhr and Po Valley), special emphasis was put on the urban and street scale emissions and air quality besides the focus on the regional and global ones. In Paris, France, two intensive measurement campaigns were performed in summer and winter to improve the quantification of primary and secondary aerosol sources in a large urban agglomeration and in its plume.

We measured the elemental composition of aerosols with a Rotating Drum Impactor (RDI) at an urban (Laboratoire de l'Hygiene de la Ville de Paris, LHVP) and a suburban site (IPSL/SIRTA) in July 2009 and January/February 2010. The RDI sampled aerosol particles with a volumetric flow of 16.6 l min^{-1} (1 m^3 h^{-1}) and particle size segregation in the ranges of 10-2.5 µm, 2.5-1.0 µm and 1.0 to approximately 0.1 µm (Richard et al. 2010). Sampling time was 2 hours. Subsequently, the elemental composition was analyzed with synchrotron radiation induced X-ray fluorescence spectrometry (SR-XRF).

These measurements can be used to document the spatial and temporal variability in aerosol composition and properties near primary emission sources and in air masses entering or leaving the agglomeration.

A first comparison is made between potassium (K) and sulphur (S) contributions in the two largest sizes and for both locations. Figure 1 shows the data of the winter measurements at the LHVP site, while Figure 2 shows the data at the IPSL/SIRTA site. The data shown is not calibrated yet. Subsequent steps involve the subtraction of blank spectra to reduce the influence of scattering of the surrounding material in the SR-XRF setup, perform a relative calibration to correct for the increase in fluorescence yield with increasing atomic number Z, and carry out an absolute mass calibration to convert the raw data into elemental mass concentrations (Bukowiecki et al. 2005; Richard et al. 2010).

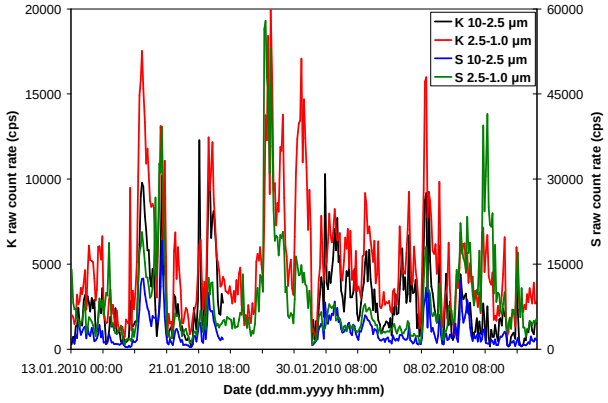

Figure 1. Selection of two-hourly size-segregated elemental amounts for potassium (K) and sulphur (S), measured by RDI-SR-XRF at LHVP in Paris (France).

Figures 1 and 2 show that at both locations most of the time the relative contribution of potassium and sulphur in the PM 2.5-1.0 µm exceeds the contribution in the largest size range. The contributions in the smallest size range appear even larger for these elements (not shown).

We will report on the elemental composition of aerosols, the emission sources analyzed with positive matrix factorization and will provide information on the local versus regional particulate sources in Paris.

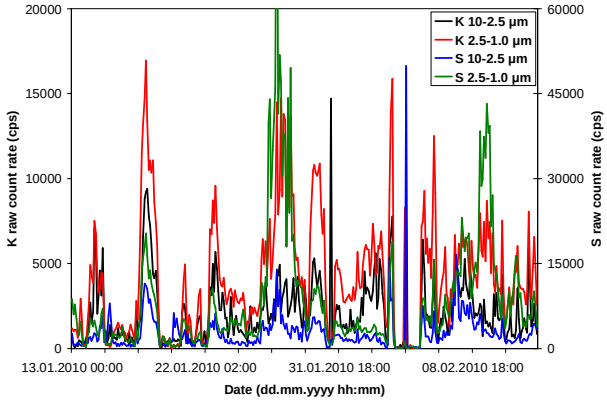

Figure 2. Selection of two-hourly size-segregated elemental amounts for potassium (K) and sulphur (S), measured by RDI-SR-XRF at IPSL/SIRTA in Paris (France).

Aerosol physical and chemical properties were measured in two sites in Amazonia. The clean site is at Central Amazonia and is located in a pristine Amazonian forest site. A second sampling site is located in Porto Velho, Rondonia, an area strongly affected by biomass burning emissions. Long term measurements, from February 2008 are being carried out in these two sites, as part of the EUCAARI (European Integrated Project on Aerosol Cloud Climate and Air Quality interactions) and AEROCLIMA (Direct and indirect effects of aerosols on climate in Amazonia and Pantanal) projects. The dataset obtained encompass the first long term aerosol measurements ever performed in Amazonia, elucidating the differences between the biogenic aerosol population naturally released by the forest metabolism and the anthropogenic aerosols brought to the ecosystem by outer sources as well as regional biomass burning emissions.

In the pristine central Amazonia, measurements were taken at the Cuieiras forest site, tower TT34, with coordinates 2°35'40"S and 60°12'33"W, above the canopy (45m), under dry conditions (RH<40%). A MAAP 5012 absorption photometer in series with a nephelometer (TSI 3563) was used to measure aerosol absorption and scattering, respectively. Scattering coefficients were corrected for truncation errors. Observations were adjusted to 1000 mbar and 0^{o}C. Aerosol size distributions were measure using a Lund DMPS system, as well as a TSI SMPS system. Aerosol composition, and several trace gases that helps to characterize aerosol sources were also measured.

In Rondonia, a sampling station was installed close to the city of Porto Velho, in the "Parque Natural de Porto Velho" at coordinates (8,69^{o} S; 63,87^{o} O). This region have with important land use change and biomass burning emissions. A MAAP 5012 absorption photometer and an Ecotech Aurora 3000 nephelometer are used to measure aerosol absorption and scattering. A TSI SMPS measure the aerosol size distribution continuously. Diffusion dryers are used to keep the relative humidity below 40%.

In the pristine Amazonian atmosphere, aerosol scattering coefficients ranged between 1 and 200 Mm^{-1} at 450 nm, while absorption ranged between 1 and 20 Mm^{-1} at 637 nm. A strong seasonal behavior was observed, with greater aerosol loadings during the dry season (Jul-Nov) as compared to the wet season (Dec-Jun). Although the forest site is locally well preserved, it receives the influence of regional biomass burning emissions during the dry season.

During the wet season in Manaus, aerosol scattering (450 nm) and absorption (637 nm) coefficients averaged, respectively, 14 ± 22 and 0.9 ± 0.8 Mm^{-1}. Both optical coefficients were greatly increased during the dry season, averaging 58 ± 58 Mm^{-1} and 4.1 ± 3.8 Mm^{-1}, correspondingly. Angstrom exponents for scattering were lower during the wet season (1.6 ± 0.4) in comparison to the dry season (1.9 ± 0.2), which is consistent with the shift from biomass burning aerosols, predominant in the fine mode, to biogenic and dust aerosols, predominant in the coarse mode. Single scattering albedo, calculated at 637 nm, did not show a significant seasonal variation, averaging 0.86 ± 0.06 and 0.86 ± 0.04, respectively for wet and dry season, even with that large variation in aerosol sources and magnitude of scattering and absorption coefficients.

In Porto Velho, even in the wet season it was possible to observe a strong impact from anthropogenic sources. Biomass burning emissions in the dry season. $PM_{2.5}$ aerosol concentrations of about 300 ug/m² were measured in August and September for most of the years. AOT values at 550 nm above 3 are frequently observed in Porto Velho with AERONET sunphotometers. Black Carbon were measured at 20 ug/m³ in the dry season, indicating strong aerosol absorption. Aerosol light scattering above 300 Mm^{-1} were measured.

This work presents a general description of the aerosol optical properties in Amazonia, both during the Amazonian wet season, when the aerosol population is dominated by particles of biogenic origin, and during the dry season, when there is a strong influence of biomass burning emissions. It is important to describe accurately the optical behavior of these particles in order to assess the impact of anthropogenic changes on the regional climate.

Strong effect of aerosols on the CO_2 flux in the central Amazon

Glauber .G. Cirino[1], Paulo Artaxo[2] and Rodrigo Souza[3]

[1]National Institute of Amazonian Research - INPA, CEP 69060-001, Manaus, AM, Brazil
[2]Institute of Physics, University of São Paulo, CEP 05508-900, São Paulo, SP, Brazil

Keywords: Amazon, atmospheric aerosol, radiation balance, diffuse radiation, carbon fluxes,
Presenting author email: artaxo@if.usp.br

Amazonia is a strong pool in the terrestrial carbon. The carbon uptake or losses are important globally and affect the global carbon balance. During the dry season, smoke from fires dominates the aerosol picture in a large area of the Amazonian forest. Very high aerosol optical thicknesses (AOT) are observed (values of 3-4 at 550 nm) as a result of aerosol particles emitted by biomass burning. During the rainy and transition seasons, the values of AOT are very small (less than 0.08), but increases significantly during the dry season. The net radiation at the surface and even the uptake of carbon by the forest are strongly affected. A large increase in the ratio of direct to diffuse radiation is observed, with a dominance of diffuse radiation at very high AOT.

In this study, we analyzed the CO_2 flux and Net Ecosystem Exchange (NEE) of CO_2 as a function of the concentration of aerosols in two dense forests areas in the Amazon which are part of the Large Scale Biosphere Atmosphere Experiment in Amazonia (LBA). The aerosol optical thickness (AOT) was measured with MODIS (MOD04L2), which were previously validated with AERONET sun photometers operated in Amazonia. CO_2 fluxes were measured with fast response eddy covariance method. A model of clear-sky irradiance was developed from a long time series of observed data (1999-2009) to calculate a variable called relative irradiance (f), used to express the amount of solar radiation due to the presence of extinction of aerosols and clouds in the region.

Overall net absorption of carbon by forest (NEE of CO_2) varied not only with the concentrations of aerosols, but also with cloud cover, solar elevation angle (ASZ) and other parameters. In the rainforest of the K34 Tower located in Manaus Fig.(1a) and Rebio Jaru in Rondônia RBJ Ji-Paraná Fig. (1b) an average increase of 22% and 30% in the NEE was observed when the values of AOT ranged from 0.10 (background in the Amazon) to 0.70 (K34) and 1.8 (RBJ), respectively. For larger reductions of the incident radiation, the SNE was observed to be reduced to values close to zero. The increase of 20 and 30% of NEE was attributed to increased diffuse fraction of solar radiation in relation to their direct fraction.

Important influences on the observed temperature and relative humidity induced by the interaction of radiation with the high aerosol load was observed in both forest areas. In view of the transport of aerosols over long distances during fires, significant changes in the carbon flux may be occurring in large areas of Amazonia. The influence of aerosols on the CO_2 flux and NEE of CO_2 represents a very important effect for the Amazonian ecosystems and have important influence in the global carbon budget.

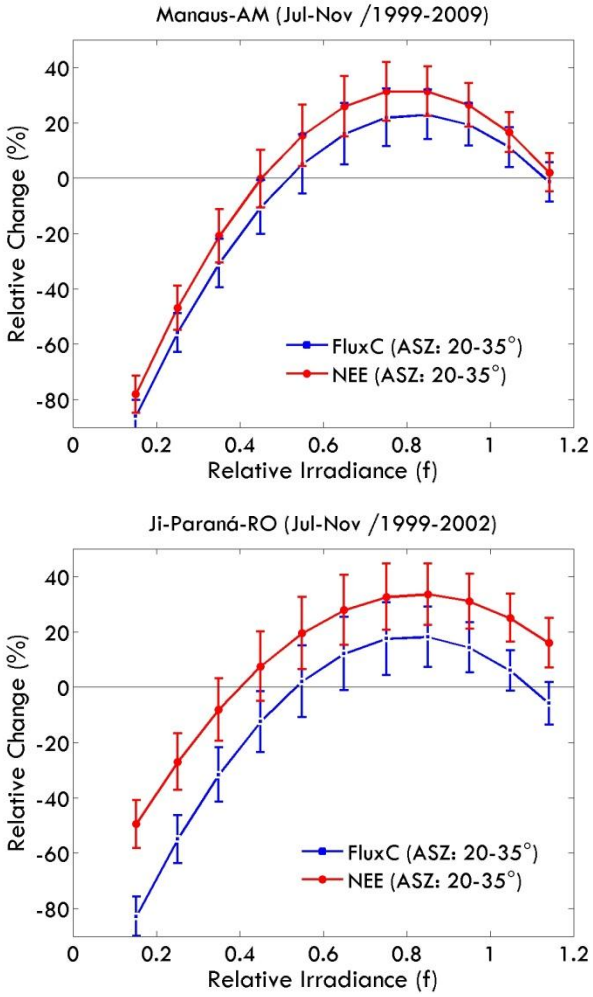

Figure1. Relative change of carbon fluxes and NEE (%) as a function of the relative irradiance (*f)* for 20-35° (ASZ) - Solar Zenithal Angle Interval for the Manaus (K34) (a) and Rondonia (RBJ) (b) sites.

We thank FAPESP, CNPq, CAPES, INPA/CLIAMB and the LBA Central Office for financial and logistical support.

Aerosol and precipitation chemistry measurements in a remote site in Central Amazonia: the role of biogenic contribution

T. Pauliquevis[1], P. Artaxo[2], L. Lara[3] and M.L. Antunes[4]

Presenting author email: artaxo@if.usp.br

A long-term (2-3 years) measurement of aerosol and precipitation chemistry was carried out in a remote site in Central Amazonia, Balbina, (1º55'S, 59º29'W, 174 m above sea level), about 200 km north of Manaus city. Aerosols were sampled using stacked filter units (SFU), which separate fine ($d < 2.5$ μm) and coarse mode (2.5 μm $< d < 10.0$ μm). Filters were analyzed for particulate mass (PM), black carbon (BC) and elemental composition by Particle Induced X-Ray Emission (PIXE). Rainwater samples were collected using a wet-only sampler and samples were analyzed for pH and ionic composition, which was determined using ionic chromatography (IC).

The results showed a predominant contribution from biogenic aerosols, mostly concentrated in coarse mode, which comprised up to 81% of PM10 concentration during the wet season. Natural biogenic aerosol also dominates the fine mode in the wet season, with very low concentrations (average 2.2 μg/m³). Large-scale transport of smoke from biomass burning was the second most important contribution, reaching 77% of fine mode particulate mass during the dry season. Soil dust was responsible by a minor fraction of the aerosol mass (less than 17%), and were mainly due to Saharan dust transport events that typically occurred in the period April-May.

In parallel, we run measurements of rainwater chemistry to investigate potential connections between aerosol and precipitation chemistry. The conclusion was that, in a similar way of aerosols, rainwater chemistry is also controlled by biogenic emissions. The volume-weighted mean (VWM) pH was 4.90, and the most important contribution to acidity was from weak organic acids. However, an important difference was that acetic acid predominated over formic acid, which is the opposite of the most common results obtained in pristine areas (Keene et al., 1983; Sanhueza et al., 1991, 1992; Chebbi and Carlier, 1996), where formic acid is the most common organic acid. In spite of this disagreement, previous studies dealing with precipitation chemistry in Central Amazonia (Andreae et al. 1988, 1990; Williams et al., 1997) show discrepant results with respect to the organic acidity partitioning, and this study brings new data to this debate.

Deposition rates for major species did not differ significantly between dry and wet season, except for NH_4^+ and acetate, which had smaller deposition rates during dry season. The long-range transport of sea salt and biogenic particles was observed both in aerosols and rainwater composition. However, while biomass burning emissions were clearly identified in the aerosol component, it was not possible to discern any presence of biomass burning emissions in rainwater chemistry. A possible explanation for this fact was the absence of a common tracer of biomass burning both in aerosols and rainwater, which makes the detection of such connection not clear.

The results showed here indicate that in Amazonia it is still possible to observe pristine atmospheric conditions, relatively free of anthropogenic influences, specially during the wet season.

This research was partially funded by FAPESP (grants 00/10677-8; 01/02968-8) and Instituto do Milenio LBA.

[3]Institute of General Botany, Johannes Gutenberg University, Johannes-von-Müller-Weg 6, 55128 Mainz, Germany

Keywords: Fungi, Bioaerosol, DNA
j.frohlich@mpic.de

Fungal spores can account for large proportions of air particulate matter (Elbert *et al*., 2007), and they may potentially influence the hydrological cycle and climate as nuclei for water droplets and ice crystals in clouds, fog, and precipitation. Moreover, some fungi are major pathogens and allergens. However, the diversity and biogeographic distribution of fungi in air particulate matter is hardly known, although air is one of the main media for the dispersal of microorganisms connecting all ecosystems at the Earth's surface.

In our study, air filter samples were analyzed for the presence of fungal deoxyribonucleic acid (DNA). All amplification products were cloned and investigated by restriction fragment length polymorphism analysis. Selected clones were sequenced, and the obtained DNA sequences were blasted in the National Center for Biotechnology Information (NCBI) database for taxonomic attribution to different phyla, classes, and species (Després *et al.,* 2007).

In continental air of central Europe (Mainz, Germany) we found pronounced differences in the relative abundance and seasonal cycles of various groups of fungi in coarse and fine particulate matter, with more plant pathogens in the coarse and more human pathogens and allergens in the respirable fine particle fraction (< 3 µm; Fröhlich-Nowoisky *et al.,* 2009). In particular, we found that the species richness of *Basidiomycot*a (club fungi) in continental air is almost by a factor of two higher than that of *Ascomycota* (sac fungi), which may be due to one or both of the following reasons: an enrichment of *Basidiomycot*a in the atmosphere (higher proportion at the atmosphere-biosphere interface, more efficient release of spores) or an underestimation of the species richness of *Basidiomycot*a in the biosphere (bias of cultivation techniques and PCR primers applied in earlier studies).

Ongoing investigations of aerosol samples collected at different locations and climatic zones around the world (e.g. Austria, Brazil, China, Puerto Rico, Taiwan) show pronounced biogeographic patterns in the species richness of *Basidiomycota* and *Ascomycota* and first insights into the global atmospheric distribution of fungal diversity.

Our results clearly demonstrate the presence of geographic boundaries in the global distribution of microbiotic taxa in air. This may be an important difference between the "blue ocean" and "green ocean" regimes in the formation of clouds and precipitation (Andreae *et* al., 2004, Pöschl *et* al., 2010), for which fungal spores can act as nuclei. Our findings also suggest that air flow patterns and the global atmospheric circulation are important for the evolution of microbial ecology and for the understanding of global changes in biodiversity.

c.ruzene@mpic.de

Biogenic aerosols are relevant for the Earth system, climate, and health on local, regional, and global scales. Up to now, however, little is known about the diversity and biogeography of airborne microorganisms although air is one of the main media for the dispersal of microorganisms connecting all ecosystems at the Earth's surface.

Peronosporomycetes (Oomycota) are a diverse group of eukaryotic microorganisms that include saprophytes and pathogens of plants, animals, and microbes (García-Blázquez et al., 2008; Philips et al., 2008). Despite having fungus-like characteristics, *Peronosporomycetes* are not true fungi but are related to algae instead and belong to the Kingdom Stramenopila. Several species like downy mildews (García-Blázquez et al., 2008) have a profound negative impact on agriculture and thus also on crops that are used as potential renewable energy sources.

In our study, air filter samples collected at different locations and climatic zones around the world were analyzed for the presence of *Peronosporomycetes* deoxyribonucleic acid (DNA). All PCR products were cloned and investigated by restriction fragment length polymorphism analysis. Selected clones were sequenced, and the obtained DNA sequences were blasted in the National Center for Biotechnology Information (NCBI) database for taxonomic attribution to different phyla, classes, and species (Després *et al.,* 2007, Fröhlich-Nowoisky et al., 2009).

A one year study (March 2006 – May 2007) of continental air of central Europe (Mainz, Germany) shows pronounced differences in coarse (>3µm) and fine particulate matter (<3µm). *Peronosporomycetes* DNA was found in 100% of the coarse particle samples but not in the respirable fine particle fraction, which may be explained by the spore sizes (>10µm). *Peronosporomycetes* DNA was found throughout the year which may be important for agriculture disease management.

Moreover, investigations of aerosol samples collected at different locations and climatic zones around the world (e.g. Austria, Brazil, China, Puerto Rico, Taiwan) give first insights into the global atmospheric distribution of *Peronosporomycetes* diversity.

Autofluorescence of Bioaerosol Standards – Characterization by Fluorescence Spectroscopy and Microscopy

Pöhlker, Christopher[1], Huffman, J. Alex[1], Fröhlich-Nowoisky Janine[1], and Pöschl, Ulrich[1]

[1]Max Planck Institute for Chemistry, Biogeochemistry Department, Mainz, 55128, Germany
Keywords: Bioaerosols, Fluorescence, Pollen, Fungal spores, Bacteria.
Presenting author email: c.pohlker@mpic.de

Primary biological aerosol particles (PBAP) such as pollen, fungal spores, bacteria, biogenic polymers and debris from larger organisms are known to influence atmospheric chemistry and physics, the biosphere and public health. PBAP account for up to ~30% of fine and up to ~70% of coarse particulate matter in urban, rural and pristine environment and are released with estimated emission rates of up to ~1000 Tg/a (Elbert, 2007).

Continuous measurements of the abundance, variability and diversity of PBAP have been difficult until recently, however. The application of on-line instruments able to detect autofluorescence from biological particles in real-time has been a promising development for the measurement of PBAP concentrations and fluxes in different environments (Huffman, 2010; Pöschl, 2010). The detected fluorescent biological aerosol particles (FBAP) can be regarded as a subset of PBAP, although the exact relationship between PBAP and FBAP is still being investigated.

Autofluorescence of FBAP is usually a superposition of fluorescence from a mixture of individual fluorescent molecules (fluorophores). Numerous biogenic fluorophores such as amino acids (e.g., tryptophan, tyrosine), coenzymes (e.g., NAD(P)H, riboflavin) and biopolymers (e.g., cellulose) emit fluorescent light due to heterocyclic aromatic rings or conjugated double bonds within their molecular structures. The tryptophan emission peak is a common feature of most bioparticles because the amino acid is a constituent of many proteins and peptides. The influence of the coenzymes NAD(P)H and riboflavin on the autofluorescence of bacteria can be regarded as an indicator for bacterial metabolism and has been utilized to discriminate between viable and non-viable organisms (Lakowicz, 1999). However, very little information is available about other essential biofluorophores in fungal spores and pollen.

In order to better understand the autofluorescence behavior of FBAP, we have used fluorescence spectroscopy and fluorescence microscopy to analyze standard bioparticles (pollen, fungal spores, and bacteria) as well as atmospherically relevant chemical substances. We found varying levels of fluorescent emission and significant differences in the spectral properties of major PBAP classes. The combination will support the quantitative interpretation of data obtained by real-time FBAP instrumentation.

Allergenic Asteraceae in urban air: DNA analysis and relevance for human health

I. Germann[1,2], J. Fröhlich-Nowoisky [1], U. Pöschl[1],and V. R. Després[3]

[1]Biogeochemistry, Max Planck Institute for Chemistry, P.O. Box 3060, D-55020 Mainz, Germany

Keywords: Bioaerosols, DNA, Ragweed *(Ambrosia artemisiifolia)*, Mugwort (*Artemisia vulgaris)*

Ragweed (*Ambrosia artemisifolia*) and mugwort (*Artemisia vulgaris*) are highly important allergenic weeds belonging to the *Asteraceae* plant family (Wopfner *et al.*, 2005). Their pollen grains are one of the main causes of allergenic reactions accompanied by asthma and other severe health problems in late summer and autumn. While mugwort is a native plant in Europe, ragweed reached Europe e.g. by bird seeds as a neophyte from North America about a hundred years ago and spreads rapidly into new areas of central and southern Europe. It is now abundant in the Rhone valley (France), northern Italy, and eastern parts of Austria, Hungary, Croatia, and Bulgaria (D' Amato *et al.*, 1998).

As the spread of ragweed has been observed in Germany during the last years, we quantified its deoxyribonucleic acid (DNA) in air to estimate the number of bioaerosols originating from this allergenic plant and thus to judge if it, also increased during the past years. Mugwort DNA was studied as a control.

A genetic analysis method was chosen as it works successfully for analyzing bioaerosols (Després *et al.*, 2007). Filter samples were collected with a High Volume Sampler separating fine and coarse particles (aerodynamic cut-off diameter ~3 µm) for a period of four years (2006-2009) in Mainz, Germany. The samples were analyzed for the presence of ragweed and mugwort DNA.

Real Time PCR was used to quantify the amount of ragweed and mugwort DNA mainly in the pollen seasons during this four year period. While the abundance of mugwort DNA stayed constant in this measurement period we found an increase of the ragweed DNA from 2006-2008 for the fine particle fraction and for the coarse particle fraction a significant increase from 2006-2008, with a minimal depression in 2007 and a decrease in 2009 for both, coarse and fine particulate filters (Fig. 1). The increase from 2006-2008 might be associated with the constant spread of ragweed in Germany over the course of the last years, while the decrease in 2009 could be caused by unfavorable plant specific growing conditions in spring and summer 2009, and growing awareness and resulting removal of ragweed plants.

There is a need for more comprehensive and long-term studies analyzing the spread of ragweed and its relation to the increase of pollinosis in late summer and autumn in Germany.

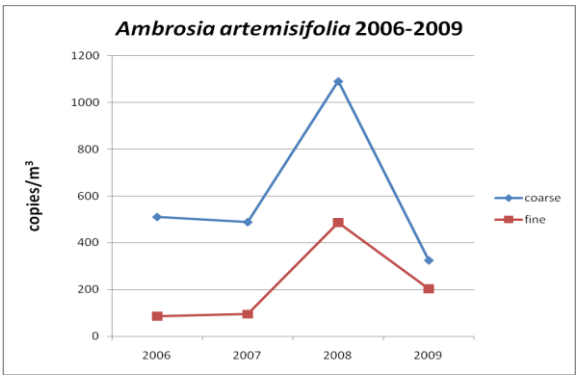

Figure 1. Tendency of ragweed DNA amount for coarse (colored in blue) and fine (colored in red) filter samples from 2006-2009.

Size distribution of viable airborne microbes in a Mediterranean suburban site

L. Raisi[1], M. Lazaridis[2], and E. Katsivela[1]

[1]Department of Natural Resources and Environment, Technological Educational Institute of Crete, Romanou 3, 73133 Chania, Crete, Creece
[2]Department of Environmental Engineering, Technical University of Crete, Polytechneioupolis, 73100 Chania, Crete, Greece
Keywords: bioaerosols, size distribution, culturable microorganisms, bacteria, fungi
Presenting author email: katsivela@chania.teicrete.gr

The biological loading of viable, culturable airborne microbes (heterotrophic bacteria, actinobacteria and fungi) in 6 size fractions as well as the three different fractions of respirable particulate matter (PM_1, $PM_{2.5}$ and PM_{10}) were studied in ambient air due to health-related interests.

Air samples were collected using an Andersen six stage viable particle sampler. Duplicates of samples were collected at each sampling period (10 campaigns in total) in a suburban, residential site of the coastal Mediterranean city of Chania (Crete, Greece) in the time period from May to June 2009. The mesophilic heterotrophic bacteria were grown in Tryptone Soy Agar at 37^{o}C for 48 h, the actinobacteria were cultivated in Actinomycete Isolation Agar containing 0.5 % (w/v) glycerol at 30^{o}C for 7d, and fungi were cultivated in Malt Extract Agar at 20^{o}C for 72 h. PM mass and number concentrations were determined using portable aerosol particulate monitors. The mean values of the ambient meteorological conditions during the measurement period were as follows: Temperature 25.1 $\pm$ 3.6 ^{o}C; relative humidity: 55.2 $\pm$ 7.9 %; local wind speed: 0.8 $\pm$ 0.3 m/s; solar radiation: 728.0 $\pm$ 115.5 W/m^2.

As shown in Table 1, the airborne fungi present significant higher concentrations than the airborne heterotrophic bacteria. The Gram-positive actinobacteria, which were the dominant bacteria isolated from bioaerosols, showed the next highest concentrations. The predominance of Gram-positive culturable bacteria in air samples is consistent with the previous work of the authors Shaffer and Lighthart (1997).

Table 1: Mean concentrations of viable, airborne heterotrophic bacteria, actinobacteria and fungi in the ambient air during May and June 2009.

Aerodynamic diameter	Heterotrophic Bacteria (CFU/m^3)	Actinobacte-ria (CFU/m^3)	Fungi (CFU/m^3)
>7μm	11	21	32
4.7-7μm	6	15	30
3.3-4.7μm	6	38	96
2.1-3.3μm	9	76	218
1.1-2.1μm	10	58	78
0.65-1.1μm	2	12	8
SUM of 6 stages	44	220	462

Particulate matter measurements at the same time period revealed that the mean concentrations of PM_{10}, $PM_{2.5}$, and PM_1 were 45 $\pm$ 14, 38 $\pm$ 14, and 34 $\pm$ 14 μg/m^3, respectively, whereas the mean cumulate counts of PM_1 particles was 4,507 $\pm$ 1,872 particles/cm^3.

Although, a nearly equal distribution of the mean concentrations of the airborne heterotrophic bacteria (Table1 & Figure 1) was observed in the six different size fractions, the highest concentrations of the airborne actinobacteria and fungi were determined at aerodynamic diameters between 2.1 and 3.3 μm (Table1 & Figure 1).

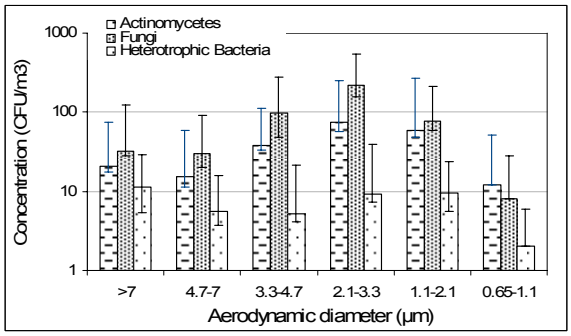

Figure 1: Mean concentrations size distribution of viable, airborne heterotrophic bacteria, actinobacteria and fungi in ambient air during the measurement campaigns.

The concentrations of the main fraction of the airborne actinobacteria showed a very good linear correlation with the residual 5 size fractions (R^2 values: 0.82-0.94) and with the ambient temperature (R^2: 0.84). In addition, a good negative correlation was obtained with the size fraction of heterotrophic bacteria with aerodynamic diameters between 1.1 and 2.1 μm (R^2: -0.88) and the UV radiation (R^2: -0.7).

The concentrations of the main fraction of the mesophilic fungi correlate well with the PM_1 particle number (R^2: 0.72) and with two other size fractions of the fungi (R^2: 0.8 for fraction with > 7 μm, and R^2: 0.78 for fraction with d_p 1.1-2.1 μm, respectively).

In addition, the mass concentration of the particulate matter PM_{10}, $PM_{2.5}$ and PM_1 and the PM_1 particle number correlate well only between each other (R^2: 0.88-0.99).

Production, sampling and microarray-based detection of bioaerosols containing *E. coli* and *L. pneumophila*

Seidel, M.[1], Hartmann, G.[1], Langer, V.[1], Niessner, R.[1]

[1]Chair for Analytical Chemistry & Institute of Hydrochemistry, Technische Universität München, 81377 Munich, Marchionistraße 17, Germany

Keywords: bioaerosols, *L. pneumophila*, cyclone separator, chemiluminescence microarrays .

Presenting author email: reinhard.niessner@ch.tum.de

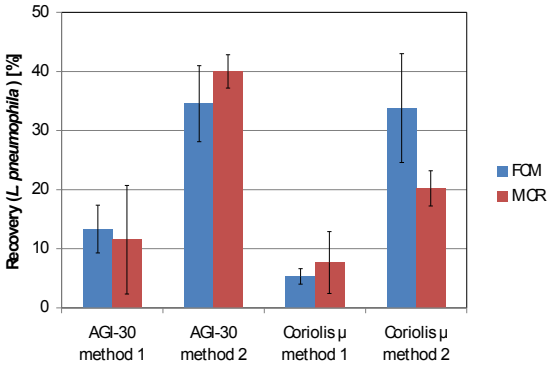
Legionella are the causing agent of Legionnaire's disease and Pontiac fever. These diseases cause hundreds of deaths every year in Europe. The most important species is *L. pneumophila* which effects 70 – 90 percent of all cases. *Legionella* live in natural and artificial water systems and are ubiquitary therein. Infection of humans occurs only by inhaling bioaerosols containing these bacteria. Such are generated, for example, by cooling towers, hot water systems, air-conditioning systems or while showering and can be a health threat for people in surrounding areas (Blatny *et al.*, 2008). By now, little is known both about the correlation of the *L. pneumophila* concentration in liquid and gas phase as well as about the dose-response-behavior of *Legionella* bioaerosols.

Standard methods for quantification of *Legionella* are time consuming and labor-intensive. Results could be obtained only after 10 days since the bacteria grow very slowly. Rapid detection methods are needed which combine the sampling of bioaerosols with multiplexed analysis to specify which *Legionella* species is in the air and how much. The rapid quantification of bacteria with flow-through chemiluminescence microarrays were established in our laboratories (Wolter *et al.*, 2008; Langer *et al.,* 2011) and is applied for bioaerosol analysis in this work.

As testing bacteria viable cells of *E. coli* and heat-inactivated *L. pneumophila* (serogroup I) cells have been utilized. Aerosols were generated by a nebulizer (Pari LC) which is commonly used in the therapy of respiratory diseases. The recovery was significantly better than with a conventional cross-flow nebulizer. Furthermore, the concentration of the bacteria suspension inside the nebulizer was constant even after some minutes of aerosol production. Consequently, it can be stated that the Pari LC is a nebulizer highly suitable for the generation of bioaerosols, providing continuously a bioaerosol of constant concentration. For the collection of airborne microorganisms the cyclone separator *Coriolis μ* was applied, a device specially designed for bioaerosol sampling with a high sampling rate. As a reference, an impinger, type AGI-30, is used. Quantification was accomplished by flow cytometry (FCM) for quantification of single bacteria species and a flow-through microarray chip reader (MCR) applying multianalyte chemiluminescence immunoassays. This system was developed at our institute and is based on a sandwich-ELISA that uses the enzymatic chemi-luminescence reaction of luminol and hydrogen peroxide for detection.

The efficiency of bioaerol sampling using the *Coriolis μ* were examined. Living *E. coli* cells were nebulized in a chamber and quantified with FCM after sampling. A recoevery of 34.0 ± 9.8 % (n = 17) was found with a high linearity between 5 x 10^5 and 2 x 10^7 cells/mL which was the working range of the FCM. The recoveries of *L. pneumophila* was 5.3 ± 1.3 % by sampling in a chamber (method 1) and 33.8 ± 9.2 % by sampling with a directed flow from the nebulizer to the sampler (method 2).

In order to determine the efficiency of the C*oriolis μ* sampler a gelatin membrane-filter system (AirPort MD8) with a retention rate of virtually 100 % was used as a reference method. The sampling efficiency was determined to be 78 % for *E. coli*, which is in good agreement with the manufacturer's data.



The impinger AGI-30 was compared with the *Coriolis μ* quantifying the recoveries with FCM and MCR. Both detection methods have yielded similar recoveries. However, the advantage of the antibody microarray on the MCR analysis platform was that a lower detection limit of 1 x 10^3 cells/mL was achieved and a multiplexed analysis was possible in 1 h. The *Coriolis μ* samples 3 m^3 of air in 10 min. Therefore, different *Legionella* species could be quantified down to 2 – 7 x 10^3 cells/m^3 in 1,5 hours which is ideal for bioaerosol measurements in the environment and in the interior.

Techniques to investigate bacterial survival within the airborne state

J. Jordan[1], T. Hawkyard[1], and R.J. Thomas[1]

[1]Biomedical Sciences, Dstl Porton Down, Salisbury, Wiltshire, SP4 0JQ, UK
Keywords: Bacteria, airborne, PCR detection, viability.
Presenting author email: jejordan@dstl.gov.uk

Bioaerosols can be produced by both natural and artificial means. Respiratory infections are transmitted by sneezing and coughing producing mucus droplets containing bacteria. Survival in the airborne state influences infectivity. Biological warfare may involve aerosol dissemination. Knowledge of the physiological response in the airborne state permits implementation of effective hazard management and biodetection regimes.

Porton Down has a history of investigating the decay of airborne bacteria (Hood, 2009). The methodology used to maintain and capture populations of aerosolised bacteria are described together with techniques that can be applied to investigate the physiological and molecular response of bacteria.

The Goldberg drum (Fig. 1a) is used to investigate the effect of modulating single parameters on survival in dynamic aerosols e.g. relative humidity. A drawback is that certain parameters that affect aerosol survival can not be studied in the Goldberg drum e.g. solar radiation. A historical technique has been revisited based on spider microthreads wound around a metal frame and placed within a metal 'sow' to capture the aerosol (Fig. 1b). This enables factors such as the effect of solar radiation on aerosol decay to be investigated.

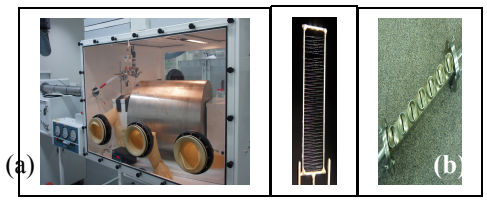

Figure 1. Apparatus used to experimentally study the effect of aerosolisation on bacterial cells (a) Goldberg drum and, (b) microthread technology

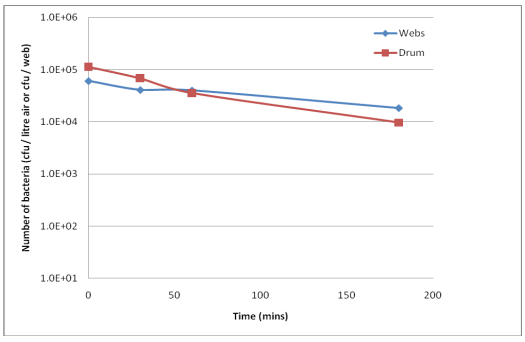

Figure 2. Comparative aerosol decay of *Escherichia coli* MRE162 in Goldberg drum and microthread apparatus at medium relative humidity (~50%)

This experiment was performed as a proof of principle in order to compare the two technologies. The conclusion from the results is that there is no significant difference between aerosol decay curves generated by the two methods.

In order to investigate the molecular mechanisms associated with survival of airborne bacteria by transcriptomic and proteomics, it is important to ascertain not just the viable fraction, but the total number of bacteria present in the collected sample. A sensitive real-time PCR method has been developed for *Yersinia pestis* GB. The method involves extracting the DNA from the bacteria in the aerosol sample using Instagene and then using this as template DNA in the real time PCR. A standard curve of real time PCR threshold cycle (Ct) versus viable count has been calculated which enables the total number of bacteria in an aerosol sample of unknown concentration to be calculated from the Ct value. The limit of detection of the assay is 94cfu/ml of aerosol sample.

Current studies are focussed on developing this PCR assay to differentiate between airborne cells that have damaged cell membranes based on uptake of propidium monoazide. Such assays have been used successfully to study bacterial viability in environmental samples such as wastewater, food matrices and soil (Nocker *et al* 2007; Cawthron & Witthuhn, 2008).

Future research will develop techniques to investigate the transcriptional and proteomic response of airborne cells and to determine the effects on nucleic acid and protein integrity.

This work was supported by funding from the UK Ministry of Defence.

The comparison of diversity of microorganisms in aerosol and seawater surface microlayer

V.A. Ternovoi, V.M. Generalov, G.A. Buryak, Yu.V. Marchenko, S.E. Olkin, B.I. Antipkin, N.A. Lapteva, A.N. Sergeev, A.S. Safatov

Keywords: atmospheric aerosols, bioaerosols, bacteria, sea spray.
Presenting author email: safatov@vector.nsc.ru

Atmospheric bioaerosols present an important component of atmospheric pollutants. In the summer of 2009, the complex evaluation of atmospheric air quality was carried out in the city of Gelendzhik (Safatov *et al.*, 2010), including the control of the concentration and diversity of bioaerosols in the city atmosphere. The seawater surface microlayer (SML) is one of the main sources of aerosol for seaside cities, and therefore, SML samples were collected from the water area of Gelendzhik simultaneously with aerosol sampling to evaluate the concentration and diversity of microorganisms present in it. The work presents the diversity of microorganisms in aerosol and sweater SML. According to literature data, different proteobacteria make the maximum contribution to the existing diversity of microorganisms in the environment. For that reason, a special attention was paid to their detection.

The presence of proteobacterial species in the test samples was revealed using unique specific PCR primers consisting of 22 – 25 nucleotides. The length of the amplification product is 1360 b.p. allows using a synthesized pair of primers for further identification of the detected microorganism by sequencing of amplified fragments. The content of the total proteobacteria in samples was determined by RT-PCR assay with hybridization fluorescent detection.

Water samples 50 ml each were filtered through filters with pore diameter of 0.22 μm (*Millipore*, USA). Before the assay, the filters had been stored at +4ºC, then nutrient medium (LB) was poured on them followed by incubation at shaking for 1 hour at 37ºC and seeding at 37ºC onto a solid medium containing 1.0% *NaCl* to obtain individual clones.

LB medium containing 0.5 or 1.0% *NaCl* was poured on the filters with aerosol samples followed by incubation for 6 hours at 37ºC and seeding at 37ºC onto solid media containing 0.5 and 1.0% *NaCl* to obtain individual clones.

The total fraction of the bacterial DNA-RNA was isolated from individual clones. After isolating the total mRNA, cDNA (RT) was constructed using random primers (*d(N)6*) and reverse transcriptase.

The concentration of viable microorganisms in SML of the water area of the Gelendzhik Bay was 7 – 120 CFU/ml, and that in the coastal atmospheric air was from 100 (detection limit) to less than 8000 CFU/m^3. Bacteria made up approximately 75% of the detected viable microorganisms.

The performed sequencing of amplified fragments of bacterial genetic material in aerosol samples and water SML showed that the representatives of the genera *Baccilus: megaterium, subtilis, cerius, anthracis* and *Actinibacter radioresistens* were detected most frequently (in decreasing order). Bacterial genera with the most numerous representatives were found both in aerosol and water SML samples.

Aircraft samples of atmospheric air collected during the same period demonstrate that the number of proteobacteria is 3 – 5 times larger at the altitude of 2000 m than at the altitude of 500 m. Such altitude distribution of bacteria can be observed in the case when their sources are located not far from the sampling places.

As similar microorganisms are found also in SML of the water area of the Gelendzhik Bay, it can be concluded that they are present both in the region's water system and atmosphere. Atmosphere and water system closely interact with each other: the dispersing sea water SML participates in the formation of bioaerosol, and the depositing bioaerosol participates in the formation of water SML. Probably, this is the reason why a large number of microorganisms of the same genera are among those found most frequently in both systems.

Thus, the obtained data once again confirm the "everything is everywhere" hypothesis of microbiogeography (O'Maley, 2008).

The work was supported by the Federal Target Program (Contract # 02.515.11.5087).

The effect of meteorological factors on bioaerosol concentration in Southwestern Siberia

A.S. Safatov, G.A. Buryak, K.E. Grishkina

Federal State Research Institution State Research Center of Virology and Biotechnology "Vector", Novosibirsk Region, 630559, Koltsovo, Russia
Keywords: atmospheric aerosols, bioaerosols, meteorology, bacteria, fungi.
Presenting author email: safatov@vector.nsc.ru

Meteorological factors can have a considerable influence on the observed concentrations of atmospheric aerosol, including bioaerosol. In the review of Jones and Harrison (2004) it was shown how emission of bioaerosols by vegetation, animals, microbiological and other sources of bioaerosol depends on temperature, humidity, wind velocity, the presence of rain, etc. In the case when measurements are conducted at a considerable distance from the sources contributing to the observed concentrations of bioaerosols, the effect of these factors can be somewhat leveled as meteorological factors have different impacts on different sources. For remote bioaerosol sources, the values of these factors can considerably differ from those measured in the sampling point. Nevertheless, as shown in (Harrison *et al.*, 2005), even in such a situation dependences of concentrations of bacteria on temperature, wind direction and velocity are revealed in 4 observation points in England.

The goal of the present study is revealing the effect of meteorological factors on the concentrations of the total protein and viable microorganisms in two observation points in Southwestern Siberia.

It was found that, depending on the wind direction, the mean concentrations of the total protein in atmospheric aerosol of Southwestern Siberia change by 3 times, and the concentrations of viable microorganisms – by 20 times, Table 1. However, taking into account the great dispersion of concentrations measured in different seasons of different observation years, the mean concentrations for wind directions proved to be statistically indistinguishable at 95% confidence level.

While the mean temperature in the sampling point during the sampling period increases, the concentrations of the total protein and culturable microorganisms in atmospheric aerosol of Southwestern Siberia tend to grow, which is confirmed by observations described in (Safatov *et al.*, 2010) illustrating the increase in these concentrations during the warm season and their decrease during the cold season. With increasing air relative humidity averaged over the sampling period, the concentrations of the total protein and culturable microorganisms in atmospheric aerosol of Southwestern Siberia tend to decrease. The dependence of the concentrations of the total protein and culturable microorganisms on the mean wind velocity during the sampling period has a multidirectional character: with increasing wind velocity, the concentration of viable microorganism increases, and the total protein concentration decreases. These data conflict with those presented in (Harrison *et al.*, 2005), according to which with increasing mean air velocity the concentration of bacteria in three observation points decreases, and in another point remains practically constant.

The obtained results indicate the presence of dependence of concentrations of culturable microorganisms and the total protein in atmospheric aerosol of Southwestern Siberia on meteorological parameters determined during the sampling period.

The Study of Surviving of Bacteria on Charcoal Filters under Nutrient, Moisture Regain and Water Content Conditions

Chane-Yu Lai[1], Chun-Wei Chen[1], Shin-Ran Wun[1], Po-Chen Hung[2], Cheng-Ping Chang[2]
[1]Department of Occupational Safety and Health, Chung-Shan Medical University,
[2]Institute of Occupational Safety & Health, Council of Labor Affair

When the severe acute respiratory syndrome（SARS）or Hemagglutinin 1 Neuraminidase 1（H1N1）virus attacked human beings all over the world, some people in Taiwan wore activated carbon mask to prevent inhalation of hazardous bioaerosols. However, activated carbon mask is designed to adsorb gaseous contaminates, but not to use for filtrating of aerosols. The activated charcoal may provide better space for the survival of bacteria, and indirectly hurt human body for re-entrainment of bacteria.

The study used a Collison nebulizer to generate *Bacillus subtilis* endospores or *Escherichia coli* as challenge aerosols. The single stage Anderson sampler was used to monitor the bioaerosol concentrations of the tested chamber. The charcoal filters, were loaded inoculum by using pipette. After that, the filters were added different nutrients（included sterile water, artificial saliva and artificial perspiration）, placed in constant temperature and humidity incubators, and stored in different conditions. The moisture regain of activated charcoal were included in the experimental parameters. The ultimate goal of the study will provide people selecting proper masks in the outbreaks of epidemic diseases.

The results showed: the six type activated charcoals and surgical charcoal mask had high moisture regain and water content at 95 % relative humidity. The *Bacillus subtilis* loaded in the six type activated charcoals had obviously growth-and-decline succession under 95 % relative humidity and 25 □ conditions. This phenomenon could reveal that *Bacillus subtilis* survived in the six type activated charcoals. Moreover, the similar survival results occurred in *Bacillus subtilis* loaded in the surgical charcoal masks. However, *Escherichia coli* could not survive in the six type activated charcoals last for 24 hours, except in columnar activated charcoal under adding artificial saliva, distilled water or artificial perspiration.

Differences in Positively and Negatively Charged Bacterial Aerosol Diversity in Indoor and Outdoor Environments

Fangxia Shen and Maosheng Yao *

Principal Contact: Maosheng Yao, Professor, State Key Joint Laboratory for Environmental Simulation and Pollution Control, College of Environmental Sciences and Engineering, Peking University, Beijing 100871, China, Ph: +86 010 6276 7282, Email: yao@pku.edu.cn,

Abstract

In this study, the positively and negatively charged culturable bacterial aerosol concentration and diversity were investigated both in indoor and outdoor environments. For both positively and negatively charged bioaerosols, the air samples were collected into different regions of two agar square plates using an electrostatic sampler (1.1 kv/cm) at a flow rate of 3 L/min for 40 min. The collected bacterial aerosols were cultured directly on agar plates, and the colony forming units (CFU) were manually counted. In addition, the CFUs were washed off from the agar plates, and further subjected to polymerase chain reaction (PCR) and denaturing gradient gel electrophoresis (DGGE) for culturable diversity analysis.

The results revealed that the positively and negatively charged culturable bacterial aerosol concentration and diversity strongly depended on the sampling environments. In indoor environment, negatively charged culturable bacterial aerosols dominated (p-value=0.0489), while in outdoor environment both polarities appeared to have similar concentration levels (p-value=0.078). PCR-DGGE analysis showed that positively charged culturable bacterial aerosol DGGE patterns were very different from those of negatively charged regardless of the sampling environments. In addition, positively charged culturable bacterial aerosols were found to have more phylogenetical similarity with those positively charged collected into different regions of agar plates from different environments, and the same was observed for negatively charged. Outdoor culturable bacterial aerosols were shown to have more bacterial species richness than those indoors. The information provided and the technique developed here could have great implications in electrostatic sampling and control of bioaerosols, and open a new arena for studying airborne microbes with different charge polarity

Use of Electrostatic Sampling and ELISA method in Studying Charge Distributions of Airborne Allergens

Yan Wu and Maosheng Yao*

Principal Contact: Maosheng Yao, Professor, State Key Joint Laboratory for Environmental Simulation and Pollution Control, College of Environmental Sciences and Engineering, Peking University, Beijing 100871, China, Ph: +86 010 6276 7282, Email: yao@pku.edu.cn,

Abstract

It was shown that exposure to airborne allergens has caused various respiratory problems. Among others factors, their charge levels play an important role in their sampling and deposition of human lung system. Previously, we have developed a method of using electrostatic sampling coupled with qPCR for measuring lab-prepared bacterial aerosol charge levels, preventing the problem of counting non-biologicals if an optical counter is used otherwise. Here, we have investigated the airborne allergen charge distribution in a natural environment using a similar method. The electrostatic sampler with two 96-well plates inside was operated at a flow rate of 3 L/min at an electrostatic field strength of 1.2 kV/cm for 2 h in a hotel environment. The sampling was conducted twice from morning to afternoon. The two 96-well plates were grouped into six regions, and air samples collected into each of the regions were pipetted out for airborne Alt a 1, Der p 1, Der f 1 and Bla g 1 allergens analysis using enzyme-linked immunosorbent assay (ELISA). The airborne allergen charge distributions were calculated using an aerosol calculator.

Results indicated that high levels of airborne allergens (Alt a 1, Der p1 , Der f 1 and Bla g 1) were detected in hotel environment. The concentrations for dust mire Der p1 and Der f 1allergens ranged were 209.4 ng/m^3 and 61 ng/m^3, respectively. For fungal allergen Alt a 1, its concentration was shown about 23 ng/m3, and airborne Bla g 1 was observed to have a concentration of 2.2 U/m^3. For fungal allergen Alt a 1, the charge level ranged from about 60 to 600 units of elementary charge with about 50% of them carrying a charge of 200 or 80 units. For dust mite allergens, their charge levels ranged from 500 to 5000 units of elementary charge with about 20-30% of then carrying a charge level of 1000 units. Due to lack of its aerodynamic size, the charge distribution for Bla g 1 was not calculated, but most of the allergens were collected into the last region of the six regions classified. The results from this study indicated that for carpeted hotel room those common allergens could present an important source of the respiratory problems, and the information obtained here might be used in improving their electrostatic control.

Effects of Microwave Irradiation on Culturability and Diversity of Biological Aerosols of Different Sizes in Different Environments

Yan Wu and Maosheng Yao*

Principal Contact: Maosheng Yao, Professor, State Key Joint Laboratory for Environmental Simulation and Pollution Control, College of Environmental Sciences and Engineering, Peking University, Beijing 100871, China, Ph: +86 010 6276 7282, Email: yao@pku.edu.cn,

Abstract

Increasing evidences show that exposure to airborne biological aerosols has resulted in numerous adverse health effects and diseases. Thus, it is important to develop practical control technology. Previously, we have investigated the inactivation of total bioaerosols using microwave irradiation. Here, the effects of microwave irradiation (2450MHz) on the culturability and diversity of bioaerosols of different sizes were investigated. Air samples were taken using a six-stage Andersen impactor operated at a standard flow rate of 28.3 L/min without and with microwave irradiation for 45 seconds at three different power levels(119, 385, 700 W) in different environments (lab office, hotel and outdoor). For each experimental condition, three independent repeats were conducted. Air samples collected onto different stages of the Andersen sampler were incubated directly at room temperature, and colony forming units (CFU) were manually counted and statistically corrected. The CFUs were further washed off from agar plates using deionized water and subjected to polymerase chain reaction (PCR)-denaturing gradient gel electrophoresis (DGGE) for diversity analysis.

Results revealed that for outdoor environment, larger size bacterial aerosol dominated, while for the indoor environment smaller size bacterial aerosol dominated. Use of higher power level resulted in lower culturable bacterial counts regardless of the sampler stage and sampling environment. PCR-DGGE analysis indicated that in general use of higher power microwave irradiation resulted in less culturable bacterial diversity, while for medium and low power their culturable diversity appeared to be similar to that of control experiment. In contrast, smaller culturable fungal aerosols were found to dominate regardless of sampling environment. Application of microwave irradiation for 45 s was shown to result in complex effects on the culturability of fungal aerosols of different sizes. The results obtained might be negatively impacted by the environmental variations of biological aerosol concentration and composition. Overall, this study has demonstrated a practical control technology for environmental bioaerosols.

Use of six-stage Andersen Sampler in Investigating Bioaerosol Inhalation Risks in Different Environments

Zhenqiang Xu and Maosheng Yao*

Principal Contact: Maosheng Yao, Professor, State Key Joint Laboratory for Environmental Simulation and Pollution Control, College of Environmental Sciences and Engineering, Peking University, Beijing 100871, China, Ph: +86 010 6276 7282, Email: yao@pku.edu.cn,

Abstract

Increasing evidences show that inhalation of indoor bioaerosols has caused numerous adverse health effects and diseases. However, the bioaerosol size distribution, composition and concentration level could vary with human environments, thus representing different inhalation risks. The six-stage Andersen sampler is designed to simulate the sampling of different human lung regions. Here, the sampler was thus used in investigating culturable bacterial and fungal aerosols collected onto different stages in six different environments (student dormitory, hospital, office lab, hotel, student dining hall, and outdoor environment) in this study. During the sampling, the Andersen sampler was operated for 30 min and three independent experiments were performed for each of the environments. The air samples collected onto each of the six stages were incubated on agar plates directly at room temperature, and the colony forming units were manually counted and statistically corrected.

Results revealed that for most environments investigated the culturable bacterial aerosol concentrations were higher than those of culturable fungal aerosols. The culturable concentration of fungal aerosols were shown to be in comparable levels, while office lab, student dorm and hotel room appeared to have higher culturable bacterial concentrations. For most environments tested, larger (>3 μm) culturable bacterial aerososols were shown to dominate, while for culturable fungal aerosols those 2.1-4.7μm dominated. Comparisons of the air samples collected by different stages of the Andersen sampler indicated that the outdoor environment might represent more fungal inhalation risks to human alveoli region, and the hotel room was shown to have highest culturable bacterial aerosol concentrations collected by the six stage of the sampler. The results from this study suggested that different environments even with similar levels of total microbial cuturable aerosols concentrations could present different inhalation risks due to different size distribution and composition.

Performance of a Button Inhalable Sampler with Modified MCE Filter Method in Enumerating Culturable Bacterial and Fungal Aerosol Concentration and Diversity

Zhenqiang Xu and Maosheng Yao*

Principal Contact: Maosheng Yao, Professor, State Key Joint Laboratory for Environmental Simulation and Pollution Control, College of Environmental Sciences and Engineering, Peking University, Beijing 100871, China, Ph: +86 010 6276 7282, Email: yao@pku.edu.cn,

Abstract

In this study, a modified mixed cellulose ester (MCE) filter culturing method (directly placing filter on agar plate for culturing) was investigated in enumerating airborne culturable bacterial and fungal aerosol concentration and diversity both in indoor and outdoor environments. A Button Inhalable Sampler loaded with MCE filter was operated at a flow rate of 5 L/min to collect indoor and outdoor air samples using different sampling times: 10, 20, and 30 min. As a comparison, a BioStage impactor was operated at a flow rate of 28.3 L/min in parallel for all tests. The air samples collected by the Button Inhalable Sampler were directly placed on agar plates for culturing, and those collected on agar plates by the BioStage impactor were incubated directly. The colony forming units (CFUs) were manually counted and the culturable concentrations were calculated both for bacterial and fungal aerosols. The bacterial CFUs grown were further washed off and subjected to polymerase chain reaction-denaturing gradient gel electrophoresis (PCR-DGGE) for diversity analysis. For fungal CFUs, microscopy method was applied to study the culturable fungal diversity obtained using different methods.

Experimental results showed that the direct MCE filter culturing method performed reasonably well, and in some cases it outperformed the BioStage impactor, in enumerating bacterial and fungal aerosols. For bacterial aerosol sampling, the BioStage impactor was shown to perform better, and in contrast the MCE filter method was demonstrated to enumerate more culturable fungal aerosols. In general, the microbial species richness was observed to increase with increasing collection time. For both methods, the DGGE gel patterns were observed to vary with sampling time and environment despite of their similar species richness. In addition, an increase in sampling time from 20 to 30 min seemed to not significantly alter the species richness. Regardless of the sampling methods, more species richness was observed in outdoor environment than indoor environment. Compared to the BioStage impactor, the direct MCE filter culturing method with the Button Inhalable Sampler described here can be easily adapted to provide better personal biological exposure monitoring protocols.

Effects of single-walled carbon nanotube filter on culturability and diversity of environmental bioaerosols

Zhenqiang Xu and Maosheng Yao*

Principal Contact: Maosheng Yao, Professor, State Key Joint Laboratory for Environmental Simulation and Pollution Control, College of Environmental Sciences and Engineering, Peking University, Beijing 100871, China, Ph: +86 010 6276 7282, Email: yao@pku.edu.cn,

Abstract

In this study, single-walled carbon nanotube (SWNT) filters were prepared using mixed cellulose ester (MCE) filters and carbon nanotubes with three levels of loading: 0.02, 0.16 and 0.64 mg/cm^2. Both MCE and SWNT filters were used to collect bacterial and fungal aerosols with a total volume of 200 L air sampled in indoor and outdoor environments. After sampling, the filters were directly placed on agar plates at 26 ^{o}C for culturing. The culturable aerosol counts were manually obtained both for MCE and SWNT filters, and the resulting bacterial colony forming units (CFUs) were washed off and subjected to the culturable aerosol diversity analysis using polymerase chain reaction-denaturing gradient gel electrophoresis (PCR-DGGE). For fungal CFUs, microscopy method was used to study the diversity obtained using different filter types.

The results showed that use of SWNT filters with medium and high CNT loadings resulted in significant reduction (up to 2 logs) of culturable bacterial and fungal aerosol counts compared to MCE filters in both environments. For low CNT loading (0.02 mg/cm^2), very limited inactivation effects were observed for fungal aerosols, while more bacterial counts were obtained possibly due to the split of the aerosol aggregates. PCR-DGGE analysis revealed that SWNT filters at high CNT loading (0.64 mg/cm^2) resulted in lowest culturable diversity, especially pronounced for outdoor bacterial aerosols. For low and medium CNT loading, the culturable bacterial aerosol diversity remained similar. Fungal aerosol analysis showed that use of SWNT filters with medium to high CNT loading also resulted in significant reduction of fungal species diversity. The results here demonstrated great promise of the SWNT hybrid filter in controlling biological aerosols, and suggested its potential to impact current air conditioning system.

Keywords : Single-walled carbon nanotube (SWNT), culturability, culturable bioaerosol diversity, inactivation, denaturing gradient gel electrophoresis (DGGE)

Influences of Air Volume, DNA Template, and Dilution Factor on the Performance of qPCR Coupled with a Modified BioStage Sampling Method in Quantifying Bioaerosols

Zhenqiang Xu and Maosheng Yao*

Principal Contact: Maosheng Yao, Professor, State Key Joint Laboratory for Environmental Simulation and Pollution Control, College of Environmental Sciences and Engineering, Peking University, Beijing 100871, China, Ph: +86 010 6276 7282, Email: yao@pku.edu.cn,

Abstract

There is an increased interest in integrating polymerase chain reaction (PCR) based technologies with air sampling in investigating airborne microbial community. However, a variety of factors influence the overall performance of such integration. For the sampling method, Andersen type impactors are widely used, but most of them are restricted to the agar culturing method. Here, a BioStage impactor was modified to collect air samples directly into petri dish filled with deionized (DI) water, instead of agar plates. During the sampling, the BioStage impactor was operated at a standard sampling flow rate of 28.3 L/min for 10, 20, 30 min both in indoor and outdoor environments. For each experimental condition, three independent repeats were performed. The collected air samples into the DI water under different experimental conditions were further filtered through a mixed cellulose ester (MCE) filter, and further extracted using DI water. The final sample suspension was subject to qPCR analysis. In addition to the different air sampling volumes, different sample DNA templates (2 or 5 μl) and dilution factors (10 and 50 times) were investigated on the overall performance of PCR-BioStage integration method.

Results revealed that use of the modified BioStage bioaerosol collection method resulted in successful amplification of bacterial cells. In general, use of 2 μl resulted in higher PCR product concentrations under all experimental conditions than those obtained using 5 μl DNA template. This would be helpful for further diversity analysis. Sampling time was also observed to play a role in the overall performance of qPCR, and 10 min sampling time was shown enough to allow the air samples to be efficiently amplified. The effects of dilution factors were shown to be dependent on the sampling time and environments. The results from this study have demonstrated an effective bioaerosol monitoring protocol by integrating qPCR and impaction based air sampling method by choosing an optimal combination sampling time, DNA template and dilution factor.

Exciting and measuring the intrinsic fluorescence from aerosol particles can instantly distinguish biological particles (bacteria, fungal spores, pollen or detritus) from non-biological dusts in the laboratory, but few field measurements have been performed. To establish the likely abundance of the background fluorescent aerosol, measurements were carried out on ambient particles sized 0.8—20 µm at the summit of the puy de Dôme mountain (altitude 1465 m a.s.l.) in central France during a cloud-free period between 22 June and 3 July 2010. NO_X, SO_2 and ultrafine particle measurements are consistent with a rural background.

The Wide Issue Bioaerosol Spectrometer, version 3 (WIBS-3; Kaye et al. 2005; Gabey et al. 2010) monitors single-particle particle fluorescence using two excitation and emission channels to detect two biological tracers. Particle size and morphology are quantified using elastic light scattering from a 632 nm diode laser.

Cascade impactor samples were collected between 26—29 June, when the site was influenced by north-easterly air masses. Total bacteria, spores and yeast enumerated by epifluorescence microscopy.

Results

Bacteria concentration was 2.2—33 l^{-1} ± 25%. Fungal spore/yeast concentration was 0.8—2.7 l^{-1} ± 20%. This compares well with other microscopy-based measurements at high-altitude and remote sites (Bauer et al., 2002; Matthias-Maser et al., 2000; Harrison et al., 2005), which report that bacteria dominate fungal spores, with typical biological concentrations of 1—50 l^{-1}. Quantitative size data is unavailable but the bacteria at PDD were noted to be mostly bacilli 0.5—2µm in diameter, with a 2—5µm component. Fungi and spores were typically larger than 8µm.

Mean WIBS-3 total aerosol concentration was 270 l^{-1} (σ = 66 l^{-1}), which peaked at 500 l^{-1} because of a change in air mass origin. The mean concentration of particles with fluorescence corresponding to Nicotinamide adenine dinucleotide (NADH), related to cell metabolism, was 95 l^{-1} (σ = 25 l^{-1}). These particles displayed a clear diurnal variation, increasing by up to 100 l^{-1} at night. The number of non-fluorescent particles showed the opposite cycle. This may relate to the site lying in the residual layer/free troposphere at night, or increased relative humidity.

Particles with fluorescence like the amino acid Tryptophan exhibited no strong diurnal features. Mean number was 12 l^{-1} (σ = 6 l^{-1}) and slightly anti-correlated to NADH-like particle number at night. The fluorescent size mode is at 2—3 µm. Basic morphological measurements based on the intensity distribution of elastically scattered light reveals two sub-types among NADH-type and non-fluorescent particles. This meant a total of six fluorescent and non-fluorescent aerosol components were distinguished.

Pharmaceutical deposition of peanut proteins on skin patches by EHDA in cone-jet mode

P. Ehouarn, L. Tatoulian, J. Jusseaume and B. Dupont

DBV Technologies, 27 rue du Faubourg Saint Jacques, Paris, 75014, France

.

Presenting author email: Pascale.Ehouarn@dbv-technologies.com

So far electrospray (ElectroHydroDynamic Atomization) has been largely studied by scientists, especially in its theoretical aspects [1] and more precisely in its cone-jet mode. Both researchers and industrial people consider it as a very promising process in several industrial fields, nano-particles production, genetics, film deposition, etc… [2, 3, 4]; Nevertheless, industrial applications remain much limited to electrospray ionization mass spectrometry, producing ions material of interest, especially macromolecules like proteins. In fact, as a biologic material spray generator and despite its drawbacks, electrospray has many advantages compared to others processes producing fine and controlled droplets: control of size and trajectories of the droplets, substance sparing, immediate drying, etc.

DBV Technologies has taken advantage of these benefits to develop both an electrospray deposition process and an automatic pharmaceutical machine producing skin patches loaded with an allergen extract, used by allergic patients to perform desensitization of their allergic disease. These patches are currently used and tested in human clinical trials (phase I) and fit with the pharmaceutical standards:

- Consistency (± 20%) of the amount of the active ingredient, namely peanut proteins natural extract,
- Ability to lay down different doses (20 το 500 μg),
- Sparing of relatively expensive protein extract,
- Homogeneity of the depot,
- 2 years long shelf life.

The choice of electrospray to perform the deposition of dry peanut proteins into a pharmaceutical patch has been studied and eventually chosen among others because it was the best adapted to meet these requirements, even with substantial challenges, such as:

- Solubilisation of freeze-dried protein extract in a pharmaceutical and liquid formulation with special conductivity and surface tension requirements,
- Low throughput per nozzle,
- Need to make the deposition on an electrically conductive support, etc.

The development led to:

Pharmaceutical liquid formulation

The liquid formulation comprises a pharmaceutical surfactant (Brij O20) that lowers the surface tension, ethanol and water for injection; thanks to dialysis and filtration of the protein solution, the electrical conductivity is lowered to less than 60 μS/cm.

Design of the patch Viaskin®

The patch is made of a crown in PE/EVA foam assembled with a "backing" (the part of the patch supporting the dry proteins) made of PET with a thin conductive titanium coating in order to be both highly biocompatible and electrically conductive.

Spraying head and spraying mode

The electrospray set-up comprises rows of spraying nozzles that are supplied with DC voltage, a ring plate electrode supplied with another DC voltage, and a grounded and heated electrode perpendicular to the nozzles axis. The nozzles are fed with peanut solution by a multiple syringe pump.

A ten nozzles head has been built (upgradable to eighteen) and implemented in order to reach a high production throughput.

A 2 ml/h liquid flow per nozzle has been reached in a stable and long lasting cone-jet mode, at atmospheric pressure in nitrous oxide as a dielectric protecting gas fitting with proteins.

Bioaerosol plays very important role in climate change, rain patterns and public health. The dead decaying organic material, various plants and animals products, infected host and the human handling of various materials contribute to the microbial propagates into the atmosphere as air act as a carrier and transporter of the fungal and bacterial spores and fragments. The concentration of airspora varied with the change in meteorological conditions, temperature, relative humidity, and rainfall as well as with the change in surrounding localities. Indo-gangetic plain in India which host 40% of Indian population has experienced change in climatic patterns, increase in the number of epidemic diseases etc. The monthly average data of predominant fungal colonies recorded and identified from the study site. The maximum fungal

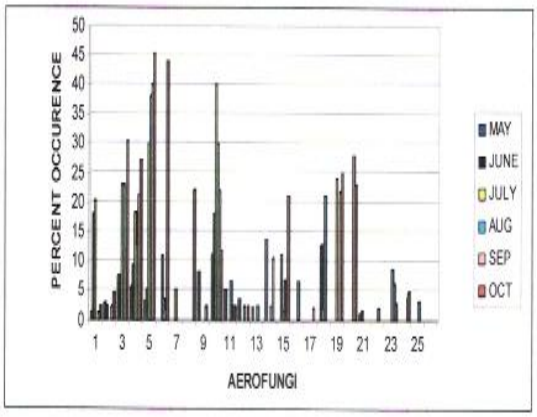

Fig. 1: An average monthly percentage of dominant fungi present in aerosol.

colonies were recorded during the month of October and lowest were recorded in month of June. Agarwal and Shivpuri, 1974 have reported similar trends. Aerial fungal were highest when the mean temperature ranges between 20°C-30°C. It has been reported that meteorological factors like rainfall, relative humidity, temperature have direct or indirect influence on the spores in air. In the present study Aspergillus species were dominant amongst isolated fungi. The maximum percentage of occurrence was observed in morning. Optimal conditions for the growth of aerofungi also play an important role. Czapeck Dox Agar medium was most suitable for fast growth of aerofungi: Aspergillu and Alternaria while PDA medium was suitable for the growth of Penicillium. Protein estimation gives surrogate information about biological components of aerosol. The maximum soluble protein was observed in month of October (1.869 ppm) while minimum soluble protein was observed in month of May and June (0.04 ppm). The level of protein was in relation with presence of biological organism and debris in the aerosol.

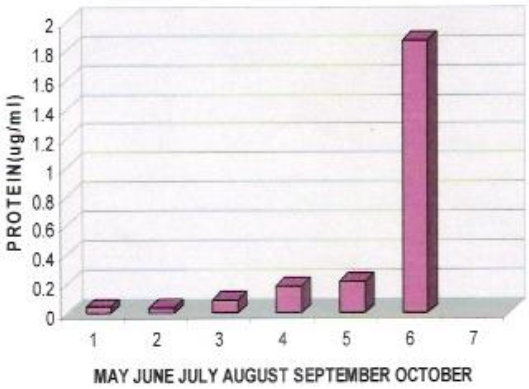

Fig. 2: Protein estimation in aerosol samples.

Secondary aerosol formation is believed to account for the majority of particles in the atmosphere (Merikanto et al., 2009). Other studies have shown that the dominant mass fraction of organic aerosol has been produced secondarily (e.g. Hallquist et al., 2009). Volatile organic compounds (VOCs) are oxidized in several steps whereby the vapor pressure of the oxidation products can be reduced. This reduction in vapor pressure increases the ability of the product to either condense on to existing particles, or take part in the formation of completely new particles.

To better understand early steps of particle formation from VOCs it is therefore of importance to measure such vapors. The most volatile vapors are typically measured by e.g. PTR-MS or GC-MS techniques. The VOCs themselves and many of their high volatile oxidation products are available at high concentrations and do not easily stick to surfaces. However, as the oxidation of these compounds progresses, the concentrations and stability in the gas phase decrease, and neither of the above-mentioned techniques are capable of detecting such compounds. Chemical ionization mass spectrometry (CIMS) has evolved a lot during the recent decade, and is able to measure both inorganic and organic acids in the gas phase down to sub-ppt levels.

The study of naturally charged ions with the atmospheric pressure interface time-of-flight mass spectrometer (APi-TOF; Junninen et al, 2010) has been shown to be very sensitive to acidic, highly oxidized atmospheric molecules (Ehn et al, 2010). Though the instrument cannot directly give quantitative estimates of the neutral compound concentrations, it is to our knowledge the most sensitive instrument available to detect many acidic trace compounds. With the addition of a chemical ionization source in front, the instrument can also be converted into a CIMS, sacrificing some of the high sensitivity and selectivity for quantitative measurements.

The APi-TOF has been deployed at a boreal forest site in Hyytiälä, southern Finland, where several typical ions were identified. During nucleation events, H_2SO_4 dominated the negative ion spectra, but during evening and night when the particles continued growing, the H_2SO_4 signal decreased significantly, and other organic peaks became visible.

To get a better understanding of the processes forming these organic species, and their role in new particle formation and growth, plant chamber measurements were conducted with both real tree emissions and single compound precursors.

Many features of the ion spectra were reproduced in the chamber experiments, both with real plant emissions from a mix of boreal species, and by using pure alpha-pinene as a precursor. Several ions typically found in Hyytiälä, lacking a conclusive identification (Ehn et al, 2010) were also detected in the chamber studies during experiments with alpha-pinene and ozone, i. e. at low OH concentrations (Fig. 1). The peaks are believed to be nitrate-containing, highly oxidized organic molecules with an O:C:H ratio close to 1:1:1. The plotted mass/charge region shows the dominant peaks in the Hyytiälä spectra, however, in the chamber also larger ions, not visible in ambient air, were detected. Additionally, observations of sulfuric acid and its clusters up to the trimer were detected during new particle formation events both in the chamber, and in the field. However, much stronger nucleation events could be produced in the chamber with only small H_2SO_4 signals, indicating the importance of organic precursors in the formation process.

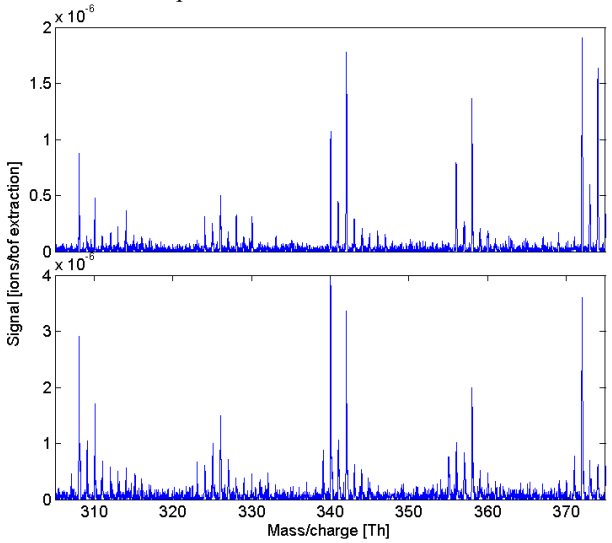

Figure 1. Ion spectra of alpha-pinene oxidation products in the JPAC plant chamber (top), and night-time ion spectrum in Hyytiälä, Finland (bottom).

Effect of relative humidity on antimicrobial filter using *Sophora flavescens* natural product nanoparticles

Gi Byoung Hwang, Jae Hee Jung, Sun Young Park, Gwi Nam Bae

Global Environment Center, Korea Institute of Science and Technology (KIST), Hawolgok-dong, Seongbuk-gu, Seoul 136-791, Republic of Korea

Keywords: natural products, bioaerosols, inactivation, *S. flavescens*.

Presenting author email: hwanggi2@konkuk.ac.kr

As people spend most of their life time at indoor, the importance of indoor air quality has increased. In particular, bioaerosols have been received scientific attention because of high potential for harmful effect on human health. Bioaerosols can spread widely with air stream, and they can cause chronic diseases. Therefore, controlling the concentration and viability of bioaerosols in contaminated indoor is necessary for protecting human health.

Recently, antimicrobial filter using natural products has been considered a pragmatic method for controlling bioaerosols in indoor environment or ventilation system because the toxicity of natural products against human is relatively lower than that of other antimicrobial materials, such as silver nanoparticle and carbon nanotube despite of their high inactivation performance.

In this study, we investigated the effect of relative humidity (RH) on antimicrobial fibrous filter where natural product nanoparticles (*Sophora flavescens*) were already deposited under surrounding condition of RH 25%. After the filters were exposed to each RH condition (25%, 57%, 82%, and 90%) for 5min, we investigated the change of the morphology variation of natural product nanoparticles on fibrous filters by SEM. In addition, their inactivation abilities were tested using *Staphylococcus epidermidis* bioaerosols.

Figure 1 shows the variation in the morphology of natural product nanoparticles on filter with increasing the relative humidity. The significant change of morphology of natural product nanoparticles on fibrous filter was observed in conditions of RH 82% and RH 90%. In case of RH 90% condition, natural products were dissolved by humidified air and coated on fibres of filter. Figure 2 showed that inactivation efficiency of the antimicrobial filter was reduced with increasing RH conditions to which each filter was exposed. However, in RH 90% condition, inactivation rate of the filter was higher than those of conditions of RH 57% and 82%.

We think that the probability to contact between natural product nanoparticle and bacteria cell on the filter fibre because the morphology of natural product nanoparticles were changed flat with increasing RH environment conditions. But, in case of the antimicrobial filter exposed to RH 90% condition, since the all surface of filter fibre were coated by natural products (increasing of contact probability each other), the inactivation rate of the filter increased compared with those of conditions of RH 57% and 82%.

The results of this study provide useful information for developing practical control method on airborne microorganism

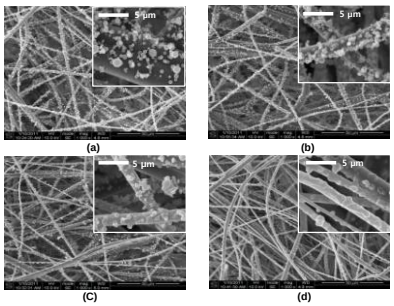

Figure 1. SEM images of (a) RH 25% (b) RH 57% (c) RH 82% (d) RH 90%

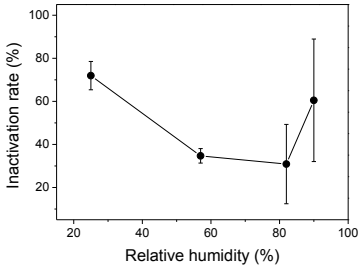

Figure 2. Variation of inactivation rate of antimicrobial filters using natural product nanoparticle under RH surrounding conditions.

Presenting author email: douglas.nilsson@itm.su.se

Colony-Forming Bacteria (CFB) and Fungi (CFF) were determined from samples collected on the east coast of Sweden, Kalmar (56°39.576'N, 16°21.687'E) from April 2007 and September 2008. The aerosol number concentrations of bacteria and fungi (N_{CFB} and N_{CFF}) were interpreted using three dimensional trajectories and a semi-lagrangian approach (Nilsson and Leck, 2003). Fahlgren et al. (2010) showed that N_{CFB} follows the total number of live bacteria, able to grow on solid media and form colonies, and their identity have a high overlap with culture-independent sequencing.

We found clear seasonal cycles in N_{CFF} and N_{CFB} peaking in summer and winter, respectively, both at about 1600 m^{-3} maxima monthly averages. Fungus and bacteria concentrations were uncorrelated, suggesting different sources. Fungi increased over land, corresponding to a continental fungi source of about 1.4 spores $m^{-3}s^{-1}$. We present parameterizations of N_{CFF} concentration and column burden as functions of water vapor mixing ratio q and surface temperature T_s. Fungi concentrations experienced a dramatic drop in concentration in air that had been through at least one episode of temperatures below approximately 0°C. This may either be explained by ice nucleation followed by precipitation, or mortality due to the low temperatures.

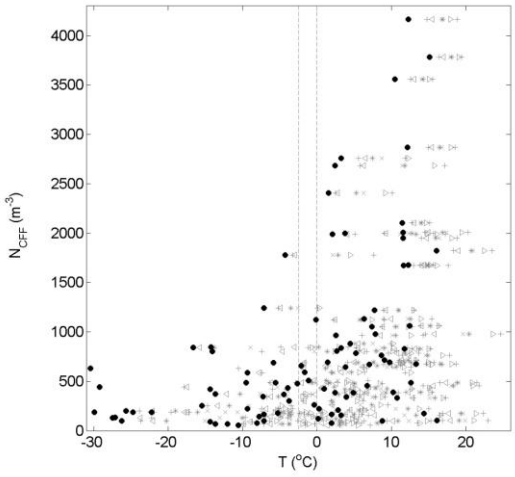

Figure 1. N_{CFF} and air temperature (5 days backward along the trajectories). Grey crosses (x) mark means and pluses (+) mark standard deviation. Grey stars (*) are the median with triangles marking the 25-75% interval. Black filled circles mark minima temperature along the trajectory. Vertical grey lines mark literature values for mortality (0°C) and IN activation (-2.5°C) of fungi.

High N_{CFB} were often associated with transport from both nearby coastal waters and the more distant Atlantic Ocean, as well as higher wind velocities over the seas than for periods with lower N_{CFB}. High N_{CFB} was best correlated to the 10-m wind speed (U_{10}^m) over the upwind ocean, which is consistent with sea spray aerosols. The concentration N_{CFB} increased exponentially with increasing wind speed according to $N_{CFB} = 10^{1.99+0.10U_{10}^m}$, see Fig. 2, in agreement with previous studies for non-biological sea spray. The bacteria emissions are estimated to be about 0.5% of the total sea spray emissions by number. Bacteria concentration did not increase over land. On average 3.4 bacteria $m^{-3}h^{-1}$ were lost over land, corresponding to a sink rate of k_{CFB}=1.49±0.67x10^{-6} s^{-1}, a turnover time of 186h, and an average deposition velocity of 0.6mms^{-1}.

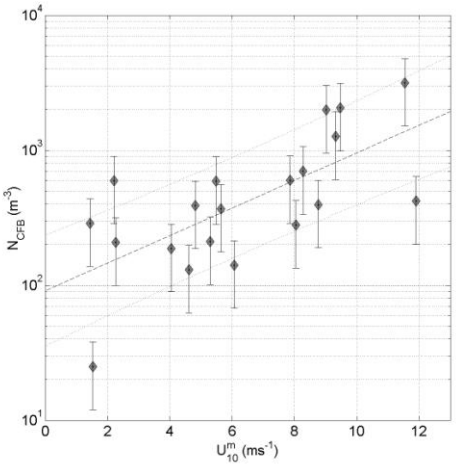

Figure 1. N_{CFB} in the air vs. the ten meter wind speed while the air was over oceans, averaged over 168h backward trajectories (grey diamonds) with sample variation error bars (black). Dashed curve is the log-linear fit, while the dotted curves are the errors containing at least 50% of the data.

Ultraviolet (UV) solar radiation has a broad range of effects concerning life on Earth. It influences human beings and also plants and animals. Furthermore, it causes degradation of materials and functions as a driver of atmospheric chemistry. There are various studies linking changes of the UV radiation field with changes in the scattering and absorption of aerosols in the atmosphere. Such changes can be comparable in magnitude with the ones caused by the stratospheric ozone decline (Krotkov et al., 1998). Moreover, UV variations caused by aerosol optical properties changes affect directly the tropospheric photochemistry:

- Increasing regional O_3 (10-20 ppb for Eastern USA) caused by increased UV levels, due to the presence of non-absorbing aerosols.
- Decreasing regional O_3 (up to 50 ppb for Mexico City and for particular days) caused by strong UV reduction due to absorbing aerosols.

The major parameters that describe radiation and aerosol interactions are the aerosol optical depth (AOD), the single scattering albedo (SSA) and the asymmetry parameter (g). We present estimates of SSA at two independently retrieved wavelengths 332 and 368 nm for an urban site situated at Athens city area, Greece. The period of the measurement analysis was from January to October, 2010. The data that have been used in this work have been retrieved from two instruments:

Since February 2009, the ground-based Atmospheric Remote Sensing Station (ARSS) is continuously operating to monitor radiation levels at ground and aerosol loadings over the city of Athens (Amiridis et al., 2009). The station is located near the city center and 10 km from the sea. ARSS is equipped with a CIMEL CE318-NEDPS9 sunphotometer for the retrieval of aerosol optical depth (AOD) at 8 wavelengths from 340 to 1640 nm, including polarization measurements. Additionally it is equipped with a UVMFR instrument for radiation measurements in the UV spectral region (Harrison et al., 1994). UVMFR measures both total and diffuse irradiance for seven specified wavelengths (here we use 332.4, and 368 nm). Measurements are recorded every 10 s, and stored as 1 min averages along with a computed direct irradiance.

Using the calibrated aerosol optical depth measurements of the CIMEL instrument we have evaluated the Langley aerosol optical depth calibration of the UVMFR instrument. The correlation coefficient of the AOD comparison is 0.98 and the slope equals 0.95 using ~1500 synchronous measurements.

After this step we have used the AOD measurements together with the direct/diffuse ratios retrieved from the UVMFR used as inputs to the LibRadtran radiative transfer model and we have calculated single scattering albedo at 368 and 332 nm for cloud free conditions.

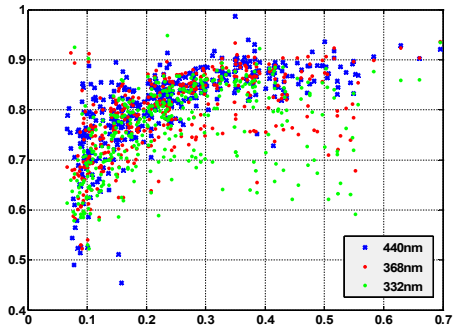

Figure 1. Single scattering albedo at 440nm (CIMEL) and 368 and 332nm (UVMFR) as a function of AOD

Comparing aerosol absorption at the UVA and UVB wavelengths with ones retrieved in the visible range (440nm), we have found lower SSA values (mean difference =0.03) for UVA and (mean difference =0.06) for UVB. Looking in more detail in diurnal retrievals, there is clear evidence that higher UV absorption compared with the visible, is evident to periods with dust aerosol events.

The use of the UVMFR 1 minute measurements reveals high diurnal variability mostly showing higher absorption for couple of hours before and diuring mid-day. Such diurnal patterns are difficult to be demonstrated using the CIMEL sun-photometer retrievals due to the fact that the AERONET-SSA retrievals are available at relatively high solar zenith angles (not close to local noon).

Presenting author email: hbwmo@heinfo.net

Hebei province locates in the north of China. Beijing and Tianjin is surrounded with its district and its east is near the Bohai sea gulf. In the past decades this region has experienced dramatic changes in air quality and climate. In this study, based on the data from airborne PCASP-100X (0.1-3.0 μm) probe of PMS system and some former research results from 2004 to 2009 for this area (Duan *et al*, 2007, 2008; Yan *et al*, 2009). Based on above study, the distribution characteristics of atmospheric aerosols including the distribution characteristics of horizontal, vertical and spectral, variety trend were analyzed by synthetical analysis over north China area.

For instance, the Figure.1 shows that aerosols concentration distribution characteristics with height in three different regions in the north of China under clear sky weather condition in 2005. The result indicates that aerosols number concentration is reached 10^3□$^{-3}$ to 10^4□$^{-3}$ over Shijiazhuang, Xingtai and Hengshui in atmospheric boundary layer of northern China, respectively. However, the aerosols concentration values are decreasing with height increasing, when height above 3000 meters, its value reduced to about 10^2 □$^{-3}$.

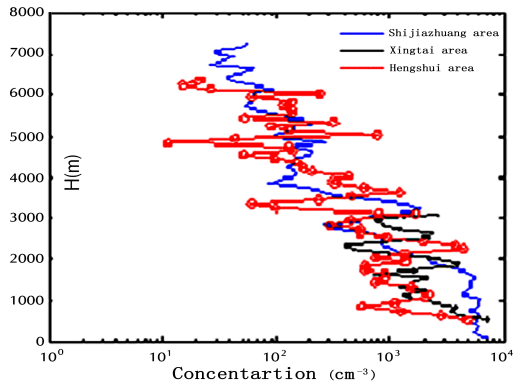

Figure.1 Aerosols concentration distribution with height in 2005

Duan et.al (2008) based on the data from aircraft PMS system detecting under clear sky weather condition in autumn over the Shijiazhuang and Handan both city area of north China, the distribution characteristics of aerosol under different city environmental condition was primarily analyzed. It included their number concentration of aerosol particle, the average diameter distribution with height in both areas over both cities of north China, respectively. Corresponding weather condition is cloudy and clearness over Shijiazhuang and Handan areas. These analyzed results were given in Figure.2.

The figure.2 shows that aerosol average diameter is various with height increasing. Its range of value is 0.17-2.0 μm; the maximum value of average diameter is 2.26 μm.

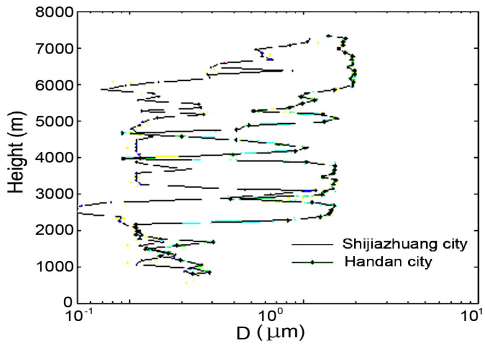

Figure.2 Aerosol average diameter variety with height over both city areas

Aerosol particle property sensitivities to choice of predictive technique in SOA partitioning calculations

D. Topping[1,2], M. Barley[2] , G.McFiggans[2]

[1]National Centre for Atmospheric Science (NCAS), Manchester University, Manchester, M13 9PL
[2] Centre for Atmospheric Science, Manchester University, Manchester, M13 9PL
Keywords: Modelling, Organic compounds, Physical properties, Hygroscopicity.
Presenting author email: david.topping@manchester.ac.uk

Introduction

Atmospheric aerosol particles are an important yet uncertain component of climate change and air quality. Comprised of inorganic and organic material, the inorganic fraction is restricted to a few well-understood compounds. However, organic material can comprise many thousands of, largely unidentified compounds with a wide range of properties (McFiggans et al 2010). Mechanistic understanding and knowledge of individual compounds involved in the chemical evolution of aerosol particles is far from complete. Full chemical analyses of the organic component of atmospheric aerosols are not available (Hallquist, et al. 2009) and significant gaps appear in even the most detailed modeling tools.

Despite this, it is possible to make highly detailed ensemble predictions of the range of organic components expected to condense to atmospheric aerosol by combining a gas/particle partitioning model with a detailed gas phase chemical mechanism. However, choice of estimation method to calculate pure component properties which dictate gas/particle partitioning can have dramatic impact on predicted mass loadings, functionality and associated chemical signatures (Barley et al 2010; McFiggans et al 2010). A large number of calculations of absorptive partitioning of organic compounds have been conducted, making use of several methods to estimate pure component vapour pressures and activity coefficients (p0 and γ). The sensitivities of the predicted particle properties (density, hygroscopicity, CCN activation potential) to the choice of vapour pressure (po) and activity coeffiicient (γ) model and to the number of components used to represent the organic mixture have been systematically compared.

Results

The variability in theoretical hygroscopic growth factor attributable to the choice of estimation technique increases with decreasing mixture complexity. Inclusion of the Joback and Reid boiling point method in the range of methods used to estimate p0, increases the variability in predicted hygroscopicity, owing to a consistent under prediction of component volatility, increasing the variability in composition across the methods.

If no instantaneous re-equilibration of organic semi-volatile components is assumed, the calculated growth factors are comparable to the low hygroscopicity of organic material that has been widely measured in the laboratory and atmosphere. Allowing re-equilibration of all components on drying produces a calculated hygroscopicity greater than has been measured for ambient organic material, and frequently close to those of common inorganic salts. This has substantial implications on aerosol behaviour in instruments designed to measure hygroscopicity and on the measured degree of equilibration of semi-volatile components in the ambient atmosphere. When it is assumed that semi-volatile material other than water does not equilibrate on drying, the sensitivity in radiative forcing, 'ΔF', resulting from the variability in predicted hygroscopicity following the choice of p0 and i estimation technique, is low when the particle organic volume fraction is less than 55 %. Any sensitivities which do exist, increase with decreasing component complexity. If it is assumed that semi-volatile material re-equilibrates to the dry state on drying, the sensitivity of ΔF to choice of estimation technique and complexity increases substantially. The concentration of organics at which the sensitivity of ΔF to choice of predictive technique becomes insensitive drops to between 16 and 22 %.

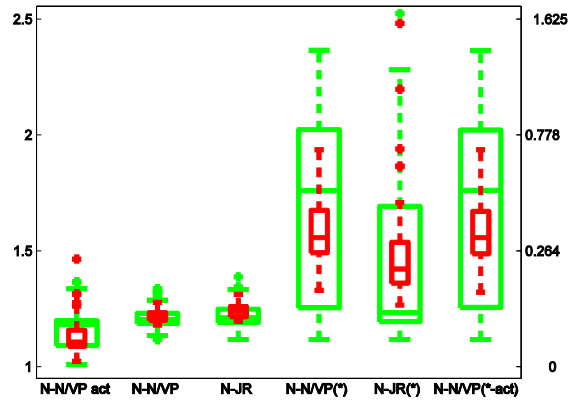

Figure 1. Predicted growth factors and kappa kohler values as a function of predictive technique and number of compounds used in the partitioning calculations. 10000 compound simulations are shown as red boxes, 2 compound simulations as green. Predictive technique acronyms displayed on the x axis, (*) denotes assumed evaporation of all semi-volatiles on drying. The left-hand y-axis lists calculated GF, the right side lists the corresponding kappa kohler values.

Presenting author email:egera@meteo.noa.gr

Solar ultraviolet radiation drives much of tropospheric and stratospheric chemistry since the photodissociation frequencies of important chemical species are directly related to the incident radiation in this spectral region. For example, the photolysis of O_3 and NO_2 is driven by ultraviolet radiation which contributes to their decomposition and removal from the atmosphere

Aerosols are produced by a variety of processes, creating differences in their physicochemical properties and hence in their ability to scatter and absorb solar radiation. Therefore, the origin of an aerosol is relevant in assessing its influence on ultraviolet/visible photolysis rates. Seinfeld and Pandis (1998) have given a complete review of the physicochemical processes involved in aerosol formation and behavior in the atmosphere.

Depending on their composition and scattering-absorption properties, aerosols can increase or decrease the actinic flux and photolysis rates. Radiation scattering increases actinic flux and consequently photolysis rates, whereas absorption decreases both values.

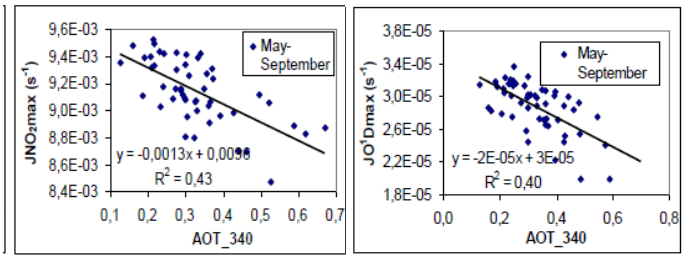
Collected photolysis rates for the period 2002-2006 are used to investigate their levels, their temporal characteristics, evaluate possible trends and their interannual variability. In particular, time series of photolysis rates of ozone (JO^1D) and nitrogen dioxide (JNO_2) at the remote coastal Finokalia station on Crete Island (25°60′E, 35°24′N), were studied in conjunction with aerosol of anthropogenic and natural origins.

Continuous measurements of the photo dissociation rates JO^1D and JNO_2 were performed by filter radiometers (Meteorologie Consult, Germany). The aerosol sun-photometric observations reported here performed by a CIMEL sun-sky radiometer, which is part of the PHOTON/Aerosol Robotic Network (AERONET) Global Network.

Aerosol optical properties, namely aerosol optical thickness (AOT), Angström wavelength exponent and volume size distributions, were used. Generally, the AOT for the specific area is characterized by maximum values during spring, due to the maximum dust loading mainly transported from African deserts, and minimum values in winter. Large AOT values persisting during summer are due to transport of urban/industrial and biomass burning aerosols but also local sources and processes, whereas secondary maximum AOT in October are attributed to autumn dust events (e.g. Fotiadi et al., 2006; Kalivitis et al., 2007).

For the period May to September 2004, the range of Aerosol Optical Thickness (AOT) during maxima of photolysis rates is 0.07-0.49 for 440 nm, 0.13-0.67 for 340nm while the Angstrom coefficient ranges between 0.5 and 2.1. Measurements showed that elevated values of AOT result to a decrease in Js (Fig. 1).

Figure 1. Correlations between AOT at 340 nm with



maximum JNO_2 and JO^1D for the period May-Sep 2004

This is due to the fact that more particles in the column lead to more efficient attenuation of the solar irradiance. J's-AOT Correlation coefficients are higher for AOT at 440 nm than 340 nm. Measurements of low Angstrom coefficients, which mean coarser particles, lead to JNO_2 decrease. Coarse particles at Finokalia, Crete, are mainly dust particles but also sea salt. These particles seem to be responsible for the major part of the decrease in maximum JNO_2 during the day, while finer particles (high Angstrom coefficients) have less impact both due to the facts that are related to lower levels of AOT and that they result to multiple scattering of radiation. It also noteworthy that the correlation coefficients for each month separately are higher than for the whole period indicative of the fact that during longer periods other factors controlling the variability of the photolysis rates become important.

This work was funded by EU (CIRCE 36961, FP6). Parts of the analysis were performed under the Marie Curie project ACI-UV, PERG05-GA-2009-247492.

Presenting author email: jrascado@uevora.pt

Atmospheric particles influence the Earth's climate in different ways. One important example is the impact of aerosols on clouds by means of the so-called aerosol indirect effects, i.e. altering the albedo, lifetime and precipitation patterns of clouds. The first aerosol indirect effect or Twomey effect is defined as the change in observed cloud optical or microphysical properties (as optical depth, albedo or cloud droplet effective radius) as a function of the change in the aerosol burden.

Many studies have been addressed to characterize the first aerosol indirect effect during the last years, most of them based on satellite retrievals. However, one uncertainty lies in the relative altitude levels of aerosols and clouds, i.e. even when aerosol and cloud layers are detected, they may not be mixed and their interaction differs (Costa *et al*., 2007). In addition, many previous studies are biased due to the absence of temporal and/or spatial coincidence, i.e. in many cases the measurements of clouds and aerosols are not available simultaneously or they are measured over non co-located areas.

In this work we present preliminary results about cloud-aerosol interaction derived from the multiwavelength Raman lidar operated routinely at the Évora Geophysics Center (Évora, Portugal, 38.6ºN, 7.9ºW, 293 m asl) (Wagner *et al*., 2010). The simultaneous aerosol and cloud optical depths were obtained by integration of the extinction profile derived from Raman signals at 532 nm. The extinction profiles at altitudes of incomplete overlap were modeled through the Raman backscatter with a constant lidar ratio. To assess the impact of the coupling between cloud and the underlying aerosol particles, the boundaries for aerosol and cloud layers have been determined following the zero-crossing method on the first derivate of the Raman backscatter coefficient. An example of night time data measured during the Saharan dust event observed over Évora between 9 and 11 December 2010 is shown in Figure 1. In order to consider the high variability of cloud layers, lidar data were averaged over 15 minutes. Thus, a dataset of more than 45 Raman lidar profiles measured during the night were obtained for this period.

To investigate the relation between cloud and aerosol optical depths (COD and AOD), AOD averaged values grouped in 0.01 intervals were computed, because of the large variability of the optical depths. Moreover, the experimental data were split taking into account the vertical distance between the cloud base and the top of the underlying aerosol layer (from now on referred to as interaction distance).

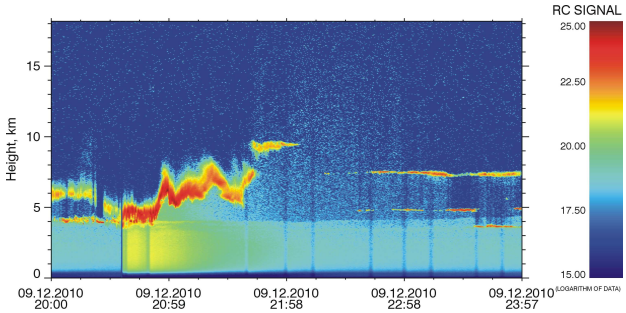

Figure 1. Temporal evolution of the range corrected signal (arbitrary units) on 9th December 2010.

Preliminary results indicate a significant correlation, $R^2 > 0.64$, between COD and AOD (in logarithmic scale) for interaction distances less than 100 m. The correlation decreases drastically for interaction distances between 100 and 1000 m, and larger than 1000 m, with correlation $R^2 < 0.28$ in both cases. Furthermore, the cloud-aerosol interaction computed as the slope of the COD versus AOD linear regression (in logarithmic scale) shows an opposite sign for data with shorter interaction distances (< 100 m) with respect to those with larger distances.

The work presented at the conference will involve the analysis of additional cases including more Saharan dust events and also other particle types as resulting from biomass burning and anthropogenic pollution.

Analysis of the ambient particle number size distributions characteristics during nucleation events in the Eastern Mediterranean

I. Kopanakis[1], S.E. Chatoutsidou[1], K. Torseth[2], T. Glytsos[1] and M. Lazaridis[1*]

[1]Department of Environmental Engineering, Technical University of Crete, Polytechneioupolis, Chania 73100, Greece

[2] Norwegian Institute for Air Research Instittutveien 18, N-2027, Norway

Keywords: nucleation, number concentration, growth rate, formation rate.

An extensive field campaign was performed at Akrotiri monitoring station in the island of Crete (Greece) in order to study the characteristics of the ambient aerosol number size distribution spectra and furthermore to evaluate the atmospheric potential for nucleation events in the area. The campaign lasted for one year (June 2009 - May 2010) and measurements were conducted for 130 days covering equally the four seasons of the year.

The station is located at an urban background/semi-rural area near the city of Chania at the western part of the island of Crete (Lazaridis et al. 2008). The measurements were conducted using a Scanning Mobility Particle Sizer (SMPS) system. The system was programmed to measure the PM number size distribution in the size range between 13.2 and 1083.3 nm, separating the particles into 44 consecutive size bins. The modal structure and the characteristics (geometric mean diameter (GMD), and geometric standard deviation (GSD)) of each mode comprising the aerosol size distribution were identified using the AMANpsd algorithm (Ondracek et al., 2009). The ambient meteorological conditions (temperature, relative humidity, wind speed, wind direction, solar and UV radiation) and PM_{10} and O_3 concentrations were continuously monitored and recorded during the whole measurement campaign. In addition, the origin of the air masses reaching the station was estimated using back trajectories provided by the HYSPLIT model.

The measurements revealed that Aitken mode particles (13.2-101.1 nm) showed higher concentrations than Accumulation mode particles (101.1-1083.3 nm) for the whole measurement period. Moreover, particle number concentrations were higher during weekends than weekdays. The mean total number concentration was 583 ± 362 particles cm^{-3}, while the maximum particle number concentration was 6148 particles cm^{-3}. The modal structure of the aerosol size distribution was mainly unimodal with GMDs ranging between 70 and 100 nm. Furthermore, the analysis of back trajectories showed that different air mass origins were associated with different levels of particle number concentrations.

Formation of new particles due to nucleation was observed and the process led to an increase of aerosol number concentration, as depicted in Figure 1. In total, 13 considerable new particle formation events were recorded. The 9 out of 13 nucleation events took place during the night or occurred both during day and night. The maximum particle number concentrations during nucleation events were observed for particles having diameters between 65 and 110 nm. The computed mean values of growth and formation rates were 5.84 nm hr^{-1} and 13.11 cm^{-3} s^{-1}, respectively.

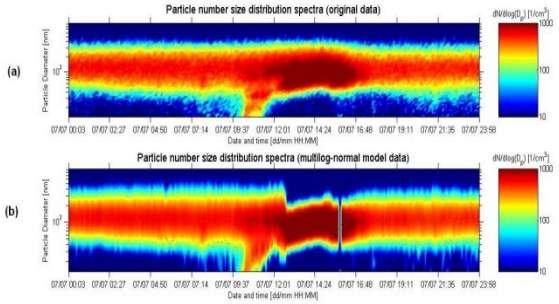

Figure 1: New particle formation event observed on summer period of 2009 at Akrotiri research station, Crete, Greece (a) raw data, (b) data derived from the AMANpsd algorithm.

Finally, the classical theory of heterogeneous nucleation for the sulphuric acid - water system has been applied to study its ability to describe the nucleation events. The theory was able to qualitatively describe the experimental observations.

Evaluation of uncertainties in determining particle volatility properties from experiments with standard thermal-denuder techniques

E. Fuentes, R. Alfarra, M. Flynn and G. McFiggans

Center for Atmospheric Sciences, School of Earth, Atmospheric and Environmental Sciences, University of Manchester, Manchester, M13 9PL, United Kingdom
Keywords: organic aerosols, thermodenuder, volatility
Presenting author email: Elena.Fuentes-lopez@manchester.ac.uk

Thermodenuders systems are increasingly used to characterise the volatility distribution and vaporisation properties of organic aerosols in both field and laboratory studies (Huffman et al., 2008). The standard procedure for application of these systems is the monitoring of the particle size distribution before and after the thermodenuder, in order to estimate the mass of organic material that is evaporated at different set-point temperatures. This type of analysis relies on the assumption that the modification of the size distributions in thermodenuders is only due the homogeneous evaporation of the particles initially injected in the system. However, factors such as the gas recondensation/evaporation occurring in the cooling and denuder sections and the inhomogeneous evaporation induced by gas velocity gradients could potentially lead to modifications in the resulting size distributions and the derived thermograms. Quantification of the error induced by these factors on the thermograms obtained from standard thermodenuder experiments is therefore needed.

In this study an axysimmetrical 2-D diffusion-evaporation model was employed to theoretically evaluate the impact of different sources of uncertainty on thermograms derived from experiments conducted with standard thermodenuder designs. The velocity gradient resulting from the non-slip condition in annular tubes and the recondensation/evaporation of gas in the cooling section and adsorbent denuder, were evaluated as potential sources of uncertainty in the determination of the particle size distributions. Thermograms obtained with a typical thermodenuder system comprising a heating, cooling and denuder section, of dimensions similar to Huffman et al. (2008), were modelled for monodisperse aerosol distributions of different volatility. Recondensation fractions from 20-70% were predicted for low volatility compounds with saturation concentrations C*≤1 μg/m^3, at organic mass loadings in the range 30-200 μg/m^3 (accommodation coefficient of unity, T=80˚C). On the other hand, recondensation was only found to be significant at high organic aerosol loadings for compounds with C*≥10 μg/m^3. These findings point at the necessity of controlling recondensation even for low organic atmospheric loadings in the range 30-50 μg/m^3 if compounds of low vapour pressure are expected to be dominant in the organic aerosol composition.

An already significant recondensation was predicted to occur in the cooling section (5.7 s residence time) between the heater and denuder sections, for organic loadings 30-200 μg/m^3 and C*<1 μg/m^3, which led to a 20% overestimation in the values of mass fraction remaining. Denudation was found not to be sufficient to hinder the recondensation of gaseous compounds with C*≤0.1 μg/m^3 at high aerosol loadings (Figure 1), which together with the recondensation already occurred in the cooling section yielded deviations up to 40% in the mass fraction remaining with respect to the heating section output. Because of the significant recondensation occurring in the cooling section and the lower efficiency of adsorber denuders for stripping gas at high aerosol loadings, thermograms of low volatility aerosols at typical laboratory concentrations should be corrected to avoid underestimations of particles volatility.

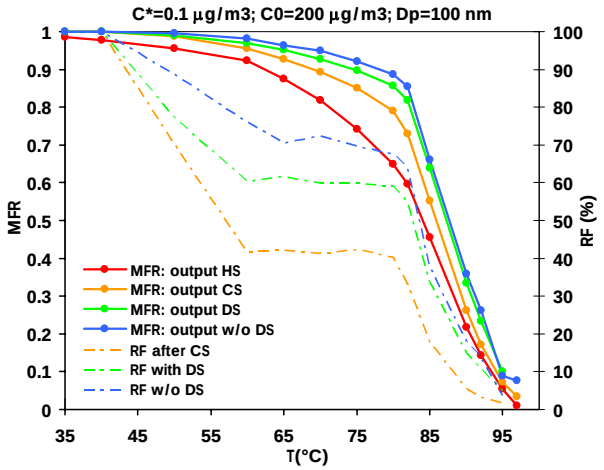

Figure 1. Mass fraction remaining (MFR) and recondensation fraction (RF) calculated for a standard thermodenuder system. HS=heating section (0.5 m), CS=cooling section (0.15 m), DS=denuder section (0.5 m). Tube diameter=0.022 m. Sample flow=0.6 lpm.

Enhanced Secondary Organic Aerosols during Fog Episodes

D.S.Kaul, S.N.Tripathi, Tarun Gupta

Department of Civil Engineering, Indian Institute of Technology, Kanpur, 208016, India
Keywords: Atmospheric Aerosol, Aerosols and air quality, Aerosols and climate
Presenting author email: snt@iitk.ac.in

PM1 samples were collected from January 16, 2010 to February 20, 2010 at Kanpur (26.5º N, 80.3º E, 142 m msl) to study the secondary organic aerosol (SOA) production during clear and foggy days. Of the 180 samples collected, 56 were from foggy days. Micro-Pulse Lidar Network (MPLNET), a part of National Aeronautic Space Administration (NASA), was used for identification of fog duration. Organic Carbon (OC), Elemental Carbon (EC) and total carbon analysis were carried out to examine total and water soluble carbonaceous component of aerosol, respectively. Trace gases and solar flux measurement by gas analyzer and pyranometer (a part of NASA), respectively were carried out to identify the photo-chemical activity. Meteorological data and pH were measured by atmospheric weather station and pH meter, respectively.

This study examines the reason of such enhanced yield and hypothesizes likely production of SOA through aqueous phase chemistry during fog episodes. SOA was estimated during foggy and clear days using tracer method. Enhanced SOA was observed during foggy days (Fig 2). Production of SOA was highest in the afternoon and lower during morning and evening. Peak of OC/EC during foggy days occurred earlier indicating role of aqueous phase chemistry in addition to gas-particle portioning which is the prevalent mechanism of SOA production during clear days. Some investigators (Offenberg et al., 2009) have documented enhanced SOA yield via acid catalysis pathway, though similar finding in ambient has not be confirmed (Tanner et al., 2009). To observe similar relationship, pH measurements on all samples were carried out. Poor correlation of OC/EC with pH during foggy days (R^2=0.04) and clear days (R^2=0.085) was observed, though their correlation was high for pH < 7. These findings suggest acid catalyzed SOA production but its contribution is insignificant. The possible contribution of biomass burning to SOA was also examined. It was found that WSOC are removed by water droplets during foggy episodes, its removal followed inverted bell shaped curve with highest during night time (37 to 49 % of OC) and lowest at 4:00 PM (0.03 % of OC). OC removal was further examined by analysing OC in fog water. Higher concentration of OC was observed in fog which further supports WSOC removal. Such removal indicates that though due to low temperature during foggy days, more biomass may have been burned but they are removed due to their hygroscopic nature during foggy days thus contributing insignificantly to SOA during the episodes. Details of the finding and related contribution of sources to SOA will be presented.

Aerosol-cloud interactions as well as the chemical composition of particles were investigated during the field campaign Hill Cap Cloud Thuringia (HCCT) in September and October 2010 on a mountain site in Central Germany (Schmücke, 938 m a.s.l.). Orographic cloud residual particles were analysed by the Aircraft-based Laser Ablation Aerosol Mass Spectrometer (ALABAMA, particle size range 150 nm - 900 nm) (Brands *et al.*, 2011) behind a counterflow virtual impactor (CVI), which samples cloud droplets and subsequently evaporates the cloud water. Additionally the total background aerosol population was sampled through an interstitial inlet (INT, cut-off diameter 5 µm) before and after cloud events. Parallel to the ALABAMA the particle size distribution was measured by an optical particle counter (OPC) with a size range between 0.25 µm and 32 µm.

The ALABAMA allows the qualitative chemical analysis of submicron single aerosol particles by laser ablation with a time resolution of 70 ms. This method gives information about particle size as well as composition and consequently helps to distinguish between different particle types. Although being developed for aircraft-based measurements, the ALABAMA is also suitable for ground-based measurements.

About 200000 positive and negative single particle mass spectra were recorded during the field campaign. A comparison of the averaged mass spectra for activated (CVI) and total (INT) aerosol shows that cloud residual particles contain a higher fraction of nitrate-containing particles, but a lower fraction of organic particles than particles of the background aerosol (see Figure 1). Besides, the relative fraction of sulphate is smaller. For further analysis, the mass spectra are separated in clusters, representing a certain particle type, by different clustering algorithms e.g., k-means. The relative abundance of the clusters will be related to meteorological conditions as cloud events, wind direction or back trajectories.

The time series of the number concentration measured by ALABAMA and the OPC show a good correlation between the two instruments, whereas the size distributions have different maxima due to various detection limits and sizing methods. Further analysis of the size distributions of cloud residual particles respectively background aerosol particles in addition with the mass spectra gives a hint for answering the question whether particle size or composition is the determining factor for particles to act as cloud condensation nuclei (Dusek *et al.*, 2006).

Contrails, and their spreading into cirrus, are one of the most visible human influences on the Earth's climate, e.g. Stordal *et al*. (2005). Contrails reflect solar radiation and trap terrestrial long-wave radiation, with the latter effect expected to dominate for contrails and thin cirrus: resulting in a positive radiative forcing (Penner *et al.*, 1999). Soot emission in the aircraft exhaust is thought to play a role in the formation of contrails (e.g. Heymsfield *et al.*, 2010), though the role of soot in forming cirrus ice crystals downstream is highly uncertain.

There is very little known about the properties of older contrails and contrail-cirrus because of a lack of observations. Aircraft measurements of contrail ice particle size distributions only exist for line-shaped contrails because, once they lose their initial shape, non-linear contrails are very difficult to identify. The transition of line-shaped contrails into cirrus-like clouds is neither well understood nor well represented in climate models.

The work presented here is part of the COntrails Spreading Into Cirrus (COSIC) campaign. In order to improve our understanding of contrails, measurements of aerosol and cloud microphysical properties for several contrails were collected using the FAAM BAE-146 aircraft. Preliminary results from these measurements are discussed here. The research aircraft is fitted with a suite of aerosol and cloud probes including a Cloud Imaging Probe (CIP), Cloud Droplet Probe (CDP), 2D optical array probe (2D-S) and a Single Particle Soot Photometer (SP2) for size-resolved sub-micron aerosol black carbon mass.

During a flight on 03 June 2009, contrails were produced and sampled over the sea to the south-west of the UK within busy air traffic lanes. Upper air forecasts (27-34kft) for this period suggested northerly flow of low to moderate strength and little natural cloud. Forecasted humidity fields showed a pattern of increasing humidity on a north-west to south-east axis, which at >30kft was above ice saturation over much of the southern UK. Figure 1 shows data collected when sampling a contrail initiated in a previous aircraft orbit; a difficult task. An example of measurements within one contrail pass is shown. Cloud particle concentrations increase towards the centre of the pass, along with black carbon measurements. Size distribution measurements show that elevated number concentrations of smaller particles within the centre of the contrail (stars) are often observed compared to when at the contrail edge; where a peak in the size distribution at significantly larger sizes (200μm) can be seen. We will discuss the contrail cloud microphysical evolution within this trafficked region as well as the aerosol black carbon loadings in this region to determine how the two may be related.

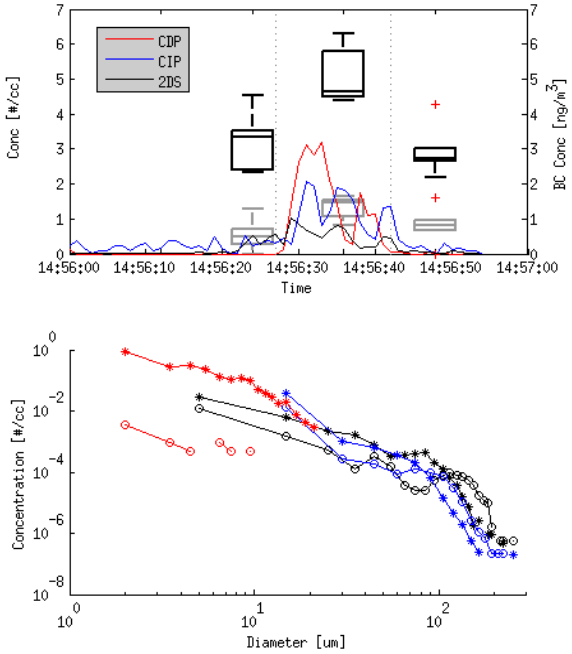

Figure 1. a) Concentration of particles detected by the 2DS (black), CIP (blue) and CDP (red). Also box and whiskers for the total scattering particle concentration (black) and total black carbon number (grey) from the SP2. b) Averaged size distribution for the regions indicated by the box plots in part a: within the contrail (stars), at the contrail edges (circles).

Weather condition – air quality relationships in Eastern Germany (1999 – 2009)

Silvia Leise, Andreas Hoy, Frank Zimmermann, Jörg Matschullat

Interdisciplinary Environmental Research Center, Technische Universität Bergakademie Freiberg, Brennhausgasse 14, D-09599 Freiberg, Germany
Keywords: Aerosol characteristics, air quality, weather conditions, climate change
Presenting author email: silvia.leise@ioez.tu-freiberg.de

PM_{10} and $PM_{2.5}$ data from the past ten years in Saxony (Eastern Germany) were used to investigate the relationship between air quality and weather conditions. Six research sites, four urban and two background locations, with almost continuous measurements of PM were analysed from 1999 to 2009 (Figure 1). The results are the basis for event-based measurements to analyse the influence of climate change on air quality.

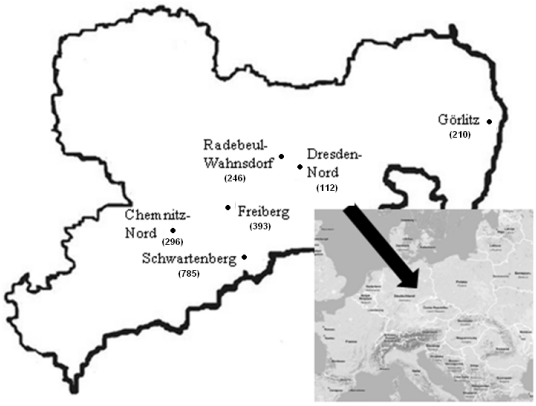

Figure 1: The investigation area with its stations and altitude (m. a. s. l.)

The classification methods used in this work are the *Grosswetterlagen* system, originally developed by Baur et al. (1944), and the objective weather type classification of the German weather service (DWD). 29 *Grosswetterlagen* (GWL) are grouped into four directions of inflow (GWL-DI) to make them more comparable to the DWD classification and to allow data validation. Their database dates back to 1881 AD; thus conclusions of past-time behaviour of aerosol concentrations can be made. The objective weather classification system (DWD-OWT) is available from 1979; a validation by means of GWL for the present state is possible for 31 years. The modelled future developments of the DWD-OWT provide a starting point for conclusions about the ongoing aerosol characteristic.

Significantly higher aerosol pollution, regardless of the particle size, arises at all locations for south-eastern wind directions. Both classification systems show high air pollution for easterlies and low air pollution for westerlies. This difference is likely caused by long-range transports of aerosols from Eastern Europe. Anticyclonal weather conditions show higher pollution then cyclonic ones (e.g, because of less wind and dryer conditions). This can be concluded from both classification systems and is in agreement with further studies of the relationship of weather conditions and air quality (Buchanan et al. 2002; Buchholz et al. 2010).

The general level of aerosol concentration differs by season, whereas connections between aerosol pollution and different weather conditions are independent of seasonal influence (Table 1).

Table 1: Mean PM_{10} values [µg/m³] for the six sites (1999-2009), separated by DWD-OWT and GWL-DI (weighted mean) and a seasonal differentiation (winter and summer half years). Blue bars show the ratio of PM_{10} concentrations between the weather conditions, sites, half years and classification systems.

Spatial and seasonal variation of number concentration and size distribution of aerosol (5.6 – 560 nm) in urban and rural areas of Bologna (Italy)

Regional Agency for Prevention and Environment (ARPA), Bologna, Italy

keywords: Aerosol size distribution, ultrafine particles, number concentration, nucleation mode.

Presenting author email: vpoluzzi@arpa.emr.it

Size distribution and number concentration of low troposphere aerosol were measured during several seasons in three different environmental conditions in Bologna: a rural background site, a high traffic site and an urban background site. Knowledge about the spatio-temporal behaviour of particles in ambient air could greatly simplify the description of aerosol processes and effects, and also particles exposure assessment.

During study, a Fast Mobility Particle Sizer (FMPS TSI 3091) was used to measure particles from 5.6 nm to 560 nm with a 1 second time resolution.

Lower values of average total number concentration were found in the rural background site (SPC), respectively 8000 #/cm^3 in autumn campaign and 6000 #/cm^3 in spring campaign. The highest values were detected in traffic site (MXD): 17000 #/cm^3 in summer campaign and 20000 #/cm^3 in the campaign across winter and spring. SPC was located far from anthropogenic sources, while MXD was near a strategic highway. Urban background site (GMA) was located in a park in the urban area of Bologna, close to a very busy avenue. In this site values of average total number concentration detected were 10000 #/cm^3 during the campaign of late summer and 9000 #/cm^3 during spring.

A broad observation revealed that particles number and size distribution varies in time and space in a complex manner as a result of interaction between local sources and meteorological conditions [Costabile, 2009].

To observe how sampled particles distribute, total particles has been distinguished in ultrafine (UFP, diameter <100 nm) and not ultrafine (NoUFP, diameter >100 nm). Highest percentages of UFP particles were found in MXD (91-92%) and in GMA (87-91%), while SPC revealed the lowest values (77–80%). Presence of direct emission sources (avenue and highway) reflected on high concentration of ultrafine particles, probably mostly produced by exhaust combustion (Hussein, 2005).

Particles size distribution data have been manipulated using DistFit™ software (Chimera Technology, Inc) that fit one or more superimposed size distribution functions to such data. Software estimates a number of distribution ranges and their mean geometric diameter values. Results permitted to classify particles in three main distribution ranges: nucleation, Aitken and accumulation mode. Percentage of particles in nucleation mode respect total was relevant in MXD site, especially during spring campaign (64%). Lowest percentage particles were found in rural site (10-17%) confirming that direct emissions contribute significantly to nucleation range. Aitken mode showed variable values of particles in MXD and GMA, while high percentage were found in SPC. About accumulation mode, lowest values were registered in MXD site while highest ones were found in SPC probably due to the bigger influence of crustal fraction in rural areas.

During monitoring campaigns, a great number of particles growth events were observed in atmosphere. In warm seasons the episodes were more frequent than in cold ones, due to the high temperature and solar radiation that are responsible of photochemical reactions. Furthermore, higher PBL and, generally, more air turbulence in summer allows low pollutants concentration in lower troposphere promoting gas-to-particle conversion (Kulmala, 2008).

Keywords: chemical composition, CCN, field measurements.
Presenting author email: gerard.capes@manchester.ac.uk

We present an overview of aerosol physical and chemical properties from measurements at a rural site in southern England. As part of Aerosol Properties, PRocesses And Influences on the Earth's climate (APPRAISE), in situ measurements were taken to characterise background aerosols away from large sources of anthropogenic aerosols. Black carbon measurements were taken using a DMT Single Particle Soot Photometer (SP2), speciated mass concentrations measured by an Aerodyne Time of flight Aerosol Mass Spectrometer (ToF-AMS), particle size was measured using a range of optical particle counters and hygroscopic properties measured by a DMT cloud condensation nuclei counter (CCNc).

Local aerosol sources are identified using wind sector analysis and organic aerosol sources are characterised using positive matrix factorisation (PMF) of ToF-AMS data. The deconvolution of organic mass spectra revealed that biomass burning (BBOA), oxygenated organic aerosols (OOA) and hydrocarbon-like organic aerosols (HOA) could account for virtually all the variability in organic mass concentration. HOA consistently represented the smallest contribution to total organic mass throughout the measurement period. Number size distributions showed some diurnal dependence and variability between wind sectors, with the highest concentrations and larger sizes coming from the S-SE-E wind sectors. Analysis of long range (five day) air mass back trajectories confirmed that relatively local sources determined aerosol properties - which land masses, if any, were crossed in the final day of the trajectory revealed differences in aerosol properties, regardless of the rest of the trajectory. Typical number concentrations are around 5000 cm^{-3} reaching up to 40000 cm^{-3} on occasion.

Black carbon concentrations were generally less than 0.5 $\mu g\ m^{-3}$, but with peaks as high as 1.6 $\mu g\ m^{-3}$. Non-refractory aerosol composition was typically a mixture of organics and ammonium nitrate. Concentrations were typically 1–2 $\mu g\ m^{-3}$ for both organics and nitrate, each peaking around 10 $\mu g\ m^{-3}$. The mixing state of black carbon was investigated through consideration of particle coating thicknesses measured by the SP2.

We use this set of measurements to investigate the factors which influence the cloud droplet and ice crystal nucleating abilities of aerosols which are typical of the background aerosol population.

Composition of particles larger than 0.5 μm which may act as ice nuclei (IN) [DeMott et al., 2010] are determined by SEM analysis of aerosols collected on nuclepore filter substrates, while the number concentration of ice nuclei (N_{IN}) is derived using the same parametrisation from DeMott et al. [2010]. At -10°C, predicted ice nucleus concentrations ranged between 0.5 l^{-1} and 4 l^{-1}, at -20°C predicted N_{IN} varied between 15 l^{-1} and 800 l^{-1}, and at -30°C predicted N_{IN} fell between 170 l^{-1} and 72000 l^{-1}. Despite considerable scatter, IN concentrations showed a clear positive correlation with nitrate.

Cloud condensation nucleus number concentrations (N_{CCN}) at low supersaturation (i.e. 0.1%) were typically around 200 cm^{-3}, and rarely greater than 500 cm^{-3}. Typical N_{CCN} at 0.3% supersaturation were around 700 cm^{-3}m with peaks up to 2500 cm^{-3}. At 0.1% supersaturation, N_{CCN} correlates well with predicted N_{IN} (at temperatures between -10°C and -30 °C), but this relationship breaks down at higher supersaturations.

Aerosol critical supersaturation at different particle diameters showed a weak dependence on composition, which was broadly in agreement with a Kappa-Köhler model prediction for a mixed organic/ inorganic aerosol of varying organic mass fraction. However, variability in N_{CCN} seemed to be largely related to aerosol number concentration, rather than aerosol composition.

Anthropogenic Snowfall Events from Urban Fogs

G.J. Lloyd[1], T.W. Choularton [1]and P.Connolly[1]

[1]School of Earth Atmospheric and Environmental Sciences, University of Manchester, Manchester, M13 9PL,
Keywords: urban fog, snow, anthropogenic aerosols, ice nuclei
Presenting author email: Gary.Lloyd@student.manchester.ac.uk

During periods of anticyclonic weather, increasing numbers of Anthropogenic Snowfall Events (ASEs) from slightly supercooled fogs are being reported in the UK. The phenomenon was first recognised in the 1970s in America after work by Agee (1971) and Farn et al. (1978) noted a connection between industrial sources of aerosols created through combustion and inadvertent seeding of snowfall from fog. More recently work by Wood and Harrison (2009) described several events in the UK and striking satellite imagery provided by Van Den Berg (2008) revealed many patches of snow situated downwind of industrial areas after a period of freezing fog in the Netherlands.

In this paper we explain how the introduction of aerosol able to act as ice nuclei slightly below 0°C influences the microphysical processes that lead to these events. This is done through examination of reported ASEs, results from ice nucleation experiments using fly ash and other anthropogenic aerosol, together with analysis of meteorological data collected from the Whitworth Observatory during several events in Manchester, which for the first time provides valuable information obtained during the evolution of a number of ASEs.

A review of all reported ASEs reveals that these events occur in anticyclonic conditions in industrialised areas, close to potential sources of ice nuclei, when slightly supercooled fog is present at temperatures around -5°C. It is likely to be significant that these events occur within a temperature range where a known mechanism of secondary ice particle production occurs, as a few primary nucleated crystals fall through the supercooled fog (The Hallett-Mossop Process). Just one ASE at temperatures between -10°C to -14°C was reported by Farn et al. (1978) and in this temperature zone there is no known method of producing secondary ice particles hence it is very likely that all the snow crystals observed were produced through primary nucleation by aerosol.

The hypothesis, therefore, is that man made aerosol, is responsible for initiating the ice in these slightly supercooled fogs with, in many cases, secondary ice particle production enhancing the number of ice crystals leading to a detectable snowfall.

In order to investigate this, ice nucleation experiments using a cold stage and drops of deionised water polluted with fly ash confirmed the effective nature of this particular combustion product in triggering ice formation at higher temperatures, the average onset of ice nucleation being -3.4°C. Future ice nucleation experiments with man-made aerosol will be conducted to further investigate these preliminary findings and the results will be presented. This will identify whether an anthropogenic source of ice nuclei is able to cause ice formation in a temperature range where natural ice nuclei are very few.

Analysis of data obtained from the Whitworth Observatory Disdrometer reveals the precipitation types as an ASE on the 20th December in Manchester took place. Initially freezing drizzle is recorded before a transition to snow grains and eventually snowfall. Temperatures recorded at the beginning of this event were -2°C falling to -2.7°C. It is likely that further ASEs will be recorded by the observatory, providing the opportunity for detailed comparison of events, which will be crucial in the understanding of snowfall from urban fogs.

This sequence of precipitation provides one possible answer as to how an ASE may triggered. The introduction of efficient ice nuclei from a source of combustion, close to Manchester City Centre, will cause some of the fog droplets to freeze and as these fall they begin to sweep up other supercooled drops, growing by riming as they do so with the precipitation type making a transition to snow grains. As this riming takes place the Hallet-Mossop Process provides a powerful secondary ice production mechanism that is sufficient enough to cause the subsequent snowfall.

The significance of these results extends beyond that of the local importance of snowfall from radiation fog. The ability of certain man made aerosol to initiate snowfall from slightly supercooled layer cloud will substantially influence the water balance, water content and microphysics of these clouds. This will in turn shorten the lifetime of the clouds and their radiative properties. Hence this is potentially an important man made aerosol indirect effect in the atmosphere.

The effect of coronal mass ejections on cloud microphysics

J. Svensmark,[1] M. B. Enghoff,[1] and H. Svensmark[1]

[1]National Space Institute, Technical University of Denmark, Copenhagen, DK-2100, Denmark
Keywords: Cloud microphysics, satellites, ion-induced nucleation
Presenting author email: enghoff@space.dtu.dk

During close passages of coronal mass ejections, which cause Forbush Decreases in the incoming galactic cosmic radiation, a measurable and significant change in the clouds microphysics appears to take place. Expanding a study by Svensmark, Bondo, and Svensmark the present work investigates the response of six cloud parameters, using MODIS data, to these Forbush Decreases.
We rank the Forbush Decreases according to their impact on ionisation in the lower atmosphere since this is where an effect is expected.
Investigating the 5 strongest events we find that cloud emissivity, cloud fraction, liquid water content, and optical thickness all show reductions in signal above the 2-3 sigma level 7-9 days after the minimum in atmospheric ionisation. Similarly we observe a rise in the droplet effective radius just below the 2 sigma level, but it is not possible to resolve a significant response in the column density of cloud condensation nuclei. The significance of the found results is tested using Principal Components Analysis.

We find no correlation between Forbush Decrease intensity and UV radition. A signal is seen in the TSI 2 days prior to the Forbush Decrease minimum (about 1.5 W/m^2 for the 5 largest Forbush Decreases) but we are not aware of any mechanism that can cause such a forcing to produce a cloud signal about 10 days later.

Furthermore there appears to be a systematic link between the reduction in amplitude of the cosmic ray ionisation and the size of the response of the studied parameters. These results add further support to the suggestion that ions play a role in the formation of clouds.

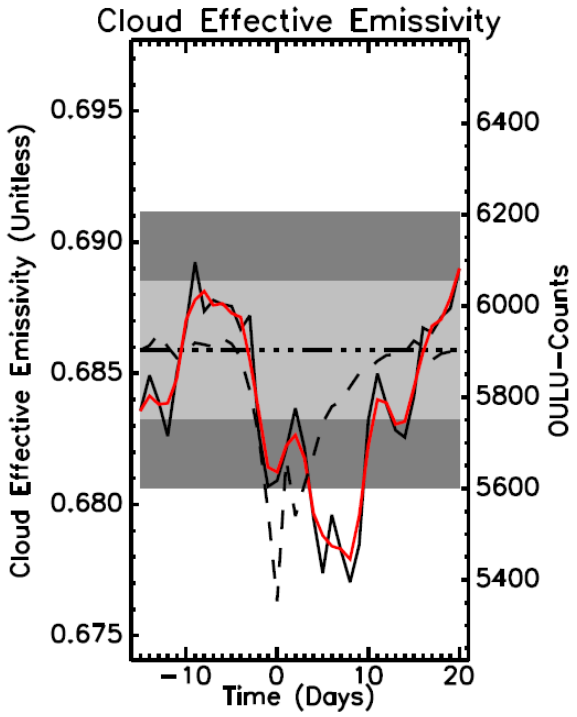

Figure 1. Cloud Emissivity is one of the six investigated parameters. The black dashed line shows the count rate in the OULU neutron monitor. The fully drawn black line is the response in the Cloud Effective Emissitivty, averaged over the 5 strongest Forbush Decreases, while the red line is a 3-day running mean. The light grey box shows 1 standard deviation while the dark grey box shows 2 standard deviations.

It is well established that clouds play an important role for atmospheric chemistry. Inside a cloud, the chemical reactions pathways, which are much different from the ones provided by the gas phase chemistry, are leading to modified atmospheric aerosols after cloud dissipation impacting the oxidative capacity of the atmosphere.

Impact of orographic clouds to the local aerosol chemical composition was measured during the Hill Cap Cloud Thuringia 2010 (HCCT-2010) field campaign which took place in autumn 2010 at the Schmücke Mountain in the Thuringia forest (Germany). Three sampling stations were equipped: a first one on the top of the Mt. Schmücke where clouds were sampled and two valley stations located upwind and downwind to the summit of the mountain. The main objectives of the HCCT-2010 project are to assess the effects of clouds on particle composition, gas phase oxidant budget, changes of hygroscopic properties and activation of aerosol particles.

In order to follow changes of aerosol chemical composition, a total of four Aerodyne ToF-AMSs were deployed during the campaign. One at each valley stations and two at the summit station; one connected downstream of a Cloud Virtual Impactor (CVI) for droplet residuals and one connected to an interstitial inlet measuring interstitial particles (Figure 1). The AMS measurements at both valley stations were completed by PM_1 Particle-into-liquid sampler measurements (PILS, *Weber et al., 2001*) and at the upwind station by a PM_{10} Monitor for Aerosols and Gases in ambient Air (MARGA, Applikon Analytical, NL, *ten Brink et al., 2007*).

The three stations provided simultaneous measurements of the sized resolved aerosol chemical composition before, inside and after a cloud. Based on air mass trajectories, gas tracer experiments and meteorological parameters, it is possible to identify periods during which the air mass of the three stations were connected. According to this, the three AMS results will be compared in order to follow the cloud induced modification of the aerosol chemical compositions as well as modification of the chemical size distribution. Here we will present the first results of this project.

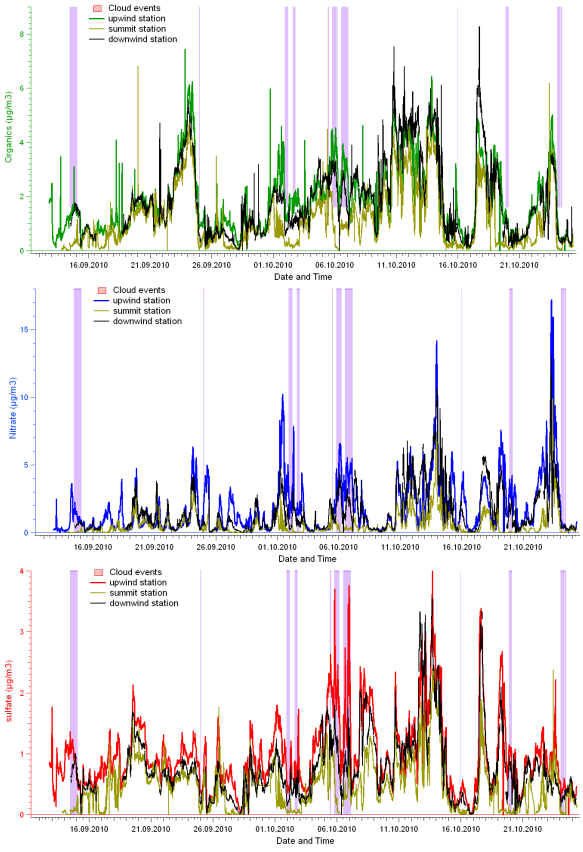

Figure 1: AMS time series measured at the upwind, summit and downwind stations during the entire campaign.

Atmospheric particle number concentrations and nucleation events in an urban background site

M. Sastre, F.J. Gómez-Moreno, M. Pujadas, J. Plaza[†], J.J. Rodríguez-Maroto, P. Martínez-Lozano[¶] and B. Artíñano

The ambient particle number concentration and size distribution have been measured in an urban background site in Madrid, a continental Mediterranean area, over more than two years (Oct 2006-Dec 2008). They have been measured with a TSI-SMPS (15-600 nm) instrument (Wang and Flagan, 1990) and with a modified Vienna type DMA (3-80 nm) and a CPC 3025 (TSI) during six months. The first objective of the present work is to discuss the differences between the working days and weekend particle number concentration taking into account the seasonal effect. The second aim is to discuss the frequency of nucleation events, their distribution along the year and their classification.

The measurements were carried out at the CIEMAT facilities, an urban background site located in the NW corner of the city of Madrid. Since its industrial activity consists essentially of light factories, the Madrid plume is typically urban, fed by traffic emissions and also by heating systems in winter.

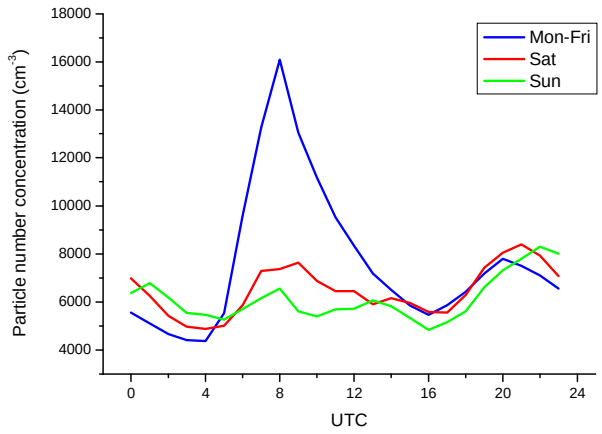

Figure 1. The annual averaged daily pattern for the particle number concentration during the year 2008.

Figure 1 shows the daily evolution of the particle number concentration during 2008 for working days, Saturdays and Sundays. Working days (Mon-Fri) present a leading peak in the morning due to the traffic and daily human activities in general. Then, after a concentration decrease, a secondary peak is reached in the evening. It might be related to traffic again.

Saturdays and Sundays have been treated separately and not as a whole because some differences in particle behaviour can be found, probably induced by commercial activity distinction. It is remarkable how after the evening peak concentrations decrease on working days and Saturdays whereas on Sundays concentrations remain increasingly until the end of the day, achieving the highest values. A possible explanation for this fact is the return traffic to the city on Sunday evening, which is delayed compared to working days.

Particle nucleation is not a frequent phenomenon in this measurement site, where 63 events per year have been observed. They mainly occurred during spring and summer periods, with the minimum number during winter. This suggests that insolation and temperature are important variables in nucleation. Class Ia nucleation events (Dal Maso et al., 2005; Cheung et al., 2010), where particle growth rate can be determined or observed and the typical banana shape is clear, mainly occurred during spring and summer. Class II events, where particle growth determination is not possible or the accuracy of the results is questionable, mainly occurred during winter months, especially during 2007, and also during springtime. However, the influence of high wind speeds during these events was more important than that of the seasonality, as the particles suffered low growth or lost their semivolatile compounds. Class Ib events had characteristics between those of classes Ia and II. They occurred during all the year, although in winter they had a low frequency.

Ground based measurements of aerosol number size distributions from Vavihill (9 years) and Hyytiälä (10 years) have been combined with MODIS (Moderate Resolution Imaging Spectrometer) cloud data to investigate how aerosol loading affects convective clouds over Scandinavia.

Aerosol size distributions data from DMPS (Differential Mobility Particle Sizer) instruments at Vavihill in Southern Sweden (56.01° N 13.9° E) and Hyytiälä in central Finland (61.51° N 24.17° E) have been used to calculate the daily average number concentrations for particles larger than 80 nm (N_{80}). Satellite images, from the two MODIS instruments onboard Terra and Aqua, were investigated for the days with available aerosol data from Vavihill and Hyytiälä. A limited area surrounding each station was examined and satellite scenes containing convective clouds were selected. Satellite level 1B data were used to calculate the cloud top temperature at a 1 by 1 km pixel resolution and the cloud effective radius (r_e) data were obtained from the level 2 Cloud Product data. The approach developed by Rosenfeld & Lensky (1998) has been applied to find vertical r_e profiles of the clouds by plotting the r_e against the cloud top temperature. Furthermore, several meteorological parameters from ECMWF (European Centre for Medium-Range Forecasts) have been used to examine how these affect the clouds. Finally, precipitation data from Hyytiälä and SMHI for Vavihill have been investigated to find how the aerosols influence precipitation.

The number of profiles included in the study is 569 for Vavihill and 474 for Hyytiälä. The results show that the profiles of r_e are clearly affected by aerosol loading since profiles with higher aerosol number concentrations measured at the ground, have lower values of r_e as can be seen in Figure 1. The figure shows profiles divided according to N80 for both Vavihill (a) and Hyytiälä (b). There is a larger difference between the profiles for Vavihill both since the values of N80 are higher here, and because the correlation between N80 and cloud base temperature T_b and specific humidity are higher in Hyytiälä. The specific humidity which is well correlated with T_b opposes the effect of the aerosols by increasing the r_e.

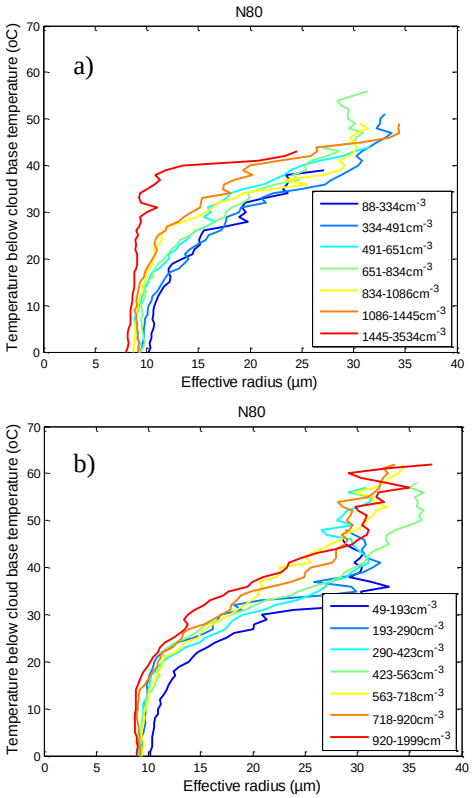

Figure 1. Effective radius profiles divided according to N80 for Vavihill a) and Hyytiälä b).

No correlation has been found between any aerosol parameters and the amount of precipitation. There is however a weak, but significant at a 99% confidence level, correlation between the convective available potential energy and the amount of precipitation. There is also a significant correlation between the latter parameter and the vertical extent of the profiles.

In this study, based on several hundred cases, aerosols effect on convective clouds at the mid-latitudes has been investigated. The results show that aerosol number concentration and T_b are important for the cloud droplet sizes but that the atmospheric instability and the vertical extent of the clouds control the amount of precipitation produced by the clouds.

Hygroscopicity parameter measurements of cloud condensation nuclei from nucleation experiments at the CLOUD chamber

G.T. Tsagkogeorgas[1], H. Wex[1], F. Stratmann[1], and CLOUD collaboration

[1]Department of Physics, Leibniz Institute for Tropospheric Research, Leipzig, 04318, Germany
Keywords: CLOUD experiment, new particle formation, CCN activity.
Presenting author email: george.tsagkogeorgas@tropos.de

The possible effect of cosmic rays on Earth's clouds and climate remains an open question. Atmospheric ions created by cosmic rays may enhance the formation of aerosol particles. A fraction of these may grow into cloud condensation nuclei and may therefore have an effect on climate. The CLOUD 2010 experiments aimed at the investigation of the role of cosmic ray ionization on atmospheric new particle formation and the hygroscopic properties of cloud condensation nuclei.

A variety of laboratory experiments to study the effects of cosmic rays on new particle formation and cloud condensation nuclei activity were carried out under precisely controlled laboratory conditions at the CERN Proton Synchrotron (PS) in 2010. The experiment included several unique aspects such as the CLOUD chamber, a cylindrical electropolished stainless steel research vessel, exposed to a de-focused secondary pion beam from the CERN PS, the capability to create an ion-free environment with an internal electric field cage, precise adjustment of the ultra-violet illumination from a fibre-optic system, and highly stable operation at any temperature between 30°C and -30°C (Duplissy et al., 2010). For atmospheric new particle formation, besides sulphuric acid, which is considered to be the primary vapour responsible, the relative humidity plays a major role. Therefore, the water vapour concentration in the CLOUD chamber was carefully controlled and the gases fed into the chamber were distributed within via two stainless steel fans, operating at selected fan speeds. The contents of the chamber were continuously analysed by trace gas analysers, particle counters, size analysers, mass spectrometers, and a cloud condensation nuclei counter.

We found that the hygroscopicity parameter, κ for a variety of different experimental conditions was substantially below the κ-value found for H_2SO_4 (κ =0.68–0.74 for dry diameters 30–80 nm), Shantz *et al* (2008). κ-values increased with time during the CLOUD Spring campaign 2010 (Figure 1). Mass spectrometer data for organic material concentrations confirm the existence of volatile organic carbon (VOC) vapours inside the chamber of low carbon content (C1-C4). Efforts are underway to reduce these contaminants.

To our knowledge this is the first experimental study to investigate the effect of galactic cosmic ray with the use of a particle beam on new particle formation and cloud condensation nuclei activity. Besides sulphuric acid, trace amounts of organics, even in the cleanest experimental conditions, are responsible for the particle growth (Jimenez, 2009, Wang, 2010).

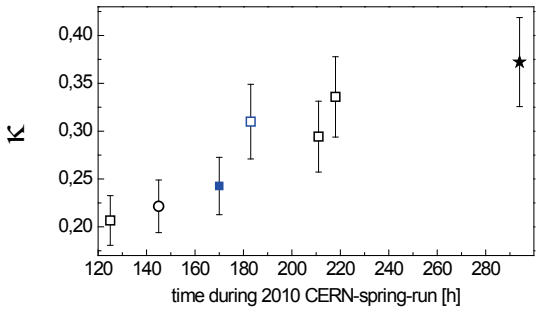

Figure 1. The figure illustrates derived κ-values from CCN activation measurements for different initial experimental conditions of different runs during the CLOUD Spring campaign 2010. Open symbols represent charged pion beam conditions, filled symbols neutral conditions, black symbols low relative humidity and blue symbols higher relative humidity conditions at CLOUD chamber temperature of 20ºC. Star symbol represents CLOUD chamber temperature of 5ºC. Error bars are related to 1σ in dry particle diameter and supersaturation.

We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. This research has received funding from the EC's Seventh Framework Programme under grant agreement number 215072 (Marie Curie Initial Training Network "CLOUD-ITN"), from the German Federal Ministry of Education and Research (project number 01LK0902A), from the Swiss National Science Foundation and from the Academy of Finland Center of Excellence program (project number 1118615).

Presenting author email: avalenzuela@ugr.es

Dust particles interact with the solar and terrestrial radiation modulating Earth's radiative budget. The Iberian Peninsula is frequently affected by African dust air masses that modulate the aerosol climatology in different areas, especially in the south. It has been shown that the radiative budget is sensitive to the dust particle's source region, because their radiative properties vary depending on the source and on the chemical and physical processes occurring along the trajectory. The back-trajectories analysis is a powerful tool commonly used to study the transport of atmospheric constituents and particles from an origin source to receptor sites.

In this work we analyze the African air masses that reached Granada (37.16ºN, 3.60ºW, 680 m a.s.l) from 2005 to 2010, by means of back-trajectory analyses using HYSPLIT model. In addition we characterize the aerosol radiative properties taking into account sun-photometric measurements and the air mass history. The aim is to determine how columnar aerosol properties observed differs depending on source region and transport pathways from North Africa to Granada. Two air mass classification methods were used: the first identifying the desert dust origin sources and the second on the basis of cluster analyses (Pace et al., 2006; Toledano et al, 2009). The dates and confirmation of the African dust episodes arriving to southern Spain were supplied by CALIMA project (www.calima.ws).

Radiative aerosol properties were simultaneously retrieved from sun-photometric measurements (CIMEL CE-318, instrument #18, AERONET network) according to the methodology described by Olmo et al. (2008). This method uses the Aerosol Optical Depths (AOD) and sky radiances measured in the solar principle plane. The instrument provides solar extinction measurements at 340, 380, 440, 670, 870 and 1020 nm, and sky radiance measurements at 440, 670, 870 and 1020 nm using the almucantar and principal plane configurations. Annual calibrations were performed by Langley plots (extinction measurements) and integrating sphere (radiance measurements) by AERONET facilities (Holben et al., 1998).

To classify the aerosol properties we have defined three broad geographical sectors: Sector A (Northern Morocco, North-western Algeria), Sector B (Western Sahara, North-western Mauritania and South-western Algeria), and Sector C (Eastern Algeria, Tunisia). Table 1 shows the mean values of AOD (440 nm) and Angström parameter (α) for the analyzed period.

	Sector A	Sector B	Sector C
AOD ±SD	0.25±0.16	0.28±0.12	0.27±0.11
α±SD	0.45±0.21	0.40±0.22	0.46±0.23

Table 1. Mean values and standard deviations of AOD and α from 2005 to 2010 using the sector classification.

Using clustering analysis we obtained two back-trajectories clusters for 1500 and 3000 m a.g.l. Level 1500 m: Cluster 1 (from the East of Algeria) and Cluster 2 (from Morocco). Level 3000 m: Cluster 1 (from Southwest of Algeria) and Cluster 2 (from Sahara and the South of Morocco). Table 2 shows the retrieved mean values of AOD and α for the analyzed period.

Table 2. Mean values and standard deviations of AOD and α from 2005 to 2010 using the cluster analysis.

Level (m)	Cluster	AOD±SD	α±SD
1500	1	0.28±0.13	0.39±0.19
	2	0.24±0.16	0.43±0.20
3000	1	0.29±0.12	0.37±0.19
	2	0.23±0.14	0.42±0.19

As shown in Tables 1 and 2, the sectors classification can not discriminate between different air masses except for Sector B, and the cluster technique is a powerful tool from AOD and α classifications showing differences. On the other hand, sector classification and cluster technique show significant differences (Tables not shown) for Single Scattering Albedo, Coarse Modal Radius and Coarse Volume Concentration mean values. The Fine Modal Radius and Fine Volume Concentrations show high mean values and no significant differences in any classification, showing the importance of local polluted fine particles at our station due to the anthropogenic influence associated to the synoptic conditions.

Dust particles play an important role in the Earth's radiation budget. In this sense, radiative forcing calculations need size-dependent optical properties. Remote sensing techniques as Lidar (profile particle parameters) and sun-photometers (columnar integrated parameters) have demonstrated their potential. As example, AERONET, EARLINET and CALIPSO database provides a wide-range, long-term database of atmospheric aerosol properties. However, lidar data have been predominantly based on the Mie theory, and does not adequately reproduce the scattering properties by desert dust particles (Veselovskii et al. 2010). Ground-based AERONET network uses sun-photometric measurements (sky radiance and extinction) to retrieve columnar effective particle size distribution and refractive index values, as well as other radiative properties like absorption aerosol optical depth, single scattering albedo (SSA) and asymmetry parameter, using a mixture of polydisperse, randomly oriented spheroids (Dubovik et al, 2006). These parameters, however, do not have a strong dependence on particle shape. Lidar measurements, on the other hand, allow quantities like backscattering and particle depolarization ratio profiles, to be measured.

In order to study the parameters that are sensitive to particle shape, a set of computer simulations was carried out. A pre-calculated database on light scattering properties for nonspherical particles (ALFA), developped at our group, was used for this purpose. As example, size and composition values were chosen from the Eyjafjoll volcano eruption of May 2010, as given by the AERONET direct measurements and inversion data (ITF-Leipzig Station, April 19, 2010, 14:49:37 GMT).

The Leipzig particle size distribution for April 19 was approximated as a bimodal volume log-normal distribution (PSD), as Table 1 shows. Size parameter refers to the equivalent-volume-sphere radius. Values of the refractive index ($m=n+ik$) as retrieved by AERONET, and those chosen for simulation, are shown in Table 2. In the present study, particle shape distribution was assumed to be a 50% volume mixture of oblate and prolate spheroids, with varying axial ratio (ε) values from 1.2 to 1.8; this axial ratio can be independently set for each mode.

As expected, some parameters such as extinction and absorption coefficients, asymmetry parameters, and SSA, show a small variation with shape. SSA remained constant to within 0.08%. Extinction and absorption coefficients showed a slightly larger difference (about 2% for extinction, 4% for absorption). Angstrom parameters for both extinction and absorption also showed small variations.

On the other hand, backscattering parameters show a large dependence on shape. Backscattering coefficient values have been found to decrease for increasing axial ratio, with a difference of up to 70% as axial ratio goes from 1.2 to 1.8. Other parameters related to backscattering, such as the Lidar ratio (extinction to backscattering ratio), and the color ratio (backscattering ratio at two wavelengths, 440 and 870 nm), and the depolarization ratio, show similar behavior. As a result, depolarization ratio and lidar ratio are two decisive parameters in order to retrieve particle shape by inversion methods from Lidar measurements.

While no attempt was made to fit our simulated data to AERONET inversion products, reasonable results were nevertheless obtained. Extinction, SSA and asymmetry parameter values obtained with ALFA simulations agreed to AERONET data to within 2%.

Additional computer simulations were carried out for other values of m, similar to those of Table 2. Again, the trend observed is a weak shape dependence of extinction, SSA and asymmetry parameters; and a large variation of backscattering-related parameters (Lidar ratio, depolarization ratio, color ratio). Changes in the imaginary part of the index of refraction strongly affects the values of the absorption coefficient, and therefore of the absorption Angstrom exponent.

Table 1. Particle size distribution parameters

	Mode 1	Mode 2
Concentration ($\mu m^3/\mu m^2$)	0.080	0.078
Modal radius (μm)	0.205	1.721
Width σ	0.485	0.631

Table 2. Refractive index values, m=n+ik

	n	n
AERONET (441 nm)	1.4632	0.004013
ALFA (440 nm)	1.4588	0.003598
AERONET (869 nm)	1.4855	0.002557
ALFA (880 nm)	1.4782	0.002197

Number concentration measurement of nanometer-sized particles and its correlation with wind velocity

H. Saghafifar

Physics Group, Faculty of Science, University of Isfahan, Isfahan, 81746, Iran
Keywords: number concentration, wind velocity
Presenting author email: saghafifar1@yahoo.com

We have designed and constructed an Expansion Condensation Particle Counter (ECPC) and its operation has been tested in the laboratory conditions (Saghafifar, *et al* , 2009).
Urban aerosols of nanometer size can be measured by ECPC. Two identically made ECPCs were used in the field applications and number concentration of atmospheric aerosols was measured in Isfahan, Iran. The ECPCs were operated over several weeks in different quarters of 2007 and 2008.
An ECPC was located near the south gate of Isfahan University, near a busy street and number concentration of aerosols was measured among the atmospheric pollutant trace gases. The experiments showed a good correlation between number and NOx concentrations.
Two ECPCs were operated at the same location and their results were the same as shown in figure 1.
One of the ECPCs was removed away from near street site which result in reducing of its readings.
At night both ECPCs showed nearly the same results and as the traffic was started, the readings of the near street site increased by a factor of 2 to 3. (Fig. 2)
The meteorological parameters were obtained by a portable station. Wind velocity was considered as parameter which could correlate with number concentration. The number concentration is decreased by increasing the wind velocity.
The number concentration was measured every 10 seconds and for correlation it was averaged over an hour or a day.
Despites changes in the situation of the measurements in two periods: 18 days in March 2008 and 8 days in May 2008, the same linear fit was obtained for correlating the number concentration to the wind velocity (Fig. 3). If one can find the same formula for a lot of periods for a site, the number concentration could be predicted.

Changes in the size distributions of aerosol particles and the microphysical properties of fog events are examined based on the air mass origins and prevailing meteorological conditions. This evaluation is based on measurements made during a comprehensive field campaign November, 2010 through March, 2011 at the SIRTA research site, 30 km south of Paris, France. A new instrument, the Aerosol Particle Spectrometer with Depolarization (APSD), was been deployed during this period, measuring individual particles in the diameter range from 0.5 to 20 μm along with the degree of depolarization that is related to their shape.

A total of 25 fog events have been analyzed, whose back trajectories (Hysplit) are shown in Fig. 1

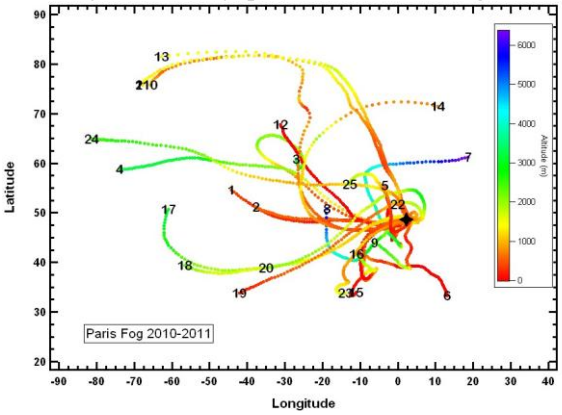

Fig 1.the back trajectories of airmasses for 25 fog event

The color is related to their altitude. Our analysis shows that the maximum liquid water content (LWC)in the fogs depends on the direction from which the air masses relative to 3, 6 and 12 hours before. It was also related to whether the air mass had come with a trajectory remaining close to the surface the previous six hours or if it had descended from higher altitude.

The local wind directions are not correlated with where the air masses were three hours before. When evaluating the size distributions, we observe distinct differences in how the aerosols are distributed by size before, during and after the fog event as a function of where the air had been three, six and twelve hours before.

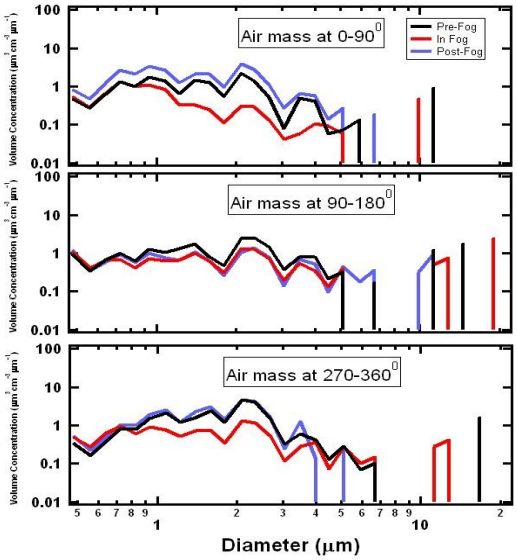

Fig 2 the volume concentration of aerosol based on air masses origin

This presentation will highlight the most salient results that show the importance of the history of aerosols with respect to fog formation, evolution and dissipation and the subsequent changes in aerosol properties due to processing by fog.

The aerosols and nanoparticles dynamic in different systems and at different conditions problem is the high spectral irradiance in the modern aerosol physics and chemistry. That problem is of interest to the nanoelectronics, electrodynamics, medicine and others.
In particular, it should be pointed out the next problems. The problem of the high dispersion aerosols transport may be related directly to the functioning of the seaports, riverports and water transports. The problem of the high dispersion aerosols particles formation takes place as a result of various natural phenomena, complex relations and interactions in the system «nature – man» (for example, forest fires and others phenomena – Akimov et. al., 2009). Of some interest is the research of the high dispersion aerosols particles spreading over water surface. Such investigations are important to make the climatic prognosis's, to rivers, lexes and seas regions and to consider the interaction of the high dispersion aerosols particles with the human organism.
In given work it is discussed the investigation of the aerosol particles transport over watersurface of central Russian rivers (Moscow-river, Oka, Volga) in a period of the motor ship scientific expedition (31.05.2010 – 10.08.2010). The measurements carried out for aerosol particles concentration and radiuses by the diffusion aerosol spectrometer (Zagainov, 2006). Figure 1 shows the example of the nanoparticles distributions on radiuses. The given results are computed by the appropriate program in given device.

The received curves can be described approximately by the gamma-distribution:

$$f_X(x) = x^{k-1}\frac{e^{-x/\theta}}{\theta^k \Gamma(k)}, x \geq 0,$$

where $\Gamma(k)$ is gamma-function, k is parameter.

In this period was carried out the precipitation of the small aerosol particles on special filters in ship ports. The received results were investigated with the help of the atomic-power microscope. The fractal analysis of the experimental results was carried out. It is shown that the fractal dimension varies from 2.009 to 2.05 mkm (Figure 2 shows such example).

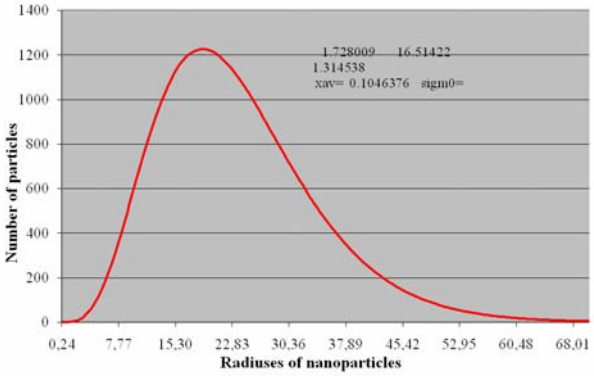

Figure1. The example of the distributions of nanoparticles (the result was received in the field work).

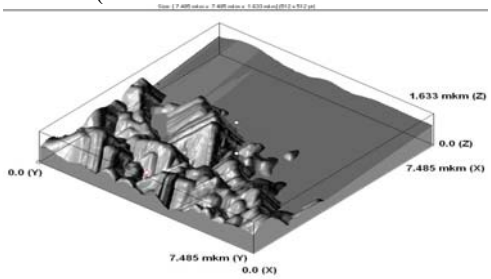

Fugure2. The example of the distribution of nanoparticles on the filter.

Given results can be used for inner problem of aerosol particles transport in a human organism (Marijnissen and Gradon, *Editors*, 2009). For the solution of this problem it is possible to use the methods of molecule dynamics and method of joker (Uvarova *et al*, 2010).
