Exploratory climate modeling suggests that aerosol effects are of comparable importance as greenhouse gases, as a driver of recent climate trends in the southern hemisphere, including Australia (Rotstayn, *et al.*, 2007; Rotstayn, *et al.*, 2010). A 2008 CSIRO review considered the possible climatic effects of natural and anthropogenic aerosol located in the Australian region (Rotstayn, *et al.*, 2008). Observations and modeling suggest that various regional aerosol sources may be important, but systematic studies of their role in climate change and climate variability are currently lacking.

In addition, the aerosol indirect effects (or the effects aerosols have on cloud formation) are currently the largest uncertainty in the IPCC report estimate of anthropogenic induced climate change (IPCC, 2007). There is a specific need to understand the processes involved with aerosol indirect effects and climate change in general on Australian regional aerosols such as dust emissions, bushfire emissions, Southern Ocean natural aerosol production, terrestrial biogenic aerosol and aerosol precursor emissions, transport and removal processes. A better understanding of aerosol effects is essential in order to reconcile modeled and observed climate variability and climate change.

To this aim, intensive ground-based measurements of ambient aerosols including cloud condensation nuclei (CCN) were made at three locations across Australia; a tropical site located at Gunn Point in the Northern Territory, an urban site located in a suburb approximately 22 km to the west of Sydney in New South Wales and a marine site located at the Cape Grim Baseline Monitoring Station located on the northwest tip of Tasmania.

A Scanning Mobility Particle Sizer (SMPS) spectrometer measured the size-resolved aerosol number concentration for particles between 15 and 750 nanometers. A nano SMPS measured the size resolved aerosol number concentration for particles between 4 and 150 nanometers at two of the three sites. An Aerodynamic Particle Sizer measured aerosol number concentration for particles between 0.5 to 20 micrometers at two of the three sites. A CCN counter measured the size resolved CCN number concentration for CCN between 0.75 and 10 micrometers, over a super saturation range of 0.1 to 0.9 %. The size-resolved chemical composition of aerosols was determined on samples collected with a cascade impactor, high volume and low volume samplers.

Preliminary investigations from the tropical Australian site, Gunn Point, indicate that smoke effected the sampling location throughout the measurement campaign. Figure 1 shows levoglucosan, an indicator of smoke, is present in all aerosol samples collected. In the presence of smoke, the number of CCN increases however the fraction of CN able to form CCN decreases.

The influence of important aerosol sources and processes to the Australian continent such as biomass burning, urban vehicle emissions, secondary formation and marine sources on CCN formation and regulation will be discussed in this presentation.

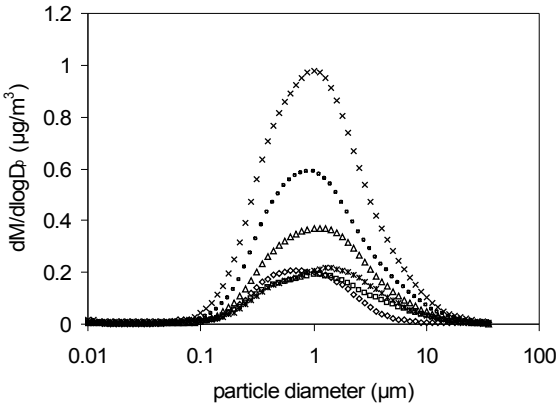

Figure 1. Levoglucosan mass concentration, in 72 hour samples collected by a cascade impactor at Gunn Point, indicative of smoke.

Presenting author email: fj.gomez@ciemat.es

Size distribution is one of the most important properties of the atmospheric particles as it determines their behavior and gives information about their origin and history. The particle size distribution measurements are a key factor to understand the radiation-aerosol interaction and the health effects as both depend on the size distribution.

In the last ten years, there has been an important increase in the number of studies related with the particle size distribution measurement (Kulmala et al., 2004; Pey et al., 2008; Sorribas et al., 2008).

There are currently five groups in Spain involved in the measurement of atmospheric particle size distributions by means of Differential Mobility Analyzers (DMAs). These groups are: University of A Coruña, IDÆA-CSIC, INTA, IARC-AEMET and CIEMAT. All the groups have to solve many common problems related with the instrumentation required for this type of measurements. For this reason, the Spanish network on environmental DMA (Red Española de DMAs Ambientales, REDMAAS) was launched in January 2010. The REDMAAS has as main objective the cooperation between the groups, which will lead to solve common problems and to optimize their facilities and protocols.

The activities planned for the first years of this network are:

- DMA calibration: the network members can check their DMA calibration. Firstly, it was necessary to check the DMA flow rates and then, a monodisperse aerosol, latex, was introduced into the DMA to calibrate the electrical mobility. Very good results were obtained.

- DMA intercomparison: one of the main objectives of the REDMAAS is to make all the instruments comparable. With this objective a first intercomparison exercise with four of them was performed during April 2010 in the INTA facilities (El Arenosillo, Huelva). The CPCs used with the DMAs were previously intercompared and later the instruments measured simultaneously the same atmospheric particles and the results were compared and assessed. An additional pair of SMPS was compared in the CIEMAT facilities during July 2010.

- Measurement quality control program: under this activity the network has prepared some protocols required for the correct operation of the systems. Protocols for flow calibrations and checks, zero checks, dry procedures for ambient relative humidity above 30% and others have been developed.

- Losses in sampling lines have been already estimated using simple deposition models. In a new activity they are currently computed by means of a CFD code. The five sampling systems are being simulated to obtain a correction factor for the particle deposition in the sampling lines.

- Support for the radioactive facility license: this activity is thought for new possible network members. For the correct DMA working, it is necessary to have a radioactive source at the aerosol inlet to assure a known particle charge distribution. This source requires the approval of the national nuclear regulatory commission (CSN) by means of a radioactive facility license.

- Webpage: all the network information and activities are included in a webpage: http://www.redmaas.com/.

- New DMA applications: DMAs are very flexible and useful instruments and have several different applications in environmental studies. This activity is based on the experience with this kind of instruments and the objective is to support the members interested in using DMAs in new applications.

This network is financed by the Ministry of Science and Innovation (CGL2010-11095-E).

New particle formation (NPF) and their growth frequently takes place in the atmosphere and is of climatic relevance (Kulmala *et al.*, 2004). Several nucleation mechanisms have been proposed and their relative contribution to new particle formation is still unclear. We can define two large groups of nucleation mechanisms: neutral mechanisms, and ion-induced mechanisms. The contribution of ion-induced nucleation to the formation of particles of climatically relevant sizes is controversial and few measurements of its importance have appeared in the scientific literature.

The Ion-DMPS (Laakso *et al.*, 2007) is an instrument especially designed to measure the charging state of aerosol populations (the ratio of the fraction of charged particles in the air sample and the fraction of charged particles in the same sample at bipolar equilibrium). The ion-induced fraction can then be estimated from the charging state. This kind of estimations were performed in Hyytiälä and Helsinki, Finland (Gagné *et al.* 2008, 2011), and similar estimations with a different instrument were performed in Boulder, Co., USA (Iida *et al.*, 2006). Another instrument that has been used to estimate the ion-induced fraction is the Neutral cluster and Air Ion Spectrometer (NAIS). Unfortunately, the NAIS in its typically used operation mode may be mis-estimating the ion-induced fraction in overcharged situation (when the charged fraction is higher than the fraction at equilibrium, when the charging state is above one, this problem is being investigated at the moment). The Ion-DMPS, and similar designs, are thus the only instruments from which the ion-induced fraction have been reliably estimated.

The Ion-DMPS has been used in a forested area (Hyytiälä) and an urban area (Helsinki). The estimated ion-induced fractions were around 6% and 1%, respectively (Gagné *et al.*, 2008, 2011). This is in agreement with other literature: the ion-induced fraction is generally higher in cleaner areas, and lower in more polluted areas (see e.g. Manninen *et al.*, 2010) and references therein).

The fraction of ion-induced nucleation varies from place to place and from event to event. It also varies during a NPF event as a function of size and time. The charging state of an aerosol population either is above or below one (charge equilibrium) when the particles are formed and tends to reach the bipolar equilibrium as it grows to bigger sizes.

The behavior of the charging state as a function of size, assuming that the small ion concentration is the same for both polarities, $N_c^+ = N_c^-$, is described in Kerminen *et al.* (2007). An improved version that does not make this assumption is described in Leppä *et al.* (2011, manuscript in preparation).

The equations presented in Leppä *et al.* (2011) and in Iida *et al.* (2008) show that the charging state can be used the retrieve the growth rate of particles during a NPF event. The method of Leppä *et al.* (2011) is applied in Gagné *et al.* (2011), and shows that taking into account that $N_c^+ \neq N_c^-$ improves the agreement of the growth rates between polarities.

In conclusion, the charging state of aerosol populations of their charged fraction provide valuable information about the participation of ion-induced nucleation and growth rates. The studies cited here show that charged particles are formed with lower vapor saturation ratios (incl. sulfuric acid and water) than neutral particles. This also implies that high temperatures lowers the chances of a neutral cluster to activate. Consequently, in urban polluted areas, where vapors are abundant, neutral nucleation is more important than in clean environments. Ion-induced nucleation being limited by the ion pair production rate, smaller fractions of ion-induced nucleation are observed when more particles are created.

Gravity waves observed as a causal mechanism for transition from closed to open cellular convection in the remote South East Pacific

This case study discusses an important observed role for atmospheric gravity waves (AGWs) in the South East Pacific (SEP) region by virtue of their ability to evidently modulate cloud radiative and dynamical properties over a wide area. The case study presented here employs satellite imagery together with measurements of satellite-retrieved cloud bulk properties during the period 7 October to 11 October 2008 over the SEP, which together serves to illustrate the horizontal propagation of a series of AGW trains, manifest by their influence on a large-scale stratocumulus cloud deck capping the local marine boundary layer (see white ellipses in Figure 1). The AGWs were observed as a periodic modulation of retrieved cloud top height by up to 500 metres peak-to-trough, whilst the horizontal direction of wave propagation was perpendicular to the synoptic boundary layer flow. The AGWs of interest appear to originate near 30 S, 85 W and were initiated for a 24-hour period beginning at midday on 7 October 2008, propagating along a vector directed approximately northeastward toward the Peruvian Coast (15 S, 70 W) over the following 48 hours as illustrated in Figure 1. During this time, the gravity waves were seen to affect both reversible and non-reversible changes in cloud radiative properties and cloud dynamics such that persistent areas of clear sky developed in the troughs of passing gravity wave fronts. (see purple ellipses in Figure 1). The formative mechanisms for such cloud-free regions, or so-called Pockets of Open Cells (POCs), observed as cell-like (openly-convecting) cloud-free areas embedded in remote marine stratocumulus sheets, are currently the subject of intense speculation and scientific interest due to their ability to allow solar radiation to reach the ocean surface in regions where atmospheric models predict dense cloud cover.

In this case study, we will investigate the effects of gravity waves on the SEP stratocumulus cloud deck and investigate the synoptic scale disturbances which initiate gravity waves in the area.

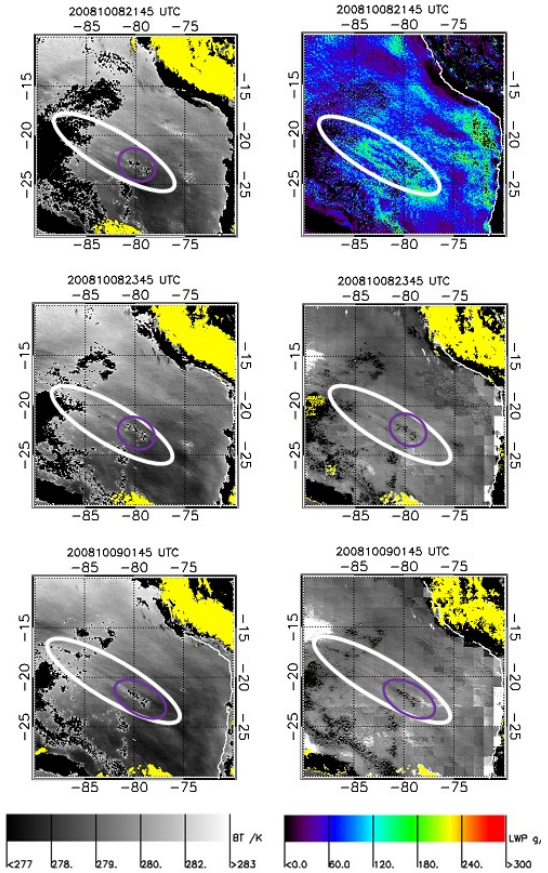

Figure 1 Time sequence of GOES-10 channel 4 brightness temperature (BT; left panels) and retrieved cloud top height (CTH) or liquid water path (LWP; right panels). Colour scales are given for BT and LWP. The progression of a gravity wave front is highlighted by a white ellipse, with a developing POC feature in a purple ellipse.

Apparent particle density in Helsinki during the ULTRA II campaign

O. Hänninen[1], R. Sorjamaa[1], J. Cyrys[2,3], M. Pitz[2,3], J. Pekkanen[1], and T. Lanki[1]

Particle properties, including density, are affecting the particle behaviour in penetrating indoor air from outdoors, remaining suspended, and being deposited on surfaces in indoor spaces as well as in the respiratory tract. Particle density also may correlate with the volatile components found in PM due to the typically lower density of water and SVOCs. Limited amount of analyses have been performed on urban $PM_{2.5}$ that have been shown to be the most significant environmental health hazard in developed countries (Hänninen & Knol, 2011). From $PM_{2.5}$ data of more than 1000 days a mean apparent particle density of 1.5 g/cm^3 was determined by Tuch *et al.* (2000) in Erfurt, Germany. Pitz *et al.* (2003) analyzed the seasonal, weekday and daily variability of the apparent density of $PM_{2.5}$ and observed higher densities during spring and during the afternoon to evening hours as well as slightly higher values for weekdays. Pitz *et al.* (2008) found similar densities of ambient $PM_{2.5}$ in Augsburg, Germany. A multiple variable regression model explained nearly 64% of the day-to-day variation of $PM_{2.5}$ apparent density by particle composition and meteorological conditions. The aim of the current analysis is to understand the relationship of aerosol as observed by EAS versus the gravimetric $PM_{2.5}$ concentration that forms a reference point for $PM_{2.5}$ infiltration analysis.

The current analysis uses ULTRA2 data collected in Helsinki in 1998-99, including electrical aerosol spectrometer measuring particle number concentrations over 12 size classes (EAS; Mirme *et al.*, 2002), collection of daily $PM_{2.5}$ samples on Teflon filters and XRF-analysis of their elemental composition (Vallius *et al.*, 2003). Interpolation method was used to estimate the volume concentration of particles smaller than 2.5 µm in diameter. Two alternative models were used in the particle volume calculation; one assuming spherical particles and another using shape factors and fractal dimensions estimated based on author judgment. The results show apparent densities of 1.3 and 1.2 g/cm^3, respectively, indicating that the result is not very sensitive to the particle shape and fractal dimension. Higher densities were observed for the days affected spring dust episodes, characterized also with higher $PM_{2.5}$ concentrations. Lower observed density in comparison with the cited German studies could be related to source profiles and need to be further considered.

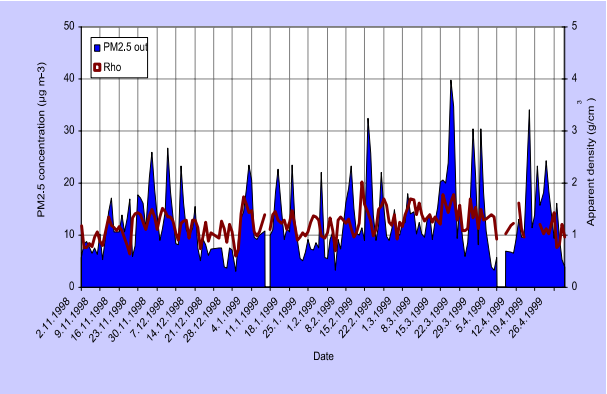

Figure 1. Time-series view of the daily PM2.5 concentration and corresponding apparent particle density (second y-axis).

Keywords: CCN, CLOUD EVENT
Presenting author email: antti.jaatinen@uef.fi

Newly formed aerosol particles become climatically important if they are able to grow to sizes of 50 nm and larger. Particles in this size range can act as cloud condensation nuclei (CCN) and therefore may contribute to the indirect aerosol effect, a series of proposed impacts that include increased cloud albedo due to increase in CCN concentration (Twomey, 1991) to increased lifetime of clouds (Albrecht, 1989). Once particles grow to a size where they can become CCN, their ability to activate into cloud droplets depends on their chemical composition, and the maximum water supersaturation in the air parcel forming cloud.

The fourth Puijo Cloud Experiment (4th PuCE), an intensive campaign measuring aerosol and cloud properties, was conducted by the Finnish Meteorological Institute and University of Eastern Finland at the Puijo semi-urban measurement station. The measurement campaign was carried out during 21.9 – 27.10.2010 for the observation of cloud events. The station is located at the top of the Puijo sight-seeing tower, 306 m a.s.l. and 224 m above the surrounding lake level, thus being a very suitable site for aerosol-cloud interaction measurements (Leskinen *et al*., 2009; Portin *et al*., 2009). Aerosol sources are subject to influence from long-range transport from continent and ocean, but also the local pollution, likely traffic, pump mill, heating plant and other urban emissions.

In this work, the properties of cloud activation were studied using DMPS (Differential Mobility Particle Sizer), DMT CCNc (Cloud Condensation Nuclei counter), Aerosol Mass Spectrometer (AMS) and Tandem Differential Mobility Analysers (TDMAs). During the measurements the DMPS inlet was switched between a PM1 (interstitial) and a total inlet (all particles), and during cloud events the particles activated to cloud droplets were resolved as a difference between the measurements performed in each inlet. In addition, we measured size-resolved CCN to get information about size dependence, and on the other hand data about the true supersaturation inside the cloud during a cloud event.

During the campaign, a total of nine cloud events were observed. The duration of the events ranged from a couple of hours up to about twenty hours. As an example, we have chosen one cloud event day for closer scrutiny, 9.10.2010, 00:00 – 05:45. From Figure 1 we can see that the minimum size of particles forming cloud events was around 100 nm and D_{50}-size (the size where half of the total particle concentration activate into cloud droplets), i.e. the size where blue and black line cross, is 195 nm. From CCN measurements the mean D_{50}(SS=0.1%) is 160 nm and D_{50}(SS=0.2%) is 120 nm. Thus the mean supersaturation during cloud formation has been less than 0.1%.

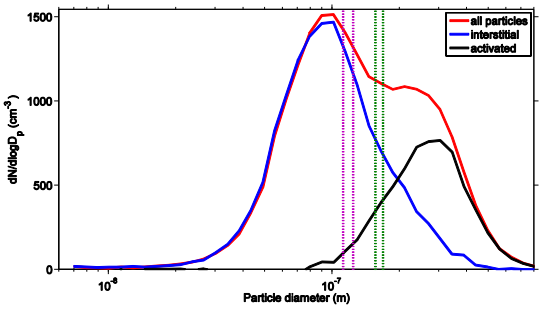

Figure 1. Size distributions of all particles (red), interstitial particles (blue), and activated particles (black). Green and purple dotted lines represent the range of the critical diameter (D_{50}) derived from the CCNc data during the cloud event, for SS=0.1% and SS=0.2% respectively.

During the cloud event the mass fraction of ammonium-sulphate was around 30% the rest being mainly organics. This is in good agreement with CCNc measurements.

In future analyses, we shall analyze other measured data (such as meteorological and chemical) to investigate how the size dependent composition of particles vary during cloud events, and how the diameter of smallest activated particles depend on the composition of particles.

Commonly it has been thought that only aerosol particles with substantial amount of water soluble matter can form cloud droplets at the ambient conditions. However, recently it has been proposed that also insoluble, but hydrophilic, particles can act as a cloud condensation nucleus (CCN) even at atmospheric supersaturations (Sorjamaa and Laaksonen, 2007, Henson, 2007). In the theory water adsorption is described by isotherms which give the amount of adsorbed water on the particle surface as a function of relative humidity in subsaturated conditions. One example of such an equation is the so called FHH-isotherm giving the number of adsorbed water layers on the surface as:

$$\ln\frac{1}{S} = \frac{A}{\Theta^B} \quad , \qquad (1)$$

where S is the gas saturation ratio, Θ is the surface coverage, i.e. the number of water layers, and A and B, are fitted parameters dependent on the surface properties. In the traditional Köhler equation the term describing the solute effect (Raoult's effect) can be replaced by solving the S from Eq. 1 (Sorjamaa and Laaksonen, 2007),

$$S = exp\left(\frac{4\sigma M_w}{RT\rho_w D}\right) exp(-A)\Theta^{-B} \quad , \qquad (2)$$

from which the critical supersaturation can be calculated.

It has been shown by Romakkaniemi *et al.* (2001) that the hygroscopic differential mobility analyzer (HTDMA) can be used to study water uptake by adsorption on aerosol particles at subsaturated conditions. With small enough particles it is possible to detect the formation of water layers, although the depth of monolayer is approximately only 3Å. In this study we produced silica particles from an aqueous solution. The amount of water adsorbed on the particles at RH's between 40 and 90% was measured with nano-HTDMA, The growth of particles at super-saturated conditions was measured by CCN counter.

The adsorption of water on small aerosol particles composed of silica follows FHH-adsorption isotherm. Based on the HTDMA measurements for 8nm and 10 nm particles, the parameters A and B in Eq. 1 are found to be 4.82 and 2.16, respectively. These values are slightly higher than values reported in Kumar *et al.* (2010) for typical dust and mineral samples. By using parameters A and B in Eq. 2 we get the critical supersaturation as a function of particle size.

In Figure 1 we present the activated fraction of 114nm and 150nm particles as a function of supersaturation. For this type of curve a sigmoidal function can be fitted and from that we can determine D50, the diameter at which half of the aerosol are activated. Also presented are expected values for critical supersaturations calculated from Eq. 2 with parameters from HTDMA measurements. As can be seen the particles activate in slightly lower supersaturation than expected. However, corrections for multiple charging in DMA and shape of particles would move activation curves to right (Kumar *et al* 2010).

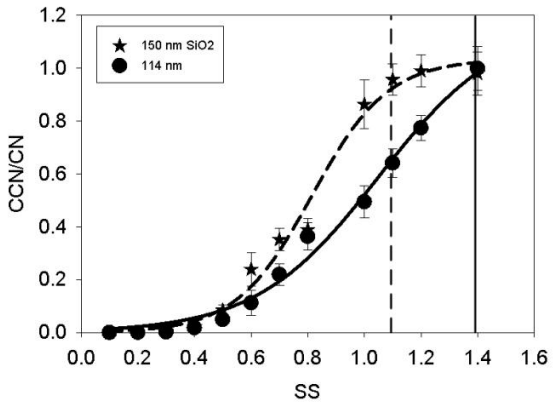

Figure 1. Activation curves from CCN counter. The data are not corrected for shape or multiple charges in the DMA.

Atmospheric aerosol particles can act as cloud condensation nuclei (CCN) and can this way influence the microphysical properties of clouds and further the climate. The so called indirect aerosol effect is still subject to great uncertainties (IPCC 2007) and one big question mark is whether the size or the chemical composition of particles governs their activation to CCN (Dusek et al., 2006a). As CCN are predominantly found in the size range <100 nm, while chemical data are usually available only from total filter samples, we intend to investigate this question by focussing on the investigation of ultrafine (<100nm) particles.

From July 2007 to December 2008 we performed a long-term study to investigate the activation behaviour of the atmospheric aerosol in Vienna. In this first part of the study we conducted field measurements on the rooftop laboratory of the Physics Building of the University of Vienna which is situated in downtown Vienna. The measurement station is about 35m above ground-level and separated by courtyards from the closest main street so that the aerosol can be characterized as urban background aerosol.

During this study, we measured the activation ratio (A=CCN/CN) of the atmospheric aerosol with the University of Vienna CCN Counter (Giebl et al. 2002, Dusek et al. 2006) at a supersaturation of 0.5%, the number size distribution with a Vienna-type DMA and we obtained long-term size selected samples with low-pressure Berner impactors (size range: 0.1 – 10 µm) equipped with back-up filters. As the lower cut-size of the impactors was 0.1µm the material collected on the back-up filter contained only particles with aerodynamic equivalent sizes < 100 nm.

In the subsequent laboratory study the material collected on the back-up filters was first eluted in water and chemically analyzed for elemental and organic carbon, sugars and inorganic ions. Secondly, we generated "synthetic atmospheric aerosols" by nebulizing the eluates with a Collison atomizer and investigated the activation behaviour of these particles with the CCN-counter. Activation curves as well as activation diameters of this aerosol were measured. Figure 1 shows typical activation curves of the eluted filter samples. On average the activation diameter was found to be 58nm at a supersaturation of 0.5% which is much lower than the average apparent activation diameter found for the atmospheric aerosol (162nm) by integration of the DMA number size distribution.

This presentation focuses on the activation diameters of the "synthetic ambient aerosols" in relation to their chemical composition and compares them as well to the apparent activation diameters of the atmospheric aerosol.

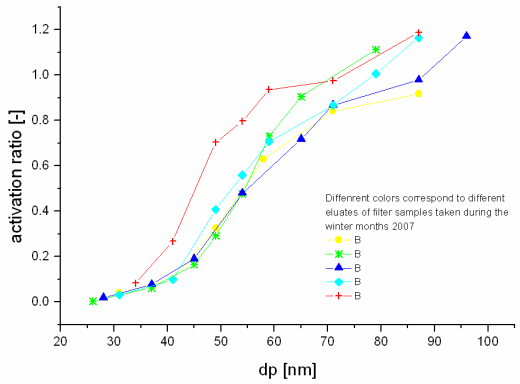

Figure 1 Examples of activation curves of the eluted filter samples. Different colours correspond to different eluates.

The cloud condensation nuclei (CCN) number concentration is known as an important parameter of the indirect aerosol effect of clouds on earth's climate. Within the project HAze in CHIna, the main parameters which influence the total CCN number concentration were investigated at an anthropogenically influenced and heavily polluted site in the North China Plain.

CCN number concentrations were determined from size segregated CCN measurements by using a cloud condensation nucleus counter (Droplet Measurement Technology). From supersaturation scan data, the hygroscopicity parameter κ (Petters and Kreidenweis, 2007) was calculated for 100 nm particles. Additionally, the aerosol particle (CN) number concentration and standard meteorological parameters were measured. Measurements were performed in 2009 during two intensive campaigns in March and July/August 2009 at Wuqing Ordinary Meteorological Observing Station, China (39°23'8.53"N, 117°1'25.88"E), which is located 60 km south east of Beijing and represents a typical regional site in this megacity region.

For the investigation of a possible dependence of κ and the total CCN number concentration on the aerosol source region, air mass backward trajectories were calculated and different source regions were derived through trajectory clustering. Statistical tests were performed to study if there was any dependence of the derived activation behaviour of the particles on the meteorological parameters (air pressure, temperature, absolute humidity, wind speed) and on the CN number size distribution, respectively. The number size distributions were parameterized by fitting several lognormal distributions, which were described by their maximum, width and the centre of the mode.

The κ values derived for 100 nm particles did not differ significantly between the summer and winter campaign. The average κ values derived from CCN measurements for both campaigns were 0.52 ± 0.13 and 0.47 ± 0.07, respectively. The cluster analysis showed that the main source regions of the investigated aerosol were the Gobi desert and Beijing (direction NW), a maritime region (Bohai Sea, direction NE), an industrial region (Hebei, direction SW) and the great Tianjin area (cluster local). However, no significant dependence of κ was found with respect to different air mass origins. The particles were already highly influenced due to aging along the whole trajectory path and by the local sources around the measurement station. No dependences of κ on the meteorological parameters or the mode parameters were found, either. For the seasonal and source depending investigation of the total CCN number concentrations at 0.07 % and 0.10 % supersaturation, it was found that they were predominantly determined by the total CN number concentration of the accumulation mode. This means, the higher the CN concentration in the accumulation mode, the more CCNs were available (Figure 1). CN of the nucleation and Aitken mode did not influence the CCN concentration significantly. It was also not influenced by the meteorological parameters and κ. Due to the effect that the CN number concentration in the accumulation mode differed with the air mass origin, the CCN number concentration differed, too. The highest CCN concentrations were found, if the air masses experienced a local recirculation over the Tianjin area.

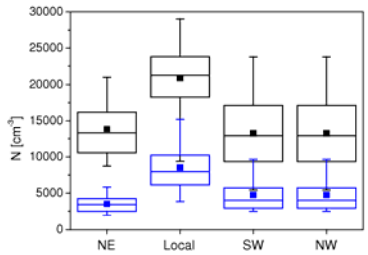

Figure 1. Comparison of the CN number concentration (black boxes) and the CCN number concentration for 0.07 % supersaturation (blue boxes) for the air mass origins at Wuqing (China) during the winter campaign.

It can be concluded that for heavy polluted regions like the North China Plain the CCN number concentration is more or less only depending on the CN number concentration in the accumulation mode for supersaturations of 0.07 % and 0.1 %. The influence of the chemical composition on the CCN number concentration is rather small. This is due to the fact that the size of the aerosol particles is three times more important for their activation behaviour than κ and that larger particles activate earlier to cloud droplets than smaller ones.

A Sensitivity Study: The Influence of S_{crit} on κ

K. Mildenberger[1], S. Henning[1], J. Voigtländer[1], H. Wex[1] and F. Stratmann[1]

[1] Department of Physics, Leibniz Institute for Tropospheric Research, 04318 Leipzig, Germany

Keywords: sensitivity study, kappa, critical supersaturation, CCNC
Presenting author email: milde@tropos.de

The relation between aerosol particle size and water saturation ratio in the equilibrium state can be described by the Köhler equation. This equation consists of two main parts, describing the 'curvature' effect (Kelvin term) and the 'solution' effect (Raoult term) of the solution droplets. The Raoult term is a function of chemical composition, which is normally unknown for atmospheric aerosol particles. For that reason, single hygroscopicity parameters are usually applied to describe the hygroscopic growth and activation of such particles. A frequently used parameter is κ (Petters and Kreidenweis, 2007). Often, a constant κ, calculated on the basis of activation measurements, is applied.

In this study, a sensitivity study was performed to investigate the uncertainty of κ–values derived from cloud condensation nuclei (CCN) activation measurements, e.g. by means of a Cloud Condensation Nucleus Counter (CCNC). The study is based on the equation for κ-Köhler theory, given by:

$$S = \frac{D_{wet}^3 - D_{dry}^3}{D_{wet}^3 - D_{dry}^3(1-\kappa)} \exp\left(\frac{4\sigma M_w}{RT\rho_w D_{wet}}\right) \qquad (1)$$

where S is the water vapour saturation over the droplet surface in the equilibrium state, D_{wet} the wet diameter of the droplet, σ the surface tension, M_w is the molecular weight of water, ρ_w the density of water, R the universal gas constant and T the droplet temperature. For this study, σ was assumed to be equal to that of pure water and the temperature 293.15 K. D_{dry} was varied between 10 nm to 500 nm (step width 1 nm) and κ between 0.01 and 1.4 (step width 0.01) in the calculations. Based on equation (1), the critical supersaturation (S_{crit}), which is known as the supersaturation (SS) at the point of particle activation, was calculated. Furthermore, $dS_{crit}/d\kappa$ and dS_{crit}/dD_{dry} were computed for the sensitivity analysis.

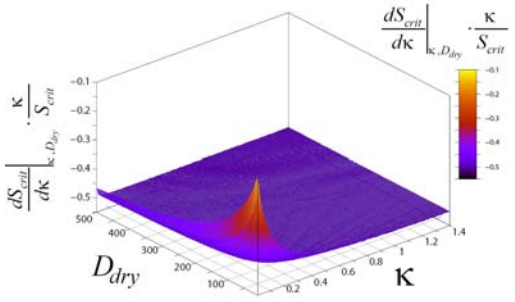

Figure 1. Relative sensitivity of S_{crit} related to κ.

It was found that the relative sensitivity of S_{crit} with respect to κ is mainly constant at -0.5 (Fig. 1) and -1.5 for D_{dry}. Only for small κ and D_{dry} values the sensitivity change significantly. But note that in this regime S_{crit} ranges between 4 % and 18 %; i.e. values are not encountered under atmospheric conditions. From results shown in Fig. 1 it has to be concluded that the sensitivity of S_{crit} to D_{dry} is a factor of 3 higher than that to κ. In other words, changes in D_{dry} change S_{crit} three times more than the same relative change in κ. This means, small changes in κ do not affect S_{crit} significantly. That size matters more than chemistry was also pointed out in Dusek et al. (2006).

In turn, small changes in S_{crit} lead to large changes in κ. This is valid for the above described regime where the sensitivity of S_{crit} to D_{dry} is constantly a factor of 3 higher than that to κ. For our studies we assume that the uncertainty of SS is ±0.01% absolute. This value was found by calculating the standard deviation of multiple *SS* calibrations with a CCNC (Droplet Measurement Technology). To study the effects of this uncertainty in measured S_{crit} on κ, $\Delta\kappa/\Delta S_{crit}$ was computed from S_{crit} and S_{crit}+0.01%, respectively S_{crit}-0.01%. This leads to three different κ values: κ_{max}, κ, κ_{min}. Then κ_{max} was divided through κ, respectively κ through κ_{min}. The results give the percentage accuracy for κ determined with the CCNC (Fig. 2). It is obvious that κ can be calculated with the same accuracy independent of D_{dry}. On the other hand, the accuracy is strongly dependent on SS. For example, at 0.1% SS κ can be calculated with an error of 17%, while at 0.5% SS the error in κ is only 4%. This holds for all applications where a κ larger than 0.006 is determined from CCNC measurements in the range of 0.1% to 0.5% SS and with an experimental uncertainty of ±0.01% absolute, no matter which D_{dry} is studied.

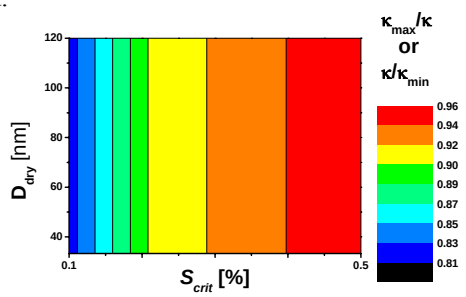

Figure 2. Percentage accuracy for κ from CCNC measurements.

Correlation between aerosol parameters measured in-situ and by means of Sun-photometer technique.

Aleksander Pietruczuk, Janusz Jarosławski

Institute of Geophysics Polish Academy of Sciences, ul. Księcia Janusza 64, 01-452, Warsaw, Poland

Keywords: Aerosol, size distribution, air pollution, optical properties.

Atmospheric aerosol influences earths climate directly by scattering and absorption of solar radiation and indirectly playing important role in cloud physics. Aerosol optical properties are measured by numerous networks in global and continental scale. Some of them uses Sun-photometer technique [AERONET, ESR] which allows to obtain aerosol microphysical properties form measurements of direct and diffused solar radiation. On the other hand aerosol influences human life and air quality and particulate matter (PM10 and PM2.5) concentrations are routinely measured by national environmental agencies. However aerosol microphysical properties are measured by only a few other institutions like universities and research institutes.

In this work we presents correlation between parameters of aerosol size distribution measured in-situ and by means of Sun-photometer as well as correlation between Aerosol Optical Thickness (AOT) and PM10 concentration. We compared modal and effective radius and width of fine and coarse mode of distribution defined according to AERONET definitions. Such a study of parameters obtained by different techniques and representative for different atmospheric layers seams to be interesting especially when satellite data could be used. In – situ measurements are concentrated mainly in urban or industrial region and rural and remote unpolluted regions are not covered by measurements networks but are covered by satellite measurements. On the other hand in-situ measurements could be used to estimation of columnar aerosol microphysical properties when Sun-based measurements are not possible, for example during cloudy days.

Presented data were measured in Geophysical Observatory of Institute of Geophysics PAS at Belsk. Belsk is a small village located in rural area around 50 km at south from Warsaw. Two Sun-photometers, CIMEL CE 318 and POM 01L made by Prede company, are collocated in the Observatory. Both of them provide aerosol size distribution. Aerosol size distribution is also measured in-situ by means of Scanning Mobility Particle Sizer (SMPS 3034) and Aerodynamic Particle Sizer (APS 3321) made by TSI Company. PM10 concentrations are measured by means of TEOM ambient particulate monitor with FDMS module.

Scatter plot of AOT versus PM10 concentration is shown at Figure 1. We found correlation coefficient R=0.93 and regression coefficient 0.0047 ± 0.002.

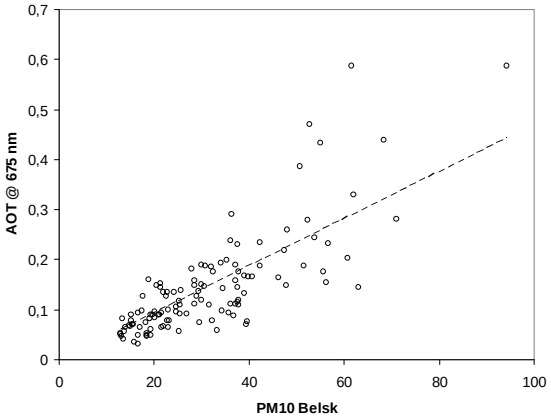

Figure 1. Correlation between AOT and PM10 concentration at Belsk.

We also found correlation coefficient for fine mode modal radius equal R=0.58 and for coarse mode R=0.33. Worse correlation in case of coarse mode is caused probably by uncertainties in estimation of aerosol size distribution in this range. APS registers small number of large particles which causes large errors in aerosol size distribution, especially when number distribution is recalculated to volume one.

Aerosols play an important role in the dynamic atmospheric system. They tend to affect the radiative balance of the climate system and affect the hydrological cycle through the direct effect (scattering and absorption of the incoming solar radiation) and the indirect effect (acting as cloud condensation nuclei and hence changing cloud properties). Relative humidity (*RH*) is a key meteorological parameter which has a direct bearing on aerosol radiative properties. A Humidograph system was built and deployed from July, 2010 at the Mace Head Atmospheric Research Station (53^0 19'N, 9^0 54' W), on the west coast of Ireland, to study hygroscopic properties of aerosols associated with different air masses arriving at the research station.

Due to its unique location on the north east edge of the North Atlantic Ocean, Mace Head encounters a variety of air masses with diverse aerosol optical and physicochemical properties (Dall'Osto et al, 2010). Furthermore the above mentioned aerosol properties also exhibit a unique seasonal pattern with organics dominating the submicrometer aerosol mass range during high biological activity periods from spring through autumn and sea-salt dominating in the winter season (O'Dowd et al, 2004). Fierz-Schmidhauser et al (2010) measured the aerosol light scattering enhancement factor *f(RH)* associated with marine air masses and polluted air masses arriving at Mace Head during the winter season to be 2.22(±0.17) and 1.12(±0.31), respectively. *f(RH)* for marine air masses during the summer season was 30% lower, at 1.54(±0.34), as compared to the winter season (Vaishya et al, 2010) which can be attributed to lower sea-salt production and a higher concentration of water insoluble organics.

In the present study, we measured the *f(RH)* values for different air masses arriving at Mace Head and analyzed the associated radiative, physical and chemical properties using collocated measurements with other instruments. The criteria for selection of stable air masses were: i) stable values of aerosol scattering coefficient over a period of 8 hours or more and ii) 96 hours back trajectories, as obtained using the on-line HYSPLIT model, should have the same origin at the start and end of the stable state period. Furthermore, black carbon mass concentrations of <50 ng/m^3 and >150 ng/m^3 were used as indicators for the air mass to qualify as clean air mass or polluted air mass, respectively.

Results are presented for the hygroscopic properties of aerosol with reference to their optical and chemical properties.

An Improved Description of Cloud Droplets Development in Climate studies over the Mediterranean Region

C. Mitsakou, G. Kallos, S. Solomos and J. Kushta

Atmospheric Modelling and Weather Forecasting Group (AMWFG), Department of Physics, University of Athens, 15784, Greece
Keywords: cloud droplet, natural/anthropogenic aerosols, hygroscopic growth, ice nucleation.
Presenting author email: christina@mg.uoa.gr

Determining the net effect of aerosols on the climate of Mediterranean is a difficult task, since the area is strongly affected by the presence of aerosols from different origins and ages. The complexity of the physico-chemical processes and the potential interactions and feedbacks across all scales in the climate system reveals the necessity for an integrated approach in order to examine the aerosol impacts on the regional climate and vice versa. Recently, a limited-area atmospheric model RAMS/ICLAMS has been further developed by AMWFG (Solomos *et al.*, 2011) with the incorporation of natural and anthropogenic pollutants cycles, detailed gas/aerosol chemical mechanisms and an advanced radiative transfer scheme. Furthermore, the suspension of aerosols with various composition generates the need for introducing more physically based descriptions of aerosol physico-chemical processes in the atmosphere, which is the scope of the present study.

RAMS/ICLAMS model characteristics

RAMS/ICLAMS is based on RAMS atmospheric modelling system (Cotton *et al.*, 2003) that includes advanced microphysical schemes with eight categories of hydrometeors (vapor, cloud droplets, rain droplets, pristine ice, snow, aggregates, graupel and hail). The recent developments include an interactive mineral dust and sea salt cycle, biogenic and anthropogenic pollutants emission/transport/depletion processes, gas and aerosol chemical reactions and an improved radiative transfer scheme.

New cloud formation/growth schemes

In the new model development, the rate of cloud droplet diameter increase by hygroscopic growth described by the well-known Mason's equation, as following:

$$\dot{d} = \frac{4}{d}\frac{\left(S - 1 - \frac{4\sigma}{d\rho_l R_v T_g} + \frac{6\chi n_s m_0 M_l}{\pi M_s \rho_l d^3}\right) f_{FS}}{f_{mass} + f_{heat}}$$

where S is the saturation ratio (relative humidity), σ the droplet surface tension, ρ_l the water density, R_v the gas constant for water vapor, T_g the air temperature, χ the soluble fraction of the aerosols, n_s the degree of each aerosol component ion dissociation, m_0 the aerosol mass, M_l the water molecular weight, and M_s the apparent molecular weight of the aerosol soluble components. The factors f_{FS}, f_{mass}, f_{heat} represent the Fuchs correction term, the contribution associated with mass transfer and the contribution due to heat conduction. Coagulation is described with the help of a Smoluchowski-type formulation (Jacobson *et al.*, 1994), specific to sectional representation of the size distribution. For the ice nucleation, advanced formulations for the different physical mechanisms (homogeneous nucleation, deposition nucleation, immersion freezing, condensation freezing, contact freezing) are under implementation in the modelling system.

Model sensitivity and evaluation runs

A case study occurred on 28 January 2003 and characterized by a low pressure system and a dust storm over the Eastern Mediterranean was firstly investigated. The centre of the low moved from Crete through Cyprus accompanied by a cold front. Deep convective clouds were developed along the frontal line, while heavy precipitation events were reported over the East Mediterranean coastline and a few kilometres inland.

The impact of naturally-produced aerosols (mineral dust, sea salt) on cloud formation and precipitation has been investigated. In general, mineral dust particles are considered as non-hygroscopic and they can act as ice nuclei (IN) in heterogeneous ice nucleation processes. However, aged dust aerosols may be coated with sea-salt or sulfates and become partially hygroscopic, increasing their efficiency as cloud condensation nuclei (CCN). As a result, the coexistence of dust and sea-salt particles affect significantly the cloud formation. The increase of the hygroscopicity of dust particles (from 0.05 to 0.2) revealed an increase in the concentration of small liquid droplets inside the cloud (Figure 1). As a result, a lower fraction of cloud droplets turned into rain and thus, significant amount of water was lifted to above freezing level.

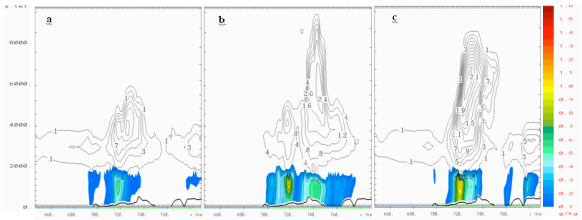

Figure 1: West to East cross-section across East Mediterranean of rain mixing ratio (color palette in g kg^{-1}) and ice mixing ratio (black line contours in g kg^{-1}) by assuming a) 5% hygroscopic dust, b) 20% hygroscopic dust and c) 5% hygroscopic dust and ice nuclei(IN)×10 on 28 January 2003 at 11:00 UTC.

Additional model sensitivity runs and more explicit evaluation tests are carried out by utilizing in situ and laboratory experimental measurements. In particular, the influence of the anthropogenic emissions and the suspension of mixed aerosols on the cloud formation along the Mediterranean region will be further investigated.

Size distributions of charged and neutral aerosol particles in the mobility diameter range of 1 – 42 nm were measured at 12 sites around Europe during a period of 13 months in 2008 and 2009. The measurements were part of the European Integrated project on Aerosol, Cloud, Climate and Air Quality Interactions (EUCAARI) (Kulmala et al., 2009). Measurements were made in continental, remote and coastal locations, including sites at different altitudes from sea level up to the free troposphere. This comprehensive data set gives information on the diurnal and seasonal variation of ion cluster concentrations as well as on the spatial and temporal variation of new particle formation events and relevant particle formation parameters across Europe.

A persistent pool of cluster ions below 2 nm diameter was detected at all sites. The cluster ion concentration varied approximately between 200 and 600 cm^{-3} per polarity. On the continental sites the main factor controlling the cluster concentrations was coagulation to the pre-existing aerosol, whereas on high altitude sites high relative humidity is observed to suppress cluster ion concentrations.

Formation and growth events of new particles initially about 2 nm in diameter were observed between 20 to 60% of all measurement days depending on the site (Manninen et al., 2010). We determined the formation rates of both charged and neutral particles. The median charged particle formation rates varied between 0.02–0.16 cm^{-3} s^{-1} between sites, and the median total particle formation rates in the range 0.7–32 cm^{-3} s^{-1}. The charged particle formation rate was typically 1–30% of the total particle formation rate. This shows that the total particle formation rates varied much more between the sites than the charged particle formation rates.

A simple parameterization based on the concentration of cluster ions and solar radiation intensity was developed to predict the ion-induced nucleation rates (Nieminen et al., 2010). This parameterization is in principle applicable to all large-scale atmospheric models for studying the role of ions in atmospheric nucleation.

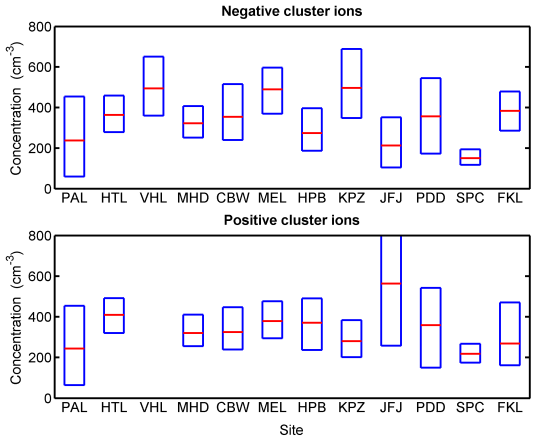

Figure 1. Median cluster ion concentrations at each of the 12 EUCAARI measurements sites during 2008–2009. Top panel shows negative cluster ions smaller than 1.8 nm and bottom one positive cluster ions. Red bar shows median and box is at 1st and 3rd quartile.

Introduction

From June to August 2010, an international team of researchers met at the High Altitude Research Station Jungfraujoch (Switzerland, 3580 m asl) for a joint campaign (CLACE2010 — Cloud and Aerosol Characterization Experiment), as a follow-up of previous CLACE campaigns. At the Jungfraujoch, comprehensive aerosol measurements have been performed continuously since 1995. The Jungfraujoch is optimally suited for this purpose, as it lies in the free troposphere but is influenced by the continental air over Europe. In addition, the Jungfraujoch is about 40% of the time within clouds, which makes it an ideal site to study aerosol-cloud interactions.

Cloud microphysics studies

During earlier studies, the cloud forming potential of aerosol particles at the Jungfraujoch was predominately derived from measurements performed under laboratory conditions at elevated temperature after having dried the aerosol (Henning et al., 2002). In the CLACE 2010 campaign we compared in situ measured cloud droplet number concentrations with CCN number concentrations that were derived from laboratory measurements. The combination of these measurements will allow for the determination of the effective peak supersaturation in the prevailing ambient cloud which was responsible for the activation of aerosol particles to cloud droplets. During the campaign the peak supersaturation of the cloud droplets arriving at the Jungfraujoch showed a mean value of 0.31% and a median value of 0.23% (Jurányi et al., 2010). Ongoing data analysis attempts to establish a link between the retrieved peak supersaturations and other parameters like temperature, updraft velocity and weather situation (i.e., cloud type).

Investigation of aerosol optical properties

Additionally, the optical properties of the aerosol layer at and around the Jungfraujoch were examined using a variety of remote sensing equipment. These remote sensing experiments were also simultaneously performed at lower altitude in 4 km distance of the Jungfraujoch (Kleine Scheidegg, 2061 m asl) for the first time. The main goal of this activity was to get the closure between in-situ measurements of aerosol optical properties at the Jungfraujoch with different kinds of remote sensing data.

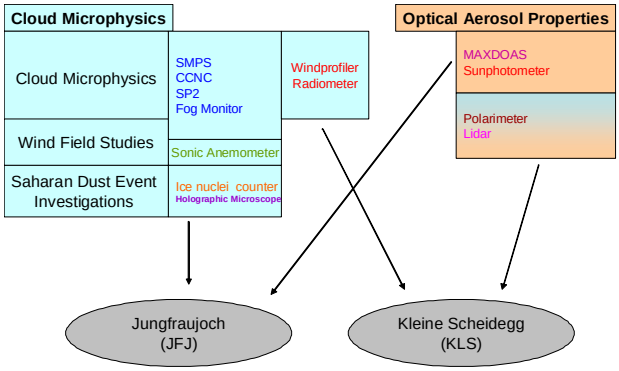

Figure 1: Combined study of cloud microphysics and optical aerosol properties during CLACE 2010.

This work was supported by MeteoSwiss within the Global Atmosphere Watch program of the World Meteorological Organization, the Swiss Federal Office for the Environment, as well as the EC project EUSAAR (contract no 026140) and GeoMON (contract no 036677). We thank the International Foundation High Altitude Research Stations Jungfraujoch and Gornergrat (HFSJG) for the opportunity to perform experiments on the Jungfraujoch.

Introduction

To study the interaction of aerosol particles, meteorological conditions and cloud or fog formation is a challenging task. Since aerosol properties and meteorological conditions are variable in time and space, every single cloud is unique. Here we will present measurement results obtained with the Droplet Aerosol Analyser (DAA, [1]), an instrument for studies of the interaction between cloud/fog droplets and interstitial particles. First results from in-cloud measurements at the summit of Mt. Brocken (51.80° N, 10.67° E, 1142 m asl) in the Harz region in central Germany, autumn 2010, will be presented.

Instrumentation

The DAA processes aerosol in several steps: aerosol charging mechanisms, diffusion drying, and electrostatic aerosol spectrometry (using Differential Mobility Analysers, DMAs). This gives a unique three-parameter dataset (ambient diameter, dry residual particle diameter and number concentration). A number of related aerosol/cloud parameters can be determined: ambient number size distribution of cloud/fog droplets and interstitial, number size distribution of dry residual particles, the relation between ambient diameter and dry (residual) diameter on a single droplet/particle basis, characterization of the droplet activation as defined by the Köhler equation, the size dependent scavenging of particles due to activation, concentration of soluble matter in the individual droplets (solute concentration), liquid water concentration. A second generation of the instrument has been developed with a higher time resolution and more suited for long-term measurements. Calibration of the ambient diameter (Dd) is in progress.

Results

Starting from June 2010 measurements at the sumit of Mt. Brocken have been performed. The project is in collaboration with the Air chemistry group of the Technical University of Brandenburg (BTU Cottbus), who has a cloud measurement site at Mt. Brocken since many years. Figure 1 shows a cloud event with activated droplets.

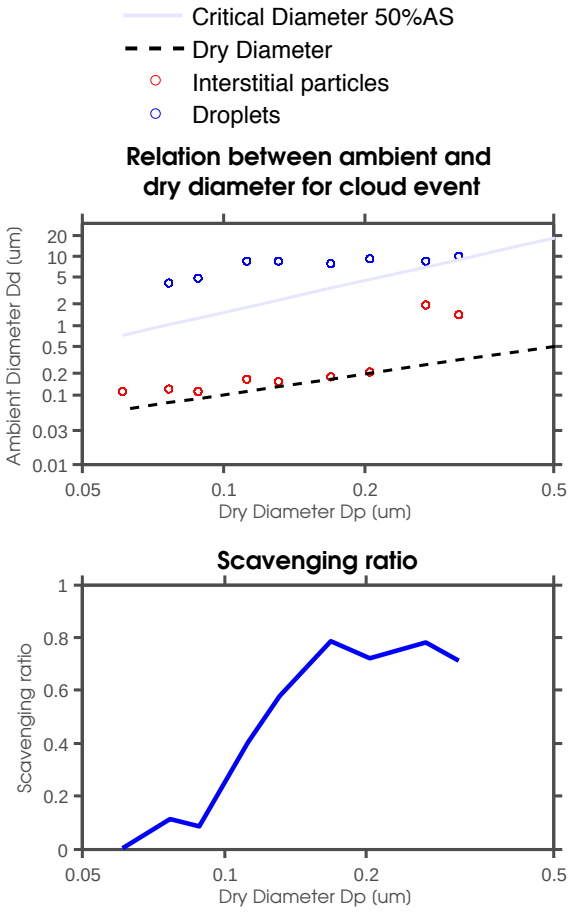

Figure 1: Preliminary results from a cloud event at Mt. Brocken, Germany, 27. Sep. 2009 06-07 am.

The influence of biomass burning on PM2.5 at urban and rural background sites in the Czech Republic

Jaroslav Schwarz[1], Jindřich Karban[1], Eva Chalupníčková[2], Radek Pokorný[2], Jiří Novák[2], Jiří Smolík[1]

[1]Intitute of Chemical Process Fundamentals AS CR, Prague, CZ-16502, Czech Republic

Keywords: PM2.5, chemical composition, biomass burning, levoglucosan.
Presenting author email: schwarz@icpf.cas.cz

PM10, and PM2.5 were sampled every 6th day from Feb 2009 till Mar 2010 at two sites in parallel. One site was urban background site Suchdol at NW border of Prague. The second site was rural background site Kosetice that is about 80 km south east from Prague. Both PM10 and PM2.5 were sampled on double quartz fibre filters to access OC positive sampling artifacts. The samples on both front and back quartz filters were analyzed using ion chromatography for anions and cations, TOT for OC/EC and front filters also by GC-MS to measure levoglucosan concentration. Moreover, another PM2.5 sampler loaded with TEFLO filter was used at both sites and these samples were analyzed using PIXE for elemental composition. All filters were weighted before and after sampling to get aerosol mass concentrations. In this work we will concentrate on the influence of biomass combustion on overall concentration of PM2.5 and OC and its seasonal variability.

Table 1: Average seasonal concentrations of EC, OC, levoglucosan (lvg) and calculated percentages of biomass combustion OC (BBOC) in total OC and organic matter (BBOM) in PM2.5 mass at urban and rural background sites Suchdol and Košetice

Urban background site Suchdol					
	EC µg/m3	OC µg/m3	lvg µg/m3	BBOC /OC	BBOM /Mass
Spring	1.12	4.18	0.15	36%	11%
Summer	1.02	2.31	0.06	24%	6%
Autumn	2.22	6.01	0.28	46%	14%
Winter	2.37	9.21	0.44	48%	19%

Rural background site Košetice					
	EC µg/m3	OC µg/m3	lvg µg/m3	BBOC /OC	BBOM /Mass
Spring	0.63	3.57	0.1	28%	10%
Summer	0.38	1.99	0.02	10%	3%
Autumn	0.67	3.60	0.11	32%	9%
Winter	0.77	4.53	0.22	50%	15%

The main results are summarized in Table 1. All parameters exhibit some seasonality but levoglucosan concentrations changes are clearly the largest, while the EC concentrations have the smallest seasonal variation. This reflects seasonal source variability of both EC and levoglucosan. Winter maximum of levoglucosan that is tracer of biomass combustion shows its importance as a source of PM2,5 mass and OC in Central Europe. The amount of BBOC was calculated from levoglucosan concentration using conservative factor of 10 (Szidat et al. 2009) and BBOM was calculated from BBOC using factor 1.4. Despite of using quite conservative factors, the calculation showed that biomass combustion is responsible for almost 50% of OC in central Europe in winter. This is in agreement with Puxbaum et al. (2007).

Comparison of urban background site and rural background site shows about 3 times higher levels of EC at urban site comparing to rural site at most of seasons except for spring when this factor was smaller then 2. OC was almost the same in spring and summer at both stations, while it was about twice higher at urban site in autumn and winter. Levoglucosan levels were about 50% higher at urban site in spring, 3 times higher in summer, 2.5 times higher in autumn and twice as high in winter. The relatively high level of levoglucosan at urban site in summer are probably caused by various biomass combustion events in gardens and cottages that are very common around Prague area. Local barbicues at Suchdol may also increase levels of levoglucosan in summer.
BBOC percentages are quite similar at both sites except for twice as high portion in summer at urban site. The autumn percentage of BBOC on the total OC was about 50 % higher in autumn at the urban site comparing to the rural site. These ratios were similar to the comparison of the percentage of BBOM on PM2.5 mass. It is question if the ratio 1.4 used in our calculations is properly set and if this could not be higher. This study anyway clearly showed that biomass combustion is especially in winter very important source of PM2.5 OC and mass.

The ionic composition of PM2.5 at a rural background site in Central Europe on daily basis

J. Schwarz

Intitute of Chemical Process Fundamentals AS CR, Prague, CZ-16502, Czech Republic
Keywords: PM2.5, chemical composition, water soluble ions
Presenting author email: schwarz@icpf.cas.cz

PM2.5 concentration and chemical composition were measured on a daily basis at the rural background site Košetice in the Czech Republic. The sampling was done using a Leckel gmbh sequential sampler loaded with TEFLO filters with 3 µm nominal porosity. The sampler was loaded with 15 filters, but the sampled filters were removed mostly daily. The flow rate was 2.3m^3/h. The filters were analyzed using ion chromatography and particle induced x-ray emission method.. We will concentrate on results of ion chromatography at this work.

Ion chromatography (IC) was used for determination of cations and anions. A circle 16 mm in diameter was cut out from each filter and extracted in a mixture of 0.5 ml methanol and 4.5 ml deionized ultrapur water with conductivity 0.08 µSm^{-1} (Ultrapur, Watrex Ltd.). After 30 minutes inside ultrasonic bath and 1 hour of shaking (half automatic, half manual), the solution was filtered using syringe Millipore filters with 0.22 µm porosity. The filtered sample was then analyzed for anions and the next day for cations. The sample solution for cation analysis was stored in fridge prior to analyze. Cations as Na^+, NH_4^+, K^+, Ca^{2+}, Mg^{2+}, Zn^{2+} and anions as SO_4^{2-}, NO_3^-. Cl^-, NO_2^-, Br^-, $H_2PO_4^-$ were determined. The analyses were provided using the setup by Watrex Ltd. with columns Transgenomic ICSep AN300 150x5.5 mm for anions and Alltech universal cation 7µm 100x4.6 mm for cations. The conductivity detector used in the setup was SHODEX CD-5.

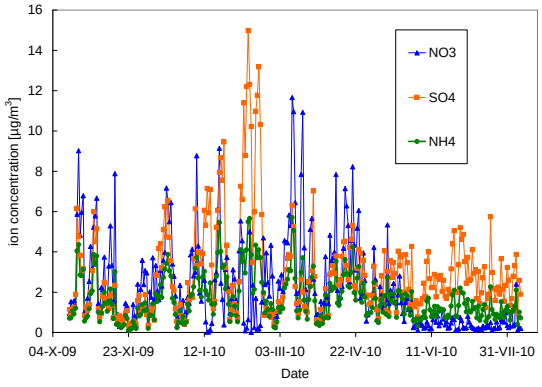

Figure 1. The time series of main ions obtained daily at rural background site Košetice.

The time series of measured concentrations of the main ions (sulphates, nitrates and ammonium) are shown in Fig. 1. There are several main features we can recognize in this graph. High variability is clearly seen especially in winter while the ion concentrations were relatively stable in summer. During summer, sulphates dominate ionic composition due to thermal instability of ammonium nitrate. The concentrations of sulphates and nitrates were mostly quite similar during spring and autumn with sometimes much higher concentration of nitrates. The most variable ratio between sulphates and nitrates was visible in winter. There were periods when nitrates were higher than sulphates (mainly those with lower concentrations) and periods when sulphates were completely dominating ionic composition and nitrates were very low. This is probably connected with the lack of ammonium to fully compensate for sulphate concentration in the atmosphere.

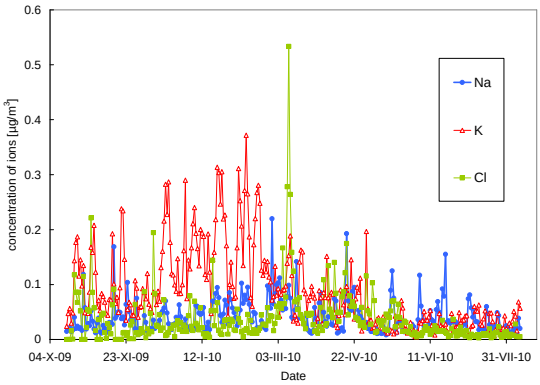

Figure 2. The time series of minor ions obtained daily at rural background site Košetice.

Concentration of chlorides, sodium and potassium ions are shown in Fig. 2. We can clearly see seasonality of potassium ion connected with large influence of biomass combustion in winter. Another interesting feature is relation between chlorides and sodium cation. Based on these data we can say that there is no tight relation between them. Moreover, the same can be seen for the relation between potassium and chlorides. We can discuss two basic possibilities to explain this behaviour. First there is another source of chlorides that is not connected with sea salt or road salt in case of sodium and with biomass combustion in case of potassium. The second possibility is that in both cases these factors comes from long range transport and chloride was depleted by interactions with nitric of sulphuric acids. This factor is strengthened by measurement of fine fraction only that subjects to these interactions more easily comparing to coarse particles.

The Size- and Time-Resolved Determination of the Water-Soluble Organic Fraction of Submicron Aerosol Particles from the Beijing Area

B. Nekat, D. van Pinxteren, Th. Gnauk, K. Müller and H. Herrmann

Leibniz-Institute for Tropospheric Research, Permoserstr. 15, D-04318, Germany

Keywords: Chemical composition, submicron particles, water-soluble organic compounds, dicarboxylic acids
Presenting author email: nekat@tropos.de

The rapid industrialization of Beijing during the last decades causes significant higher air pollutant emissions. These particle emissions affect the regional air quality by reducing the visibility due to the formation of haze and impact the radiation balance of the atmosphere by serving as cloud condensation nuclei (CCN). These effects strongly depend on the aerosol ability to take up water governed by the particle size, optical and microphysical properties. The CCN chemical composition, especially of the water-soluble fraction, can play a major role in cloud microphysics as well and strongly varies with particle size, season and day-time. Small water-soluble organic compounds such as dicarboxylic acids can attach to the surface of the liquid particle phase due to their polarity leading to a higher hygroscopicity of the CCN. The increased hygroscopicity possibly facilitates the water uptake and the activation to cloud droplets influencing cloud formation processes, precipitation and the radiation balance of atmosphere. The HaChi-project (Haze in China) targets to study the water-soluble organic fraction of submicron aerosol to associate the chemical composition with the ability to act as CCN.

To address this matter, two intensive campaigns were realized in March and July 2009. At a background site between the two megacities Beijing and Tianjin size- and time-resolved samples were collected with a 10-stage-Berner low pressure impactor (BLPI) in a 6 hours day/night regime.

This study presents the chemical composition of the water-soluble organic fraction of submicron particles in terms of particle size, day-time and season as well as different meteorological conditions such as haze. The samples were analyzed for mass, inorganic ions, elemental (EC) and organic carbon (OC), and the water-soluble organic carbon (WSOC). The WSOC fraction of the Berner foils was analyzed for small polar compounds such as the dicarboxylic acids oxalic, tartronic, malonic, tartaric, malic, succinic and glutaric acid. The respective water content of particles was calculated by the E-AIM model (Clegg, Brimblecombe & Wexler, 1998) using the chemical composition of the particles and a meteorological data set from the sampling site. To investigate the origins of air masses NOAA HYSPLIT (Draxler and Rolph, 2003, Rolph, 2003) backward trajectories were obtained.

Usually, the OC fraction is dominated by WSOC. The WSOC content strongly varies with the particle size, season, day-time and meteorological condition (Figure 1). Nevertheless, the majority of samples show an increasing WSOC content with increasing particle size.

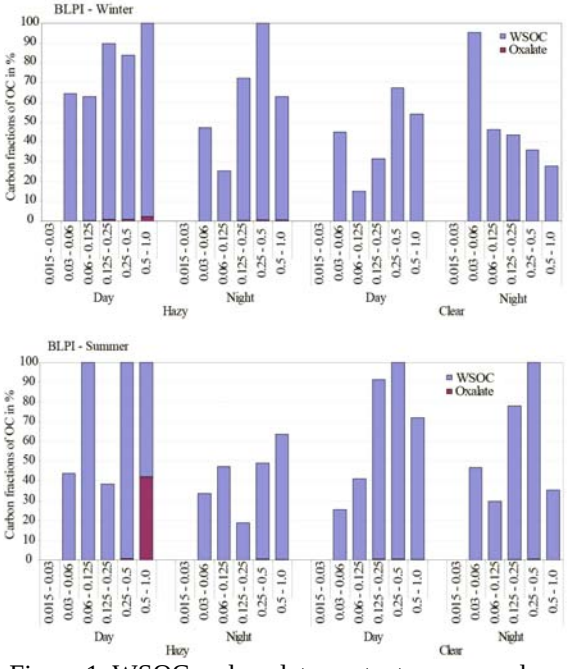

Figure 1. WSOC and oxalate contents expressed as carbon fraction of OC in % of the winter and summer campaign day/night measurements for hazy and clear sky conditions.

Organic compounds are abundant in atmospheric particulate matter, and a large fraction of these compounds are of secondary origin (Jimenez et al., 2009). Besides contributing to the total atmospheric aerosol mass, organic compounds play an important role in growing freshly-formed ultrafine particles to climatically relevant sizes (e.g. Riipinen et al., 2011). To quantify the effect of organic emissions to climate and air quality, atmospheric large-scale models need to realistically simulate the distribution of organic compounds in the atmospheric aerosol size spectrum.

Condensation and evaporation to/from aerosol particles can be reproduced with dynamic models if the thermodynamic and kinetic properties, such as saturation vapour pressures, vaporization enthalpies and accommodation coefficients of the condensing or evaporating vapors are known. In this work we investigate the condensational properties of atmospheric organic compounds, with a special focus on the low-volatile compounds growing the nucleation-mode aerosol (see also Donahue et al., *these proceedings*), and discuss the implications of these results for aerosol growth mechanisms and their representations in atmospheric large-scale models.

By comparing observed growth rates of freshly-nucleated ultrafine aerosol with condensational growth simulated by an aerosol dynamics box model we find that ambient sulphuric acid can account for only a minor fraction of ultrafine aerosol growth, the rest being organics. This observation is consistent with the seasonal pattern of particle growth rates at e.g. the SMEAR II station in Hyytiälä, Finland, for which growth rates show a maximum in the summer along with maximal emissions of biogenic organic compounds (Yli-Juuti et al., *in prep.*). We also find that saturation concentrations of roughly 10^{-3} μg/m^3 or less (corresponding to pure component saturation vapour pressure of the order or 10^{-8} Pa or less) are needed to explain the observed growth (see Fig. 1). Consistent results are found when the evaporation of the nucleation mode aerosol in the heating section of a Volatility-DMPS is modeled with a dynamic evaporation model and compared to measurement data.

These volatilities are significantly lower than those found in fresh chamber-generated or even aged atmospheric secondary organic aerosol (SOA) mass, which typically range from approximately 10^{-2} to 10^{2} μg/m^3 (10^{-7} to 10^{-3} Pa) (see Lee et al., 2010). The observed saturation concentrations are also in the lower end of the corresponding properties of dicarboxylic acids, which are among the least volatile identified SOA molecules with measured vapor pressures ranging from 10^{-8} to 10^{-3} Pa.

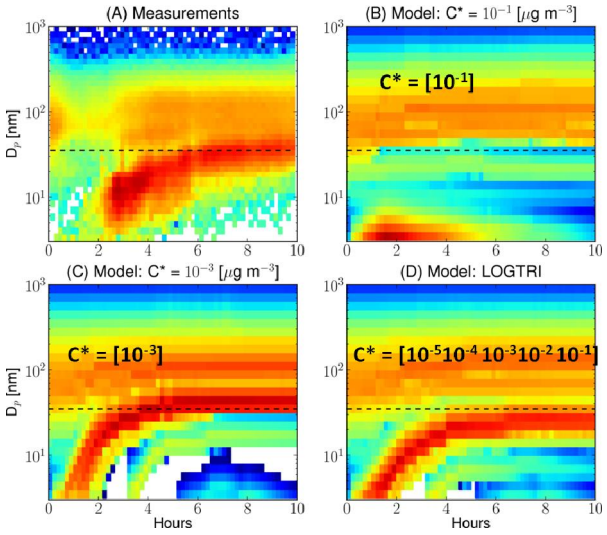

Figure 1. Measured (panel A) and modeled (panels B, C, D) evolution of aerosol size distribution on April 15th 2007 at the SMEAR II station in Hyytiälä, Finland.

Aerosol hygroscopicity distribution in size-resolved CCN measurements: the concept, validation and applications

Hang Su [1], Diana Rose[1], Yafang Cheng[2], Sachin S. Gunthe[1], Alfred Wiedensohler[2] and Ulrich Pöschl[1]

[1] Max Planck Institute for Chemistry, 55020 Mainz, Germany
[2] Leibniz Institute for Tropospheric Research, 04318 Leipzig, Germany

Keywords: CCN, hygroscopicity, HTDMA, VTDMA

This work focused on addressing fundamental problems encountered in the data analysis of size-resolve CCN measurement data. We introduced a concept of aerosol hygroscopicity distribution (HD) for the analysis and modeling of aerosol particle hygroscopicity and cloud condensation nucleus (CCN) activity. The HD concept reflects the heterogeneous properties of aerosols and corrects the misunderstanding in the traditional way of analyzing size-resolved CCN spectra.

The HD concept has been observed and firstly validated through a comparison with soot mixing state information given by a volatility tandem differential mobility analyzer in the Beijing megacity. Two other campaign data show similar HD in a rural site and in pristine rainforest air (Fig. 1).

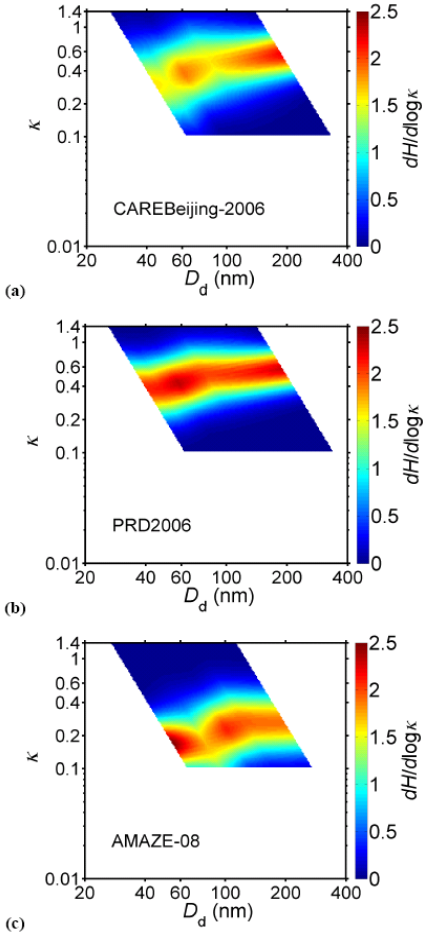

Fig. 1. HD in (a) urban site, (b) rural site and (c) pristine rainforest

Then a systematic study was carried out addressing the effects of multiple charges on aerosols and DMA transfer function, which had been supposed to significantly affect the CCN measurement results. A CCN counter simulation was developed for such purpose. The results showed that the commonly used correction approach relied on the assumption of homogeneous mixture of particles. For atmospheric aerosols, this assumption might not be valid. Several data correction approaches were evaluated and a more robust correction approach was recommended.

One important application of the CCN measurements is to provide parameters for the CCN prediction. We evaluated the performance and applicability of different κ parameters that had been used for CCN predictions. The comparison on the field measurement data confirms the results of model aerosols that the κ_{cut} and κ_t show similar performances in all the tested cases and are hence recommended for CCN prediction studies (Fig. 2). The κ_a alone is not recommended, especially in the presence of large fraction of insoluble particles (or less soluble particles below the detection limit). The κ_a multiplied by a gives a similar value as κ_t and can be used in CCN predictions.

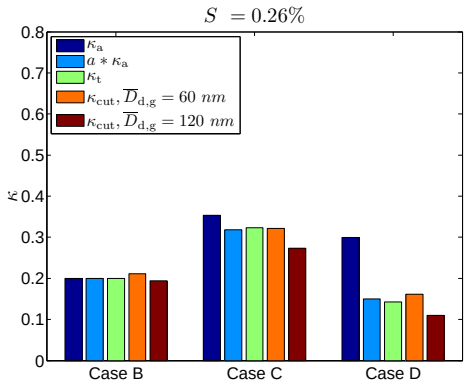

Fig. 2 Comparison of κ in CCN prediction

Effect of the biogenic emissions of isoprene and monoterpene on the CAMx model results in Central and South Europe

O. Vlček[1], L. Corbet[1], J. Liczki[2] and K. Zemánková[3]

[1] Czech Hydrometeorological Institute, Na Šabatce 17, Praha 4 – Komořany, 143 06, Czech Republic

Keywords: biogenic emissions, isoprene, terpene, fine particles, SOA, ozone, CAMx, Europe.
Presenting author email: vlcek@chmi.cz

Organic aerosols (OA) can significantly contribute to the particulate matter (PM) in continental mid-latitudes. Depending on the location they form 10 – 50% of the PM bulk mass (Kanakidou *et al.* 2005). This ratio is even higher for the PM fine fraction (e.g. Harrison and Yin, 2000). OA can be divided into the primary and secondary OA (SOA). SOA are formed through the oxidation of their volatile organic compound (VOC) precursors into semi-volatile compounds and their consecutive condensation into the particulate phase. Toluene and m-xylene are examples of the anthropogenic VOCs. Biogenic VOCs are emitted mainly by trees and include e.g. isoprene, terpenes and sesquiterpenes. In this work we assessed the effect of the inclusion of the biogenic emissions of isoprene and monoterpene into emission inputs of CAMx model. Results for the summer 2008 and winter 2008/2009 are compared to the reference run with only anthropogenic emission present.

We used version 5.2 of the Eulerian photochemical dispersion model CAMx. Aerosols were modeled in the fine/coarse mode within the chemistry mechanism SAPRC-99. **Modeling domain** consisting of 309 x 277 cells was covering Central and South Europe and also parts of the West and East Europe with horizontal resolution of 9 km. Its vertical extent was 16 levels with the average hight of the first level 15 m AGL and of the last level 8 – 9 km AGL. Input data were supplied with 1 hr time step. **Meteorology** was provided by the NWP model ALADIN/CE (version CY35T1star). Its assimilation cycle consisted of the analysis followed by 6 hr forecast at 0, 6, 12 a 18 hr UTC. **Anthropocentric emissions** corresponding to the year 2006 were prepared by the emission model developed by B. Krüger from Universität für Bodenkultur Wien. They were based on the EMEP inventory with resolution of 50 km. For Austria, the Czech Republic, Hungary, and the Slovak Republic more detailed emissions of ozone precursors were used. Normalized **biogenic emissions** were based on the merged AFOLU and USGS databases with a resolution of 1km (Zemánková, 2010). They were further processed by the version 3.12 of SMOKE-BEIS3 model.

Inclusion of the biogenic emissions of isoprene and monoterpene led to the increase of average modeled $PM_{2.5}$ by 0 – 2 $\mu g \cdot m^{-3}$ in summer and 1 – 6 $\mu g \cdot m^{-3}$ in winter over the most of the modeling domain, which corresponds to 0 – 20 % and 20 – 50 % increase respectively. Together with the increase of the biogenic SOA we observed an increase of the anthropogenic SOA. Although this increase was much smaller than for the biogenic SOA (cca 50 times in absolute numbers), it was nevertheless very significant, since in the reference run the concentrations of anthropogenic SOA were practically zero, even though a group of XYLA=ARO2 – which is a precursor of lumped SOA1 and SOA2 – was present in the athropogenic emission inputs (Environ, 2010).

Average summer concentration of ozone increased south of the 50° N mostly by 5 – 10 $\mu g \cdot m^{-3}$ (5 – 20 %). The increase was much higher over Italy (10 – 20 $\mu g \cdot m^{-3}$), and the highest increase was observed over the Adriatic Sea (10 – 20 $\mu g \cdot m^{-3}$ i.e. 30 – 60 %). In the winter average ozone concentration decreased by -6 – -1 $\mu g \cdot m^{-3}$ (i.e. 4 – 16 %) over the most of the domain.

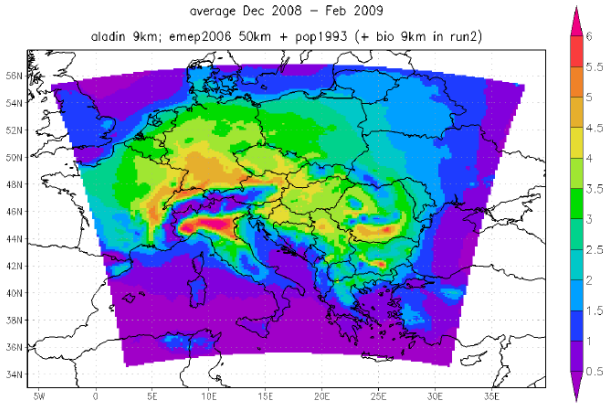

Figure 1. Dec 2008 – Feb 2009 average increase of $PM_{2.5}$ [$\mu g \cdot m^{-3}$] when biogenic emissions were included.

Wet deposition is one of the important ways in which contaminants are removed from the atmosphere. In addition to inorganic species, wet deposition contains organic acids (Avery *et al*., 2006) with an important contribution to rainwater acidity. The dicarboxylic acids are an important group of organic acids (Kawamura *et al*., 1996). Of these, the low molecular weight dicarboxylic acids are the most common species in rainwater (Avery *et al*., 2006). The chemical character of wet deposition in southern Taiwan is not well understood, with information regarding dicarboxylic acid content particularly lacking. Therefore, the wet deposition at a suburban site in southern Taiwan was collected and analyzed for inorganic species and dicarboxylic acids.

Rainfall samples were collected over a period of May 2005 and December 2008, and were grouped for analysis according to season and / or type of rainfall into six categories. These were *Plum Rain* (continuous rains that typically occur in Taiwan in May-June), *Typhoon Rain*, *Typhoon Outer Circulation* (TOC) *Rain*, *Summer Rain* (July to September), *Autumn-Winter Rain* (October to February), and *Spring Rain* (March to April). Prior to analysis of ionic species, all of the 402 samples were used for pH measurement. Twelve ionic species were analyzed: HCO_3^-, Cl^-, NO_3^-, SO_4^{2-}, Na^+, NH_4^+, K^+, Mg^{2+} and Ca^{2+}, and oxalic, malonic and succinic acids.

Wet deposition was mostly of pH 5.0-6.0 (346/402 samples fell within this range), indicating that the study area is not impacted significantly by acid rain. Table 1 lists the rain volume and volume-weighted mean (VWM) equivalent concentrations of the total ionic content and percentage contribution of inorganic cation and anion and dicarboxylic acid. It shows that Spring Rain had the highest equivalent ionic concentration. Spring Rain follows the dry winter season and is less frequent than other categories of rainfall. These factors combined explain the high ionic concentration of Spring Rain. In contrast, the Plum Rain that follows spring had the lowest equivalent ionic concentration less than one third of Spring Rain. The VWM concentration of inorganic anions composed between 41.15% and 58.41% of the total ionic concentration, and dicarboxylic acids between 0.29% and 0.58%. Plum Rain had the highest equivalent dicarboxylic acid content of 0.58% and TOC the lowest of 0.29%. Although Autumn-Winter Rain and Spring Rain had equivalent dicarboxylic acid content of only 0.37-0.38%, respectively, their higher total equivalent ionic concentrations lead to dicarboxylic acids being at their highest levels in these two rainfall types.

Table 1. Ionic concentration and percentage contribution of cations, anions, and dicarboxylic acids.

Rainfall type	Amt[b]	Volume-weighted mean (VWM) concentration			
		Ionic conc.	Cations	Anions	Dicarboxylic acids
	(mm)	μeq L^{-1}	%	%	%
Plum (*n*=148)	665	354.3	48.33	51.09	0.58
Typhoon (*n*=55)	456	579.7	48.08	51.59	0.33
TOC[a] (*n*=9)	22.5	942.5	41.30	58.41	0.29
Summer (*n*=133)	650	467.2	52.01	47.59	0.40
Autumn-Winter (*n*=42)	118	692.8	55.87	43.76	0.37
Spring (*n*=15)	32.5	1125.9	58.47	41.15	0.38
May 2005-Dec. 2008 (*n*=402)	1944	485.2	50.33	49.25	0.42

The ion balance (IB) ratio in relation to the pH of Plum Rain with and without HCO_3^- is shown in Fig. 1. The correlation coefficient (*r*) for this relationship without HCO_3^- was between .686 (TOC Rain) and .900 (Autumn-Winter Rain). The *r* for this relationship with HCO_3^-, however, was between .983 (TOC Rain) and .996 (Plum Rain), indicating a very high correlation between the IB ratio and pH. These results show that the IB ratio based on the ionic species studied including HCO_3^- does reflect the actual pH variation and ionic equilibrium of the wet deposition. The major species that influence the acidity of wet deposition and its neutralization include anions: HCO_3^-, Cl^-, NO_3^- and SO_4^{2-}, cations: Na^+, NH_4^+, K^+, Mg^{2+} and Ca^{2+}, and dicarboxylic acids: oxalic, malonic and succinic acids.

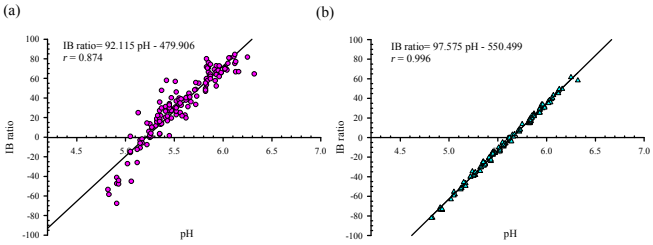

Fig. 1. Ion balance ratio in relation to the pH of Plum Rain with (a) HCO_3^- excluded from IB ratio calculation and (b) HCO_3^- included in IB ratio calculation.

Session 5A: PM Sources

Particle size distribution, number concentration, CO and sources of aerosol particles in Nairobi, Kenya

J. Boman[1], M.J. Gatari[2], S. Thorsson[3] and A. Mooe[1]

Many developing countries experience an exceptional urbanization rate. In Sub-Saharan Africa (SSA) the rate is estimated to be over 3% per year for at least twenty years (United Nations Population Division, 2008). With this increased urbanization follows a deterioration of the urban air quality. It is also in these areas the greatest health impacts are found, as a result of not only the bad air quality but also due to poverty (Fullerton et al., 2008).

Particulate matter (PM) and CO are some of the common criteria pollutants monitored in many parts of the world, as they are a health threatening pollutants whose concentration increases with the increased urbanization and life style. To provide new scientific data on the air quality, CO was measured and aerosol particles were counted at an urban background site in Nairobi, Kenya, between 14 January and 8 March 2010. The background site was about 2 km north of the commercial center of Nairobi where PM and CO were measured at a height of 17 m above ground while the latter was also measured at another lower site at 7 m above ground, in the same compound. The focus was to determine the size distribution of aerosol particles, identify their sources by correlating particle size fractions with local wind patterns and CO concentrations.

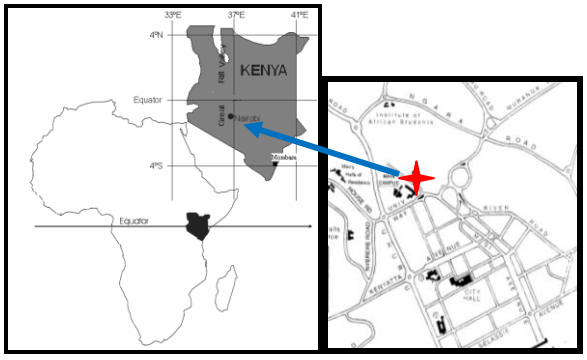

Figure 1. Map showing the location of Nairobi in Kenya, Africa and the sampling site in red within the central district of Nairobi city.

The measurements period was during the longer of two dry seasons with prevailing East-North-East winds, mainly sunny, dry and stable weather conditions. The maximum daytime temperature was around 28 ºC and wind speed was 10 m s^{-1}. The evenings and nights were calmer with more stable atmospheric conditions.

Particles were counted using an optical particle counter (Grimm 1.108). The counter is facilitated to collect the counted particles on polytetrafluoroethylene (PTFE) filter. The content of trace elements in the PTFE filters was determined by energy dispersive x-ray fluorescence (EDXRF) spectroscopy (Gatari et al., 2009) and 14 elements were analyzed. Two Passive electrochemical sensor Instruments were used to measure the CO concentration.

Fe, Ca, K, Mn, Ti constituted the major part of the determined mass concentration. S, Zn, Pb showed low concentrations compared to similar studies in Nairobi (Gatari et al., 2009) and other developing countries. Principal component analysis of the detected elemental concentrations identified waste and biomass burning, red earth, mineral dust and diesel vehicles or generators as probable sources of the elements involved. The largest fraction of the diesel emissions probably had their origin in the small buses (locally known as "Matatus"). These vehicles are a major public transport system in Nairobi and Thika Road to the North East of the sampling site has a very high number of these vehicles and is also synonymous with prolonged traffic jams especially in the morning and evening hours. It is estimated that there are 12,000 "Matatus" operating in Nairobi, compared to 300 larger buses.

The diurnal particle number concentration (PNC) peaked around 8-9 AM and 9-10 PM. CO was found to correlate well with PM2.5, but not with PM3.5-20. The concentrations of CO ranged from 0.03 to 15 ppm with daytime distributed peaks that depicted the heavy traffic and jam periods. Particle mass concentration (PMC) was derived from the number concentration and estimated to 7.5 µg m^{-3} for PM2.5 and 33.4 µg m^{-3} for PM10. These values were far much lower than those obtained from other studies at the same site. Although the data requires re-evaluation the study clearly showed the undisputed impact of traffic emissions in the city of Nairobi where the ground level concentrations are expected to be higher especially for particles.

nickel@iuta.de

Epidemiological and toxicological studies have shown correlations between adverse health effects and particulate matter. Especially ultrafine particles (UFP) are assumed to be linked to these biological effects (Stölzel et al. 2007, Oberdörster et al. 2005, Ibald-Mulli et al. 2002). Particle number and surface area concentration are considered as promising assessment metrics for specific health endpoints.

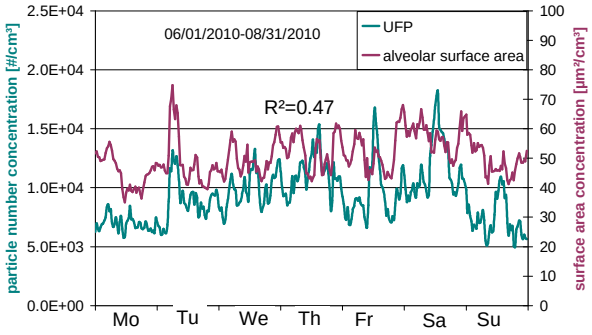
Here we report on results from ongoing measurements of particle size distributions and surface area concentrations, carried out over a two year period at an urban background station in Mülheim-Styrum in the Ruhr area in North-Rhine Westphalia, Germany.

We measured the ambient particle number concentrations using a scanning mobility particle sizer (SMPS Model 3936, TSI inc) and the surface area using a nanoparticle surface area monitor (NSAM Model 3550, TSI Inc.). The latter device measures the potential surface area which deposits in the alveolar region of the respiratory tract of a standard worker (ICRP Model 66 1994) thus a metric related to internal dose.

A Pearson correlation analysis with UFP and the measured possible deposited alveolar surface area (R^2 0.56) shows weak correlation in 2010. In 2009 no correlation (R^2 0.32) was found.

It was also identified that some single events, like the eastern bonfire combined with inversion weather conditions in 2009, when particles with a high surface area but with a low UFP concentration were detected, could be important for the weak correlation between the both metrics. Without the eastern bonfire event the correlation between the two metrics increase from R^2 0.34 to 0.45, but shows no clear correlation anymore.

Moreover, a seasonal comparison of the alveolar surface area and the ultrafine particle concentration in 2010 shows higher correlation in autumn (R^2=0.79) than in summer (R^2 = 0.47) (Fig. 1).



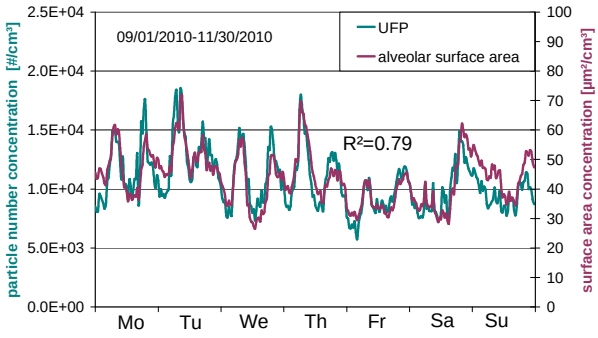


Fig. 1: Particle surface area (NSAM) and UFP (SMPS) concentration of the ambient aerosol for summer and autumn 2010.

This could possibly due to the different air chemistry, e.g. photochemical production of secondary aerosols or different sources.

For clarification, a source appointment of the measurements was conducted by applying the positive matrix factorization (U.S. EPA PMF 3.0.2.2). First PMF evaluations did not lead to robust factors for the alveolar surface area metric. A single run for September linked the surface area to particle number concentrations in the size range 50-200 nm and a second factor with the main variables of UFP, NO_2 and NO. The preliminary results will be further evaluated and their robustness tested. Especially seasonal and source dependent differences of the two health relevant metrics (particle number concentration and surface area) will be further investigated and discussed in detail to derive a comprehensive characteristic of health relevant ambient aerosol parameters.

[4]Finnish Meteorological institute, FI-00101 Helsinki, Finland

Keywords: ship emissions, mobile laboratory, particle size distribution, nitrogen oxides, Baltic Sea.

Marine traffic is a significant and growing source of diesel emissions to the local and global environments affecting human health and climate change. Recent estimates indicate that ocean-going ships represent approximately 9% of global SO*x* emissions, 18-30% of the world's NO*x* pollution and 2% of global black carbon from all sources (Gorbett and Koehler, 2003; Corbett et al., 2010). The Baltic Sea is a busy area for short-sea marine traffic; about 3500-5000 different vessels are in operation every month (Jalkanen et al., 2009). Control legislation for SOx emissions was taken effect from 16 May, 2006. Besides short-sea marine traffic other port activities contribute to the air quality.

To study port area emissions and their local dispersion, two weeks mobile measurements by SNIFFER (e.g. Pirjola et al., 2004; 2006) were performed in the port area in Helsinki and in the neighbouhood of the port area in Turku, Finland, during both winter and summer in 2010. The experiments were a part of the Shipping-induced NOx and SOx emissions - Operational monitoring network project (SNOOP). The general goal of SNOOP is to find out how ship exhaust emissions are effecting to marine environment and human health in harbour areas, and to establish a long-term follow-up network on ship emissions in the Central Baltic area (http://snoop.fmi.fi).

The van was standing at different sites at the port areas and close to the ship passage. Sampling occurred above the windshield of the van at 2.4 m altitude. Particle size distribution and total number concentration were measured by ELPI - Electrical Low Pressure Impactor. ELPI classifies particles in the size range of 7 nm – 10 µm (aerodynamic diameter) to 12 classes with one second time resolution. Particle volatility was studied by using a thermodenuder, where the temperature of the air sample reached 265°C. Also gaseous concentrations such as carbon monoxide CO, nitrogen monoxide NO, nitrogen dioxide NO_2 as well as carbon dioxide CO_2 were monitored with one second time resolution. Furthermore, $PM_{2.5}$ and PM_{10} were recorded by two Dust Tracks. A weather station on the roof at 2.9 m height provides meteorological parameters (temperature, relative humidity, wind speed and wind direction). A global position system GPS saves the van's speed and the driving route.

Typically the emitted SO_2 concentration correlated well with the total particle number concentration indicating that sulphuric acid is involved in the formation process of new particles. Fuel sulphur contents (FSC) of each ship were estimated based on the measured CO_2 and SO_2 peaks.

The size distribtions are typically composed of two modes. As an example, Figure 1 shows the size distribution of the ship plume as a function of distance. The nucleation mode is peaking at 20-30 nm and the soot mode at 80-90 nm. In winter the total particle concentration is aroung 2-3 fold compared to the summer values.

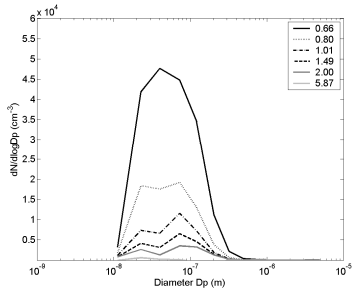

Figure 1. Evolution of the particle size distribution when the ship is receding upwind from the harbour. Distance from Sniffer in km is shown in the legend.

The experiment was financed by Cental Baltic INTERREG IV A Programme 2007-2013 and Centre for Economic Development, Transport and the Environement (ELY) of Southwest Finland

Introduction

The 27 member states of the European Union are committed to obtain 20% of their energy requirements from renewable sources, including biomass, by 2020 (EU, 2009) as part of a raft of proposals to reduce CO_2 emissions. In response to these targets, the UK Department for Energy and Climate Change (DECC) has announced the world's first renewable heat incentive, which will provide a financial incentive for individuals and businesses to switch from fossil fuel to renewables as part of a strategy to 'de-carbonise' the generation of heat in the UK. As part of carbon reduction policies the UK government will launch the world first renewable heat incentive in June 2011 (DECC, 2010a), which will target around 700,000 new domestic biomass installations by 2020 (Klevnäs, 2009). Additionally biomass boilers are being installed to meet requirements for renewable energy in new buildings. Concern has been raised over the possible urban air pollution impacts arising from the widespread installation and use of biomass heating. There is a risk that an increase in biomass burning may undermine air quality management actions aimed at achieving PM_{10} EU Limit Values and the EU exposure reduction target for $PM_{2.5}$. It was therefore felt prudent to establish a baseline for the PM from biomass burning in London against which future changes can be measured.

Methods

The contribution of PM from biomass in London was estimated using two ambient measurement methods. The first used measurements of the concentration of levoglucosan, a specific marker for PM from wood combustion, sampled during two winter campaigns in 2009 and 2010. The second used the differential absorption of UV and IR in sampled PM_{10} using aethalometers (Favez et al. 2010) at two sites over a period of 15 months. Analysis was supported by measurements of NOX, sulphate and ethane from UK national networks.

Results

Mean winter time concentrations of levoglucosan were 176 ng m^{-3} at the low end of the range of concentrations found across Europe. Analysis of levoglucosan concentrations and wind speed did not reveal any large point sources. Having used measurements of ethane (assumed to be from natural gas leakage) as a tracer for dispersion it was found that levoglucosan emissions were greatest at weekends.

Good correlation was found between estimates of PM from wood smoke using levoglucosan and UV and IR absorption (r2 = 0.76), though the estimated concentrations of organic carbon using the UV and IR absorption method exceeded estimates using levoglucosan by a factor of between 1.5 and 2 . Measurements of UV and IR absorption suggest that wood burning is a winter time pollution source in London with peak PM_{10} concentrations during evenings and especially at weekends.

Conclusions

Ahead of new policies to promote renewable energy it appears that wood burning already contributes approximately 3 µg m^{-3} to wintertime PM_{10} in London; 15% of the wintertime background concentration. No distinct point sources were detected, suggesting that wood smoke particulate originates from diffuse urban sources. The wood smoke contribution to PM_{10} was mainly a wintertime effect; occurring mostly during evenings and at weekends. This suggests that current wood burning in London is a secondary heating source. Widespread wood burning suggests that smoke control legislation is no longer effective in London.

Keywords: aerosol source apportionment, urban environment, aerosol mass spectrometer

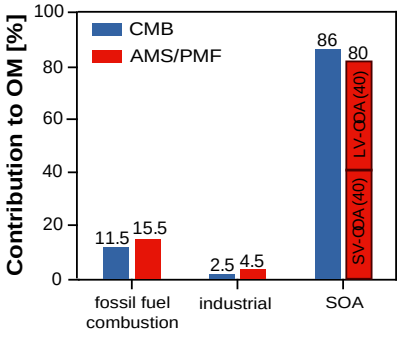
This study presents comprehensive results of the FORMES program based on two field campaigns: one in a coastal Mediterranean city (Marseille, France) during summer 2008 (30/06-14/7), the other in Grenoble, located in an Alpine valley, during winter 2009 (14.01-30/01). On line instruments (C-TOF-AMS, HS-PTR-MS, SMPS, and VHTDMA, aethalometer) were employed to investigate in detail fine particles and VOCs. Filter-based measurements were used for the measurement of a large array of chemical species including EC and OC, ionic species, metals, and molecular speciation of organic matter.

Total NR-PM_1 mass concentration in Marseille accumulates over days and rapid cleaning occurred when the meteorological conditions changed, due mainly to the Mistral wind. Sulphate and organics were the major NR-PM_1 components while the concentrations of nitrate and chloride were generally quite low. Ammonium sulphate was the dominants salt. The aerosol was often acidic and more than 40% of sulphate was in the form of ammonium bisulphate. The accumulation mode was dominated by sulphate that appears to be internally mixed with organics, while combustion-emitted organics are often the main component of the ultrafine particles (except during nucleation events). The ultrafine-mode organic aerosols were mainly associated with combustion sources (likely traffic). Few nucleation events were observed and they were always preceded by very high concentration of SO_2 (industrial sources nearby the city of Marseille).

The NR-PM_1 mass concentration in winter time in Grenoble is largely dominated by organic matter, and nitrate and BC. Hourly-mean PM_1 loadings, estimated as the sum of these compounds, vary from 1 µgm−3, during low pressure systems associated with rain, to 40 µgm−3 during typical wintertime thermal inversions. Independently of these meteorological conditions, submicron particles are mainly composed of carbonaceous material, with OM and BC constituting on average 47% and 16% respectively of the total loading. Among inorganic aerosols, ammonium nitrate largely dominates over ammonium sulphate. Similar results are obtained from the analyses of HiVol filters for the PM2.5 aerosol fraction.

Various source apportionment methods as Positive Matrix Factorization, Chemical Mass Balance and aerthalometer model (only for Grenoble) were undertaken to evaluate the organic contribution of the fine aerosol. In Grenoble, residential wood burning emissions accounted for approximately 40-50% of fine carbonaceous aerosols. Such results underline the significant impact potentially played by residential wood burning emissions on particulate air pollution in large European urban centres.

While in summertime in Marseille four major factors have been identified; the predominant factor is highly oxygenated (OOAI and OOAII type). A minor and not non-defined 4th factor called 'industrial' is found and perfectly correlates with "hot spot of PAHs" (not related to traffic emissions) which seems to related to" industrial organic source" (refinery). Figure 1 below shoes the excellent agreement found between PMF2/AMS analysis and CMB model.



The source apportionment methods and results from the two studies will be compared and discussed.

Measurements of the urban Copenhagen aerosol from 2002 – 2010: physical properties and their trends

A. Massling[1], M. Ketzel[1], T. Ellermann[1], J. K. Nøjgaard[1], B. Jensen[1], C. Nordstrøm[1] and P. Wåhlin[1]

[1]Department of Atmospheric Environment, National Environmental Research Institute, Århus University, Roskilde, Denmark

Keywords: urban aerosol, DMPS, TEOM, PSAP, PM2.5, PM10
Presenting author email: anma@dmu.dk

Introduction

In the last two decades aerosol particles have been intensely discussed because of their various health effects (Pope and Dockery, 1999). EU directives control ambient concentrations of PM10 and PM2.5, however the number concentration of fine aerosols (< PM1) has not yet been regulated. Urban particulate emissions in major cities in Europe are mostly linked to the increasing road traffic and to some extent to domestic wood burning and industrial emissions. The traffic density, the composition of the vehicle fleet and the used fuel are changing rapidly and new engine techniques are developed. In this study the physical properties and their trends within the last ten years are discussed for the urban Copenhagen aerosol.

Methods

Measurements were carried out throughout the period from 2002 to 2010 at three Danish stations, namely Lille Valby (LVBY, a regional background site 30 km west of Copenhagen), H.C. Ørsteds Institute (HCOE, an urban background site in central Copenhagen), and H.C. Andersens Boulevard (HCAB, an urban curbside station in central Copenhagen) (Wåhlin, 2008). The particle number size distribution (10 – 700 nm) was measured using a DMPS system (Differential Mobility Particle Sizer), the PM2.5 and PM10 mass was measured using a TEOM (Tapered Element Oscillating Microbalance) and the light absorption coefficient was measured using a PSAP (Particle Soot Absorption Photometer).

Results

In general all measured parameters (total particle number and volume, PM2.5 and PM10 mass, light absorption coefficient) are decreasing with increasing distance to the traffic emission sources.

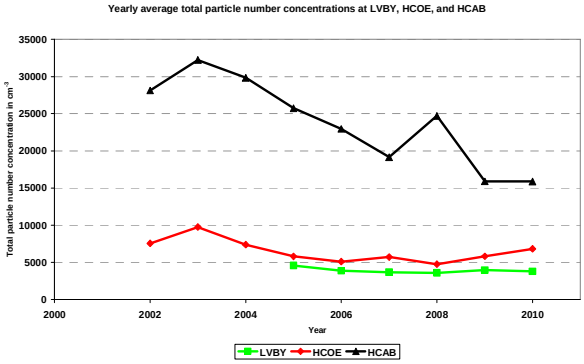

Figure 1. Average yearly particle number concentration at LVBY, HCOE, and HCAB.

This means, that the maximum values were observed at the urban curbside station HCAB followed by HCOE and LVBY. Moreover, a decrease in air pollutant values was observed at the urban curbside station HCAB as a general trend from 2002 to 2010 for all parameters except for the light absorption coefficient, which is an indirect measure for the mass of black carbon particles (BC) in the urban aerosol. Figure 1 shows these general findings for the total particle number concentration measured with the DMPS.

At the curbside station, the weekly variation of the air pollutant parameters was in clear correspondency with the weekly variation of the traffic density in the city. Figure 2 shows examplewise the average weekly variation of particle number concentration.

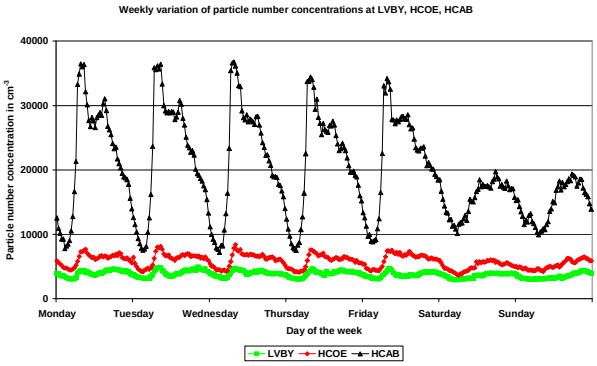

Figure 2. Average weekly variation of particle number concentrations at LVBY, HCOE, and HCAB.

The variation is most pronounced for the curbside and reduces with the distance to the traffic emission sources. Number concentrations for the curbside peak at values, which are about six to seven times higher than at the regional background and about four to five times higher than at the urban background site. Similar findings were observed for PM10 and PM2.5 mass concentrations and the light absorption coefficient.

Outlook

Trends in particle number and volume, PM2.5 and PM10 mass are discussed and linked to exposure levels induced by traffic emissions.

Particle area and number concentrations influenced by local sources at an urban background station in Germany

H. Gerwig[1], W. Pecher[1] and K. Wirtz[1]

[1]Section Air Quality Standards and Monitoring Methods, UBA – Federal Environmental Agency, 63225 Langen, Germany.

Keywords: particle area, car traffic, asphalt grinding, gas-fired CHP, airport

The European Union defined a daily average PM_{10}-limit of 50 µg · m^{-3} for the protection of human health (2008/50/EC). Epidemiological and toxicological studies give evidence that ultrafine particles (< 100 nm, UFP) show negative health effects (Knol *et al.*, 2009).

Reduction limits for diesel cars are fixed (EURO VI). To control the results of reducing emitted particle numbers from cars and especially trucks, governmental agencies in Germany started to measure ultrafine particles on a routine base (Birmili *et al.* 2009 and Löschau *et al.* 2010).

Table 1 1-h av. tracheobronchial particle area and particle conc. 09-09-2009 – 14-06-2010

	NSAM	UCPC	SMPS
	µm²/cm³	p / cm³	p / cm³
nm	10 - 1000	3 - 1000	10 - 500
Median	5.0	9 900	8 600
Std	3.1	6 100	6 000
5 Perc	1.9	4 600	3 700
95 Perc	11.7	22 500	21 000

The urban background station was situated in Langen, Germany: 15 km south of Frankfurt a. M. and 5 km south east of the airport in the Rhine-Main-Area. Three different particle measuring instruments (TSI Inc.) were running continuously (09-09 – 06-11, 1 min av. and SMPS 6 min av.) on a rooftop at 14 m above ground with cut of at 1 µm. NSAM measures the deposited tracheobronchial (= tb) particle area within particle diameter of 10 - 1000 nm. With UCPC 3776 particle number concentration from 3 - 1000 nm was measured. With SMPS 3936 and CPC 3010 particle number size distributions between 10 – 500 nm were detected. 6 size classes were calculated from SPMS data (10 |30 |50 |70 |100 |200 |500). The difference of UCPC and total SMPS was expected to be size class 3 – 10 nm Offsets between both instruments cannot be excluded.

Temperature, humidity, wind speed, wind direction, precipitation was collected by WS600 (LUFFT GmbH). Only complete datasets of 1 h av. were used for evaluation (85 % of time period). For diurnal Mo-Fr variations data from official holidays and from 23-12-09 until 03-01-10 were excluded.

During the measuring period the median of the tb particle area concentration was 5 µm²/cm³, particle number concentration from 10 to 500 nm was about 8 600 p · cm^{-3}. 1 300 p · cm^{-3} more particles were found from 3 to 1 000 nm range (s. Tab. 1). The temperature was between -15 and +30°C, wind speed up to 14 m · s^{-1}.

For diurnal variations from Monday to Friday 2 different shapes were detected (Fig 1). Shape A: Tb particle area and particles 30 – 500 nm showed a 1st min. around 4:00, max. at 9:00 and 2nd min. at 15:00, similar to previous observations at an urban background during UFIPOLNET (Wehner *et al.*, 2008). Shape B: Particles 3 – 10 nm showed 1st max between 13 – 15:00 probably caused by particle nucleation events and a 2nd max at 7:00. Particles 10 – 30 nm show almost the same diurnal variation as shape A except for afternoon, were the second min. looks as if overlayed by effects responsible for shape B.

Grinding up asphalt and other road construction work in 10 to 100 m distance caused raised particle area and number concentrations. Elevated particle concentration occurred with winds from a nearby combined heat and power gas-fired power plant (CHP). The influence of the airport will be evaluated. The influence of fireworks is described elsewhere (Gerwig *et al.*, 2011).

Presenting author email: k.bower@manchester.ac.uk

Frontal systems associated with mid-latitude cyclones generate large regions of cloud which can perturb the regional radiation balance, as well as precipitate large quantities of water to the surface. Predictability of the spatial distribution and temporal development of the radiative properties and precipitation associated with frontal clouds requires knowledge of the microphysical processes acting. The influence of aerosol acting both as Cloud Condensation Nuclei and Ice Nuclei can be large.

In-situ measurements in frontal clouds were obtained using the UK Facility for Airborne Atmospheric Measurement (FAAM) BAe146 research aircraft flying in the vicinity of the suite of radars and lidars based at the Chilbolton Facility for Atmospheric and Radio Research (CFARR). Case studies were later simulated using the Advanced Research WRF (Weather Research and Forecasting) model version 3.1 (using the dual moment Morrison microphysics scheme), and also a detailed microphysics model linking together the atmospheric aerosol (size and composition) to the formation and growth of water droplets, ice crystals and snowflakes.

In deep frontal cases, homogeneous nucleation of ice at cloud top (CT) together with heterogeneous nucleation (temperatures around -35°C or below) were seen as the primary source of ice. For lower cloud top cases (temperatures around -25°C), a layer of supercooled liquid water was often seen at cloud top. Heterogeneously nucleated ice, at or just below CT, grew via deposition and aggregation into snow. Embedded convection originating from near the surface was observed frequently and generated regions of supercooled water and high number concentrations of ice crystals (up to 100 L^{-1}) at temperatures around -6°C. These ice crystals were usually small (<300 μm in length) un-rimed columns, and most likely the result of the Hallett-Mossop secondary ice multiplication mechanism.

Data and model results from a wide range of clouds and cloud types will be presented to investigate the relationship between heterogeneous vs homogeneous ice nucleation and to assess the importance of ice crystals contributed by secondary ice particle production at temperatures around -6°C where the Hallett-Mossop process operates. The WRF model will be used to help predict the overall dynamical structure of the cloud, while the more detailed cloud microphysical model will be used to predict the number of ice, water droplets and ice crystals forming on aerosol as a function of position in the cloud. This model makes use of results from chamber studies of ice nucleation of aerosol e.g. Connolly et al 2009. Model predictions of the initial growth of the ice crystals by vapour diffusion, and then as they became large enough, by riming and aggregation, leading to precipitation from the cloud will be presented. The contribution of secondary ice to this precipitation will also be examined.

Predictions from both models will be compared with the observations. The sensitivity of the cloud structure and precipitation amount and size distribution to the aerosol available in the boundary layer and above cloud top will be examined for the different cloud types. Results so far suggest that the competition between heterogeneous nucleation and homogeneous freezing in cloud with tops colder than about -35°C is important in determining the number of ice particles nucleated at cloud top. This in turn influences the precipitation production within the cloud. Lower down in the cloud the ice crystal number and in some cases the precipitation formation is influenced by secondary ice particle production, however, this process is not well modelled by WRF and is to be investigated further.

It is hoped this work will lead to an improvement in the treatment of cloud-aerosol interactions in frontal clouds by weather forecast models such as WRF, and hence to an improvement in the forecasting of such systems on a day to day basis. In the longer term, it should also result in an increase in our understanding of the sensitivity of these cloud systems to climate change and to changes in the emissions of manmade aerosol.

Presenting author email: d.chang@mpic.de

Clouds have great influence on the vertical redistribution of energy and moisture, and consequently have impacts on weather and climate change from regional to global scales. Biomass burning is an important factor that could affect deep convection in clouds, and within this work, we used the ATHAM (Active Tracer High Resolution Atmospheric Model) model to study the properties of pyro-convective clouds and precipitation in 2- and 3-dimensional simulations. The two-moment microphysical scheme of Seifert (2002), including the hydrometeor categories cloud water, rain water, cloud ice, snow, graupel and hail, was utilized to investigate the interaction between atmospheric aerosols and cloud microphysics. The Chisholm fire that occurred in Alberta, Canada, in May 2001 was used as a base case. By assuming typical aerosol concentration conditions, we calculated the cloud droplet number concentrations under different fire intensity conditions and evaluated the effects of aerosol concentration and fire intensity on the formation of precipitation. The simulation results showed different control regimes for cloud and precipitation formation, including an aerosol-limited regime, a fire intensity-limited regime and a transitional regime, which are consistent with the results from a recent parcel model study (Reutter *et al* 2009).

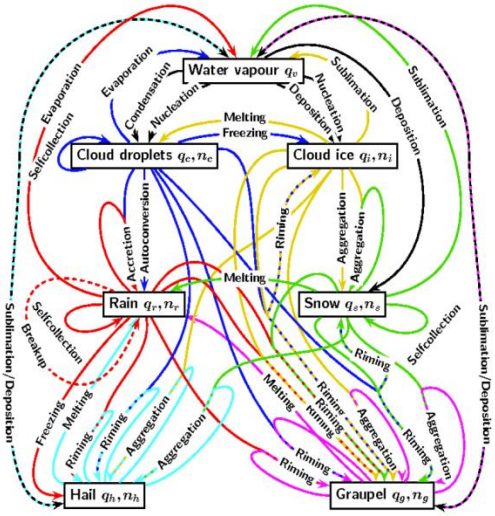

Figure 1. Simplified schematic diagram of the microphysical interactions in the two-moment Seifert scheme with respect to the particle classes cloud- and rain droplets, cloud ice, snow, graupel and hail.

The novel cloud particle spectrometer NIXE-CAPS consists of two different instruments, the CAS-DPOL and the CIP Grayscale. It can not only record particle number size distributions between 0.6 and 900 μm diameter, but also provides information on the particles phase -liquid (spherical) or ice (aspherical)- for every cloud particle. NIXE-CAPS is deployed at the cloud chamber AIDA during three campaigns where heterogeneous ice formation in mixed phase clouds was investigated -using mineral dusts, soot particles and bacteria as ice nuclei- in the wide temperature range of 220 - 275 K. Very recently, in February 2011, first airborne measurements onboard the BAe146 were performed in mixed phase clouds during the campaign COALESC out of Exeter, UK.

At the AIDA chamber, we found that in case of drop and ice coexistence conditions (see Fig. 1, middle panel, relative humidities over water RHw and ice RHi are both supersaturated), the heterogeneous freezing of the drops is dependent on the drop size. I.e. the larger drops are frozen, the smaller drops remain liquid and in between there is a size range where both drops and ice crystals coexits. This size range of drop and ice coexistance is found to decrease together with the temperature from 20-30 μm to 8-20 μm diameter.

In the case of Bergeron-Findeisen conditions (see Fig. 1, top panel, RHw $<$ 100%, RHi $\sim>$ 100%), the freezing of the drops is still size dependent as long as RHi$\sim$ 100%. Then, larger drops are frozen and the smaller the cloud particles are the more remain liquid. Only if RHi$>$ 100% the larger ice crystals ($>$ 20 μm) grow while all small liquid drops as well as ice crystals evaporate.

Preliminary results from the field campaign COALESC (see Fig. 1, bottom panel) confirm the size as well as the temperature dependence of the freezing process in the atmospheric clouds. In our first measurements we most frequently found the state where liquid and ice particles coexist instead of Bergeron-Findeisen conditions with quick complete glaciation. This is in in accordance with theoretical considerations of Korolev (2007), who proposed that the Bergeron-Findeisen process is only one possibile thermodynamic secenario in mixed phase clouds.

During the CLACE 2010 campaign performed at the High Altitude Research Station Jungfraujoch (Switzerland, 3580 m asl), an in-depth study of aerosol-cloud interactions was performed. The site is optimally suited for this purpose, as it lies in the free troposphere but is influenced by the continental air over Europe. In addition, the Jungfraujoch is about 40% of the time within clouds. The performed measurements allowed for the determination of the effective peak supersaturation in the prevailing ambient cloud which was responsible for the activation of aerosol particles to cloud droplets.

Activated fraction of the aerosol

Two examples of the diameter dependent aerosol activation to cloud droplets are given in Figure 1, showing data from the CLACE 2010 campaign (June – August 2010). These activation curves were determined by the simultaneous measurement of the total and interstitial (total aerosol minus cloud condensation nuclei) aerosol number size distribution. The upper panel shows an example of 50% activation of aerosol particles above 50 nm (critical activation diameter D_{50} = 50 nm), as indicated by an upper activation curve plateau very close to one. In other cases (lower panel) this plateau did not reach 1, indicating incomplete activation due to ice formation or entrainment. Further investigation of this phenomenon is subject to ongoing analysis. In addition, the critical activation diameter in the second example is higher (D_{50} = 80-100 nm).

Ambient peak supersaturation

The ambient peak supersaturations (SS_p) responsible for formation of the clouds observed at the Jungfraujoch were estimated using the activation cut-off diameter observed in clouds in combination with the relationship between supersaturation and critical diameter for CCN activation. The latter was taken from the 17-month CCN study at the Jungfraujoch by Juranyi et al. (2011). The statistical distribution of SS_p values observed during CLACE 2010 is shown in Figure 2. The peak supersaturation of the cloud droplets arriving at the Jungfraujoch showed a mean value of 0.31% and a median value of 0.23%. Ongoing data analysis attempts to establish a link between the retrieved peak supersaturations and other parameters like temperature, updraft velocity and weather situation (i.e., cloud type).

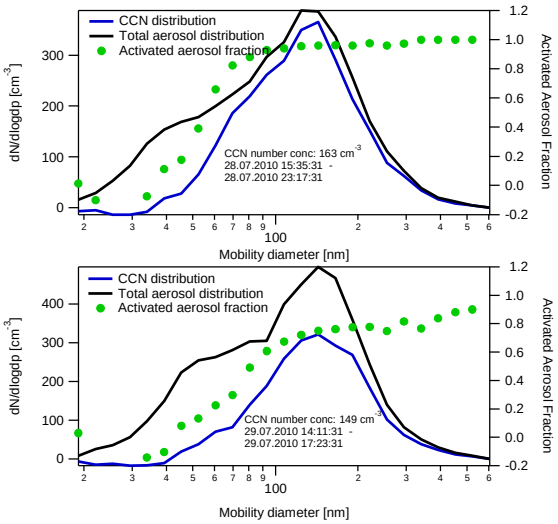

Figure 1: Two examples total and CCN number size distributions, along with the activated number fraction.

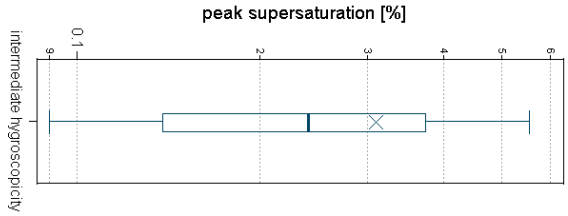

Figure 2: Box plot of the ambient peak supersaturations for stable clouds periods during CLACE 2010, using the annual mean aerosol hygroscopicity at the Jungfraujoch as determined by Jurányi et al. (2011). Box: first, second and third quartile; cross: average; whiskers: 5th and 95th percentile.

Indirect measurement of water vapour supersaturation ratios in continental boundary layer clouds using H-TDMA and DMPS data

E. O. Fors, B. Svenningsson, E. Swietlicki and M. Sporre

Lund University, Department of Physics, Division of Nuclear Physics, Lund, Sweden

The maximum water vapour supersaturation ratio (s_{max}) that is reached in a cloud formation event is an important parameter when it comes to quantifying anthropogenic influence on cloud parameters such as cloud lifetime, effective radius and precipitation patterns (Kaufman et al., 1997). s_{max} determines which particles will leave the equilibrium domain to start to grow unrestrained and form cloud droplets.

It has proven to be difficult to measure s_{max} in situ, and good statistics on s_{max} is scarce. The objective with this work is to present a new concept for estimation of s_{max} of continental boundary layer clouds, utilizing the fact that that the chemical and physical properties of a particle can change significantly from the time a particle enters a cloud and forms a cloud droplet to the time when it exits the cloud and dries out.

The ambient aerosol is most often externally mixed, and the hygroscopic growth factor probability density function (GF-PDF) can often be described by two Gaussian functions: one less hygroscopic (LH) and one more hygroscopic (MH) mode. When a particle is activated into a cloud droplet it tends to absorb water soluble gases such as SO_2, NH_3 and HNO_3, which in turn increases the particles hygroscopicity and effectively moves it from the LH to the MH mode. By investigating which particles are left in the LH mode, it is possible to investigate if the aerosol has been cloud processed, and to derive a possible s_{max}.

The new approach is based on hygroscopic growth data at subsaturation from a Hygroscopic Tandem Differential Mobility Analyser (H-TDMA) (Swietlicki et al., 2008) in combination with size distribution measurements from a Differential Mobility Particle Sizer (DMPS). Each dry size and hygroscopic growth factor is associated with a certain critical supersaturation, s_c. By combining the size distribution data with the LH mode from the H-TDMA, dN/ds_c distributions can be derived for the LH particles, which describe the distribution of LH particles with respect to their s_c values.

According to our hypothesis, if the aerosol has been cloud processed the LH mode will be scavenged on particles with s_c lower than the s_{max} during the cloud passage. In this work we have therefore defined s_{max} as the s_c where the dN/ds_c distribution reaches its half maximum value (Fig. 1).

The method was used on a data set covering more than 2 years from the Swedish background site Vavihill. It was found that the average s_{max} of the boundary layer clouds observed is around 0.15% and s_{max} ratios are very rarely above 0.3% (Fig 2). In all, we found a cloud signal during 30% of the time. Satellite data gave further support to the hypothesis, as no cloud signal from the dN/ds_c functions was associated with a higher fraction of clear skies.

We conclude that this method could be a useful tool in order to obtain a deeper knowledge on the supersaturation ratio in boundary layer clouds, as there are many data sets available which could use this approach.

To assess the sources of cloud active aerosol and their interaction with the hydrological cycle in California, the CalWater 2011 Experiment took place in winter 2011 in the foothills of the Sierra Nevada Mountains in Central California (at the Sugar Pine Reservoir, Placer County, CA; 1070 masl). Previous studies in the California Central Valley [*Chow et al.*, 2006] show that nitrates and organic matter comprise most of $PM_{2.5}$ (~70% of total mass); and the remaining 30% consists mostly of sulfates, elemental carbon and crustal material. Nitrates and sulfates are generally hygroscopic and increase the CCN activity. Rainfall data over the western part of the United States indicate a reduction in orographic precipitation downwind of urban centers [*Rosenfeld and Givati*, 2006]; hence, relating aerosol chemistry to CCN activity is vital for studying the anthropogenic influence on cloud development and precipitation.

During the CalWater Experiment, we coupled the capabilities of demonstrated miniaturized instrumentation – cloud condensation nuclei (CCN), water condensation nuclei (WCN) and microchip capillary electrophoresis (MCE) – to provide direct chemical measurements of cloud active aerosols. Ion concentrations of CCN droplets attribute the anthropogenic, marine and secondary organic contributions to cloud-active aerosols. The MCE system was also coupled to a WCN device to determine the mass fraction of soluble ions that serve as cloud-active nuclei. In addition to direct measurements of the CCN and aerosol chemistry, continuous CCN spectra (between 0.1 and 1% supersaturation, S_c), aerosol size distributions and concentrations were also measured.

CCN concentrations were low ($N_{CCN,0.4}$ < 100 cm^{-3} at 0.4% S_c) when high pressure systems prevented boundary layer development and intrusion of the Central Valley pollution to the site - suggesting relatively low aerosol sources of CCN from the surrounding forest during this period. Storm fronts and changes in atmospheric boundary layer brought aerosol and anions associated with Central Valley pollution to the field site with concentrations reaching several thousand cm^{-3}.

MCE results show that nitrates and sulfates comprise most of the fraction of the aerosol anion mass (PM_1). Nitrate concentrations were often low (0.5 $\mu g\ m^{-3}$) due to the frequent rains in February and March; however, regional sources did generate peaks of several $\mu g\ m^{-3}$ of nitrate during the passage of a storm front, which transported pollution from the Central Valley upslope. These results are in agreement with earlier filter-based measurements [*Chow et al.*, 2006]. Chloride was also an important component during precipitation events indicating contributions of marine sources as well.

CCN spectra show large variations depending on the aerosol sources and often exhibit bi-modal distributions with minima at 0.4% S_c -- similar to the so-called 'Hoppel minima' associated to number size distributions. During these bi-modal events, sulfate also increases supporting the addition of these anions during cloud processing [*Yu et al.*, 2005]. $N_{CCN,0.1}$ also coincide with increases in aerosol nitrate, which suggests that nitrate has a role in cloud formation as giant CCN and, furthermore, in precipitation processes in the Sierra Nevada.

This work was supported by the California Energy Commission under grant CEC 500-08-046.

Aerosol-cloud interactions as well as the chemical composition of particles were investigated during the field campaign Hill Cap Cloud Thuringia (HCCT) in September and October 2010 on a mountain site in Central Germany (Schmücke, 938 m a.s.l.). Orographic cloud residual particles were analysed by the Aircraft-based Laser Ablation Aerosol Mass Spectrometer (ALABAMA, particle size range 150 nm - 900 nm) (Brands *et al.*, 2011) behind a counterflow virtual impactor (CVI), which samples cloud droplets and subsequently evaporates the cloud water. Additionally the total background aerosol population was sampled through an interstitial inlet (INT, cut-off diameter 5 µm) before and after cloud events. Parallel to the ALABAMA the particle size distribution was measured by an optical particle counter (OPC) with a size range between 0.25 µm and 32 µm.

The ALABAMA allows the qualitative chemical analysis of submicron single aerosol particles by laser ablation with a time resolution of 70 ms. This method gives information about particle size as well as composition and consequently helps to distinguish between different particle types. Although being developed for aircraft-based measurements, the ALABAMA is also suitable for ground-based measurements.

About 200000 positive and negative single particle mass spectra were recorded during the field campaign. A comparison of the averaged mass spectra for activated (CVI) and total (INT) aerosol shows that cloud residual particles contain a higher fraction of nitrate-containing particles, but a lower fraction of organic particles than particles of the background aerosol (see Figure 1). Besides, the relative fraction of sulphate is smaller. For further analysis, the mass spectra are separated in clusters, representing a certain particle type, by different clustering algorithms e.g., k-means. The relative abundance of the clusters will be related to meteorological conditions as cloud events, wind direction or back trajectories.

The time series of the number concentration measured by ALABAMA and the OPC show a good correlation between the two instruments, whereas the size distributions have different maxima due to various detection limits and sizing methods. Further analysis of the size distributions of cloud residual particles respectively background aerosol particles in addition with the mass spectra gives a hint for answering the question whether particle size or composition is the determining factor for particles to act as cloud condensation nuclei (Dusek *et al.*, 2006).

The MUltiple CHamber Aerosol CHemical Aging Study (MUCHACHAS) was designed to study changes in total amount and properties of secondary organic aerosol (SOA) induced by exposure to OH radicals. A series of experiments took place at the Paul Scherrer Institute 27-m^3 chamber. Experiments began with the dark ozonolysis of α-pinene (AP) at low and high AP concentrations (10 and 40 ppb respectively). After the precursors were consumed, and mass levels were stable, OH exposure of the gas and aerosol products was initiated. Several methods of OH exposure were used including HONO photolysis and dark OH generation from the ozonolysis of tetramethylethene (TME). OH generation via HONO photolysis experiments were conducted at both high and low NO_x levels.

Gas and aerosol phase evolution was monitored with standard instrumentation including Proton Transfer Reaction Mass Spectrometry (PTRMS), Ion Chromatography Mass Spectrometry (IC-MS), High Resolution Time-of-Flight Aerosol Mass Spectrometry (AMS), and a Volatility/Hygroscopicity Tandem Differential Mobility analyzer (V/H-TDMA).

Results

In most experiments we observed a sometimes slow, but steady evolution in hygroscopicity, volatility and AMS signature of α-pinene SOA, which appeared to be independent of exposure to ozone and OH. We hypothesize that this "ripening" is caused by relatively slow transformations of the condensed phase which do not influence the SOA mass concentrations but do influence intensive physical and chemical properties such as volume fraction remaining (VFR), hygroscopicity and the atomic oxygen to carbon ratio (O:C).

Based on this observation we distinguished four phases in our reaction sequence as shown in Figure 1: O_3 mediated condensation and O_3 mediated ripening during ozonolysis and OH mediated condensation and OH mediated ripening during OH exposure. The first phases of ozonolysis and OH exposure are dominated by the impact of condensation on the aerosols physical and chemical properties. During the O_3 mediated condensation the particles volatility decreased (increasing VFR) while the hygroscopicity increased. After exposing the SOA to OH radicals an OH mediated condensation started with a significant increase of SOA mass and a concurrent increase of hygroscopicity and volatility.

The O_3 mediated ripening as well as the OH mediated ripening phases were characterized by a continued decrease of the volatility. While the ozonolysis only experiments showed little change in the O:C atomic ratio as measured by the AMS after the precursor was consumed (O_3 mediated ripening), OH exposure of the aerosol showed a much larger increase in this ratio during OH mediated condensation and ripening.

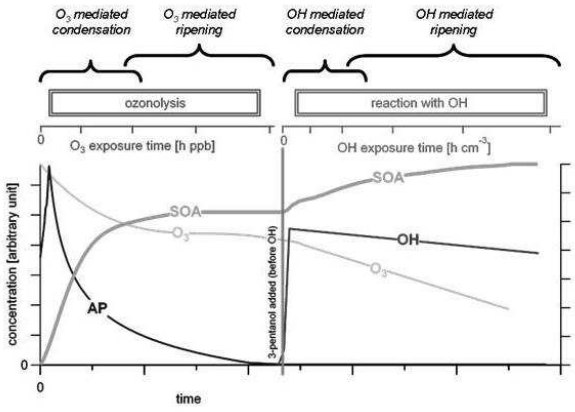

Figure 1. Four phases of transformations of secondary organic aerosol (SOA) from α-pinene (AP) as observed during ozonolysis and OH exposure.

The ripening effect may occur either by heterogeneous reactions on the surface of the SOA particles, by homogeneous reactions like oligomerization or by an evaporation – gas phase oxidation – recondensation cycle. Evidence for either of these mechanisms will be presented and discussed.

Particulate matter (PM) is one of the most important environmental health concerns worldwide. Of special concern are the submicron particulate emissions from combustion sources, because they deposit into the tracheobronchial and alveolar regions of the respiratory tract and can even penetrate through the lung tissue and reach the capillary blood vessel and circulating cells. It is noteworthy that the current data are based on the assumption that all fine particles have identical composition and health effects. However, this is not the case according to recent toxicological studies which show that the toxic potential of PM depends on aerosol size, concentration, chemistry and morphology (e.g., Paur *et al.*, 2008).

In the atmosphere the physical and chemical properties of the emission change considerably, e.g., due to photochemical reactions in the daytime and oxidation reactions in the nighttimes, as seen in a previous study with an aging diesel exhaust in an environmental chamber (Leskinen *et al.*, 2007). The aging may alter the health related toxicological responses of the emission, as discussed by Jalava *et al.* (2007). However, there is only limited scientific data pointing out which are the actual components of the emissions – both fresh and aged – that are linked to the toxicological responses. Thus, more experiments combining the aging and the toxicological studies in controlled laboratory conditions are needed.

A new experimental set-up (Figure 1) at the University of Eastern Finland (UEF) in Kuopio, introduced in mid-2011, enables on-line exposure of cells to aerosols and analysis of related toxicological health impacts. The set-up consists of 1) different biomass-fired combustion appliances, 2) a diesel engine test bench constructed according to the ISO 8178 standard and equipped with a 30 kW eddy current dynamometer system which is capable of producing a 90 Nm torque and 14000 rpm speed (later in 2011, a chassis dynamometer designed for testing vehicles in low-to-medium performance class (Max 350 kW, 2000 Nm, 350 km/h) will be installed for vehicle emission studies), 3) different types of dilutors (ejector dilutors, porous tube dilutors, a dilution tunnel), 4) a transformation chamber made of 125 µm FEP Teflon and 30 m^3 of volume, 5) an air-liquid cell exposure unit (Vitrocell®), and 6) several instruments for measuring the physical and chemical characteristics of the emission. All parts of the set-up are located in the same experimental hall, which minimizes sampling losses and artefacts between the different parts.

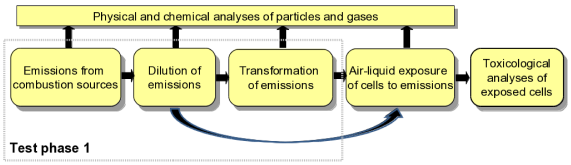

Figure 1. The new set-up at UEF that enables on-line exposure to fresh and aged combustion aerosols. (The first test phase is bounded by the gray rectangle.)

In the first test phase the deposition rate of monodisperse test aerosol particles onto the chamber walls will be determined by size distribution and number concentration measurements and model calculations. The secondary organic aerosol formation potential of diluted diesel engine emissions will be determined in the chamber both in the presence of UV light (350 nm) and in the dark, both with and without an OH (hydroxyl radical) scavenger, and with and without additional ozone and/or reactive organics. We will use the same diesel engine and test cell parameters as in our recent studies (Jalava *et al.*, 2010). The time evolution of the physical and chemical characteristics of the diesel emission and the secondary organic aerosol yield with different initial parameters will be used to estimate an adequate dose to the cells in the exposure unit.

The infrastructure has been partially supported by the European Regional Development Fund (ERDF), and the research by Tekes (the Finnish Funding Agency for Technology and Innovation).

Presenting author email: Erik.Nordin@design.lth.se

Formation of Secondary Organic Aerosol (SOA) in the atmosphere is of importance both from a climate and health point of view. Photo-oxidation of aromatic Volatile Organic Compounds (VOCs) such as Toluene and Xylene (TX) gives contribution to SOA formation in the atmosphere. Anthropogenic combustion sources such as light duty traffic contribute to emissions of light aromatics in the atmosphere. Vehicles operating on idling or cold starts have particularly high VOC emissions since the oxidation catalyst has yet to reach its operation temperature. The mass yield (the ratio between formed SOA and reacted light hydrocarbons) and the chemical composition of the formed aerosol are important parameters for understanding the mechanisms of SOA formation. The aim of this work is to improve the knowledge about light aromatics contribution to SOA formation, by examining and comparing the chemical composition and mass yields from idling gasoline exhaust and pure precursors.

The experiments were performed in a 6 m^3 Teflon (FEP) smog chamber, housed in a temperature controlled (22±1°C) 22 m^3 steel chamber. Black lights (intensity peak~350 nm) are used to initiate photochemistry; the NO_2-photolysis rate is 0.23 min^{-1}. Gasoline exhaust was injected via a heated ejector dilutor and heated inlet (120 °C). The vehicle used in the experiments was a Volvo V40 (118 kW) (1998). A relevant operating mode with sufficient emission reproducibility was identified and used. It involved a cold start and driving until engine cooler water temperature of 55°C was achieved. Emitted aerosol was then sampled to the smog chamber for 5-10 min. Nebulized ammonium sulfate was utilized as condensation seeds in all experiments. In the precursor experiment mixtures, three of the most abundant light aromatics in the exhaust (Toluene, m-Xylene and 1.2.4-Trimethylbenzene) were injected through evaporation to the smog chamber. The experiments were monitored by particle characterization instruments such as, High Resolution-Time of Flight Aerosol Mass Spectrometer (HR-ToF AMS) and Aerosol Particle Mass Analyzer (APM). Proton Transfer Reaction Mass Spectrometer (PTR-MS) and complementary GC-MS analysis was used for VOC-monitoring. The mass concentration of formed SOA was corrected for wall losses using the method by (Hildebrandt *et al.*, 2009).

Preliminary results from three gasoline and two pure precursor experiments are shown in Table 1. The reacted VOC concentration is calculated from the C_6-C_{10} data from PTR-MS. This can be used for mass yield calculations, given the assumption that C_6-C_{10} are the only SOA forming precursors. The fraction of organic signal at (m/z) 43, 44 (f43, f44) is derived from unity mass resolved AMS-data.

Table 1. Preliminary results from the campaign.

Exhaust/ Precursor	Initial VOC to NO - ratio	Reacted VOCs (µg/m^3)	Wall loss corrected SOA (µg/m^3)	f(43) f(44)
Gasoline	8.8	148	26	0.105 0.115
Gasoline	6.4	246	66	0.084 0.123
Gasoline	21.7	114	29	0.073 0.136
T + m-X	16.7	782	412	0.138 0.121
T + m-X +1.2.4-TMB	5.8	473	64	0.178 0.092

As shown in Table 1 the ratio between formed SOA and reacted light hydrocarbons for gasoline exhaust is higher than the ratio for pure precursors (for similar mass loadings), which indicates that a major part of the SOA in the gasoline experiments is formed from light aromatic hydrocarbons. The SOA formed in the gasoline experiments contains more highly oxidized material than the SOA from pure precursors. The gasoline exhaust but not the pure precursor experiments fit well with a recent compilation of AMS spectral features from atmospheric oxygenated organic aerosol (OOA) observations (Ng *et al.*, 2010). This suggests that pure precursor experiments do not recapture all of the complexity in the detailed SOA composition from idling gasoline exhaust.

Vehicles are a major source of particulate matter (PM) in urban areas (EEA, 2006). PM has significant, sometimes lethal, health effects. A large fraction, 20-90%, of the total PM consists of organic aerosol (OA) (Jimenez *et al.,* 2009). OA may be classified as primary (POA), from direct emissions, or secondary (SOA), formed via gas-phase reactions. These reactions also involve semivolatile compounds partitioned between the particle and the gas phase and remain poorly understood. Mopeds are a popular means of transport in many countries, particularly in Southern Europe and in East and South Asia. Many mopeds on the road today have two-stroke (2-S) engines, known emitters of uncombusted fuel and lubricating oil, and may therefore contribute significantly to both POA and SOA in urban areas. Characterisation of POA and SOA emissions from mopeds is therefore required to understand their health impact and to design effective future vehicle pollution regulations.

Emissions factors (EF) (g OA kg^{-1} fuel), of POA and SOA were determined during smog chamber experiments, at the Paul Scherrer Institute (PSI), Switzerland, for a EURO 1 2-S moped, a EURO 2 2-S moped and a EURO 2 4-S moped. Moped exhaust was introduced into the chamber via a heated injection system and ejector diluter. Fourier-transform infra-red (FTIR) spectroscopy of the undiluted exhaust during injection was used to quantify the emissions of CO, CO_2, and gaseous hydrocarbons. An Aerodyne high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) was used to quantify OA in the smog chamber. Proton transfer reaction mass spectrometry (PTRMS) was used to determine the concentrations of volatile organic compounds. Measurements of total hydrocarbon, CO, O_3, and NO_X concentrations were also performed. SOA formation in the chamber was initiated using UV lights. Figure 1 shows a time series of a typical experiment where both the measured and wall loss corrected (WLC) OA concentrations rapidly increase after the UV lights are switched on.

Moped POA EFs determined from the OA concentrations in the smog chamber were comparable to those calculated in previous chassis dynamometer studies at the Joint Research Center (JRC), Ispra, Italy. Moped EFs determined at both JRC and PSI are several orders of magnitude higher than those of other vehicle classes, including diesel and gasoline cars and heavy duty vehicles. Furthermore, these emissions contain large quantities of unreacted hydrocarbons, reflected by the fact that SOA comprised the main fraction of the OA after only a few hours. This is further illustrated by Figure 1, which shows that a large fraction of toluene and total hydrocarbons remain unreacted. We note therefore that the SOA EFs from this study represent only lower estimates of the total possible SOA emissions. We conclude that emission of OA by mopeds may be a major public health consideration in many urban areas.

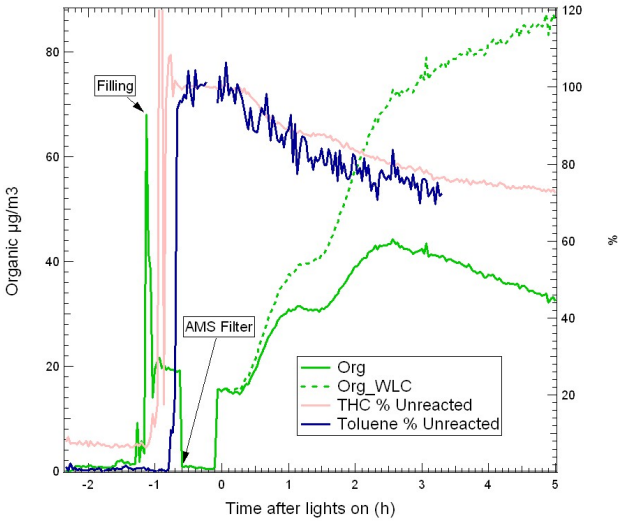

Figure 1: Time series from a smog chamber experiment on moped exhaust showing the evolution of organic aerosol concentrations together with the percentage of unreacted total hydrocarbons and toluene. The second observed increase in OA is due to the addition of NO to the smog chamber.

Microscopic fungi as significant sesquiterpene emission sources

E.Horváth[1], A. Hoffer[1], F. Sebők[2], Cs. Dobolyi[3], S. Szoboszlay[2], B. Kriszt[2], A. Gelencsér[1]

[3]University Centre of Excellence in Environmental Industry Based on Natural Resources, Gödöllő, H-2103, Hungary

Keywords**:** emissions, secondary organic aerosols, microscopic fungi, sesquiterpene
Presenting author email: horvathe@almos.vein.hu

The group of sesquiterpenes, an important fraction of volatile organic compounds (VOCs) emitted by vegetation participates in the formation and growth of secondary organic aerosol (SOA) thereby directly and indirectly affecting the Earth's radiation balance. Although gas and particulate phase atmospheric reactions and gas-to-particle partitioning have been studied extensively, important sources of SOA precursors remain poorly characterized.

Among the volatile organic compounds emitted by vegetation isoprene, monoterpenes, sesquiterpenes and their derivatives are thought to contribute most to secondary organic aerosol formation. Sesquiterpenes (SQTs) are considered to be the most important biogenic SOA precursors in the atmosphere among the several hundreds of volatile organic compounds emitted by the vegetation (Griffin *et al.*, 1999). They are generally extremely reactive in the atmosphere, and their SOA yields have been determined to be significantly higher than those of monoterpenes (Baker and Sinnott, 2009). Due to their very high reactivity emission flux measurements of SQTs are loaded with very high uncertainties. Despite the high uncertainties in BVOC (biogenic volatile organic compounds) emission measurements global VOC inventories consider plant emissions as exclusive source of SOA precursors (Guenther *et al*, 1995).

Although it is well known that microscopic fungi globally turn over a vast amount of carbon by decomposing the organic matter in the soil, various atmospheric models do not yet include emission of secondary metabolites from soil fungal communities.

Detection of fungal volatiles can be used for fingerprinting fungal infection in agricultural commodities especially in grains and in indoor environment in order to prevent the decrease of nutritional value of agricultural commodities and the occurrence of allergy related illnesses (Moularat, 2008). In indoor and agricultural studies sesquiterpenes have been identified as secondary metabolites emitted by fungi (Fiedler, 2001).

In the present study we investigated the extent of sesquiterpene emission of microscopic fungi to establish its significance in secondary organic aerosol formation. To sample the headspace of pure cultures of some common microscopic fungi we used an aseptic flow-through apparatus designed for solid phase microextraction in our laboratory. The experimental system is shown in Figure 1.

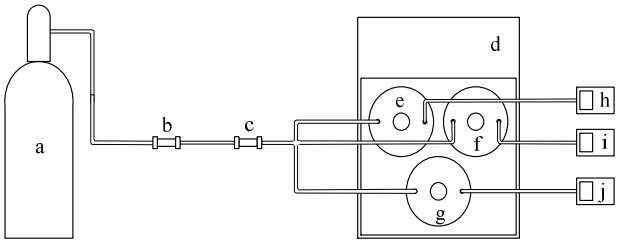

Figure 1. Scheme of the developed flow-through apparatus.
a: compressed air, b: activated carbon filter, c: HEPA filter, d: thermostat, e-f-g: sampling vials, h-i-j: portable carbon-dioxide monitor

The identified sesquiterpenes in the headspace extracts were quantified for eight strains of microscopic fungi belonging to four different genera.

Our results showed that microscopic fungi emit considerable amounts of sesquiterpenes. Based on our estimations microscopic fungi in soil can be considered as potentially significant sesquiterpene emission sources whose contribution to the secondary organic aerosol formation may be globally comparable to that of the vegetation.

Keywords: SOA, indoor/outdoor aerosols, smog chamber, gas-particle distribution, chemical composition
Presenting author email: stephanie.rossignol@ineris.fr

Among the biogenic species, limonene is one of the most abundant terpenes emitted at the global scale, with α and β-pinene, and has one of the highest Secondary Organic Aerosols (SOA) formation potential. Thus Limonene plays an important role in atmospheric chemistry and has potential important climate and health impacts (VanReken, 2005).

Furthermore, limonene is also widely employed in scented products used in indoor environments, such as fresheners or household cleaners. As indoor ozone concentration, influenced by outdoor concentration and domestic sources, can be quite high, this oxidant can attack limonene to initiate gas phase chemistry and possibly lead to SOA formation (Coleman, 2008).

This work investigates the formation of SOA from limonene ozonolysis with a focus on indoor conditions. It combines simulation chamber ozonolysis experiments and field studies in an experimental house allowing reproduction of real conditions for household products use situations.

In order to describe multiphase chemistry involved in SOA formation and to take into account gas/particle partitioning phenomena, a new analytical approach is employed. Both gas and particulate phases are simultaneously collected, respectively on sorbent tubes and filters, and molecular composition is investigated using PFBHA and MTBSTFA derivatization prior to thermal-desorption coupled with gas chromatography and mass spectrometry (TD-GC-MS) analyse.

For each experiment, chemical data are coupled with physical characterisation of formed particles: mass evolution and size and number distribution evolution.

Simulation chamber experiments

Simulation chamber experiments were performed at the EUPHORE chamber (Figure 1, Valencia, Spain) in close to reality conditions: ozone and limonene concentration around 100 ppb, presence of seeds (ammonium sulphate) and humidity close to 50 %. In average, 75 $\mu g.m^{-3}$ of SOA were formed in these experiments.

Chemical characterisation of both gas and particulate phases allowed identification of limonene ozonolysis tracers, such as limononaldehyde or limonaketone, and evaluation of gas/particle partitioning of these species for a better understanding of physico-chemical mechanisms and processes involved in limonene SOA formation.

Figure 1: EUPHORE European atmospheric simulation chamber (left) and MARIA experimental house (right)

Field campaign

A field campaign was achieved in the experimental house MARIA (Figure 1, CSTB, Marne-la-Vallée, France), which is especially designed for indoor air quality studies. It is equipped as a real domestic home. Experiments were performed following scenario of limonene containing household product use in realistic conditions. Particles formation and growth was observed consequently to the use of house cleaning product. This formation could be attributed to the ozonolysis of the so emitted limonene.

Collected data on chemical composition of both phases and gas/particle partitioning of oxygenated species are coupled with data from simulation chamber experiment in order to evaluate the potential of limonene ozonolysis to form SOA in indoor environments under realistic user conditions. Thus this study provides an insight into particle exposure in a real indoor atmosphere.

Acknowledgments: M. Nicolas (CSTB, Marne-la-Vallée, France) for organizing field campaign in MARIA. The authors want to thank EuroChamp-2 for providing access to the Euphore Chamber and ADEME for the funding of the Primequal-ADOQ program.

[2] German Biomass Research Centre, Torgauer Str. 116, D - 04347 Leipzig
Presenting author email: wuzhijun@tropos.de

Combustion of biomass is known to be a major source of gas- and particle- phase air pollution in the atmosphere and to be mainly made of a complex mixture of organics. To date, however, the atmospheric behaviours of these mixtures and their health effects are still largely unknown.

In this study, aging processes of different types of wood burning aerosols (see Table 1) are investigated. The wood burning aerosols are introduced into the IfT LEAK chamber (19 m^3, Iinuma et al. 2004) with and without ozone and /or UV lights simulating day- and night- times. Several online instruments including a Hygroscopic Tandem Differential Mobility Analyzer (H-TDMA), a Volatility Tandem Differential Mobility Analyzer (V-TDMA), a Multi-Angle Absorption Photometer (MAAP), a Scanning Mobility Particle Sizer (SMPS), and an Aerosol Mass Spectrometer (AMS) were used to measure the changes of physical and chemical properties of aerosols. In parallel to the physico-chemical study, modifications of the aerosols toxicity during the aging process were also investigated.

Table 1: Wood species and stoves

Wood	Stove
Spruce log	downdraught stove
Beech log	downdraught stove
WoodPellet	Pellet oven firing

In this abstract, the modifications in volatility and hygroscopicity of spruce burning aerosols via photochemical aging are presented as an example. Fig. 1 shows the comparisons of particle number size distributions before and after turning on the UV-lights. Fig. 2 and 3 display the temporal evolution of growth factor and shrink factor for different size particles, respectively. The growth factor is defined as the ratio of the wet particle mobility diameter D at RH=90% to dry diameter D0. The shrink factor is defined as the ratio of the particle diameter at a certain temperature (here, 120 and 300 °C) to the diameter at room temperature (25 °C).

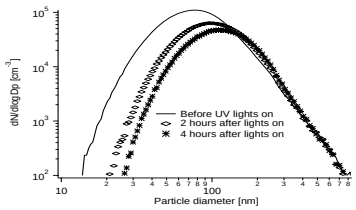

Fig. 1: Particle number size distribution

Before the UV-lights on, the growth factors for 50, 75, and 100 nm particles are within 1.3-1.4, and only 1.1 for 200 nm particles. This indicates that smaller particles are dominated by hydrophilic components, such as inorganic salts, while, larger particles are dominated by hydrophobic fraction, such as soot. After lights on, the growth factors of smaller particles decrease with time consuming. This means that more low hygroscopic organic species produced or condensed on the particles during aging process. But, no any changes in 200 nm particles were observed.

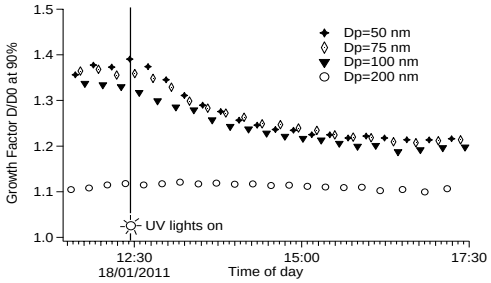

Fig. 2: Temporal evolution of hygroscopic growth

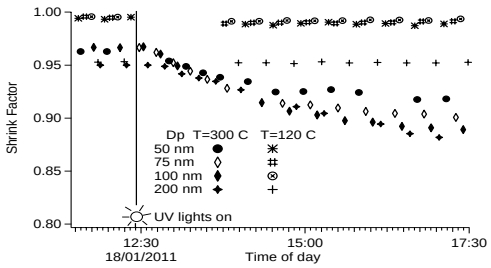

Fig. 3: Temporal evolution of volatility

At 120 °C, there is no any difference in shrink factor before and after UV-lights on, indicating that no high-volatile components, such as low carbon-number carboxylic acids, produced during chemical aging. At 300 °C, the particles freshly emitted with diameter of 50, 75, and 100 nm are non-volatile. After lights on, the aerosols are more volatile in contrast to primary particles. A detail study on the modifications in hygroscopicity and volatility of wood burning aerosols will be performed by combining the AMS data and filter measurements in the future work.

Session 5D: Aerosols in Disease and Therapy

Large particle aerosols of pathogens within high level microbiological containment

R.J. Thomas[1]

[1]Biomedical Sciences, Dstl Porton Down, Salisbury, Wiltshire, SP4 0JQ, UK
Keywords: aerosol, respiratory, deposition, pathogens.
Presenting author email: rjthomas@dstl.gov.uk

The capability to generate large particle aerosols within high level microbiological containment was developed to enable investigation of differential deposition of small and large particle aerosols of *Bacillus anthracis*, *Yersinia pestis*, and *Burkholderia pseudomallei* on the pathogenesis of infection in the murine model.

The Collison nebuliser or flow-focussing aerosol generator (FFAG) was used to generate small and large particle aerosols respectively (Thomas *et al* 2009a). The aerosol distributions were characterised with respect to mass median aerodynamic diameters (MMAD), particulate distribution within droplets (spores and vegetative cells) and deposition within the murine respiratory tract. The FFAG had the capability to generate particle distribution with a MMAD up to 100 µm. Particulate concentration within individual particles increased as particle size increased (Table 1).

Table 1. Effect of increased particle size on the numbers of incorporated particulates

	Avg no. fluospheres per droplet		
Droplet size fraction (µm)[b]	MMAD 12 µm (±SE)[c]	MMAD 25 µm (±SE)[c]	MMAD 50 µm (±SE)[c]
0–3	0.42 ± 0.04	0.44 ± 0.03	0.36 ± 0.04
4–9	2.76 ± 0.18	8.80 ± 0.97	4.45 ± 0.46
10–17	7.54 ± 0.35	11.94 ± 0.73	12.25 ± 3.64
18–23	13.62 ± 0.69	16.49 ± 0.73	23.80 ± 3.95
24–30	0.00 ± 0.00	25.93 ± 1.47	29.33 ± 5.04
31–50	0.00 ± 0.00	47.00 ± 5.8	40.36 ± 0.97
51–75	0.00 ± 0.00	0.00 ± 0	80.38 ± 6.04
76+	0.00 ± 0.00	0.00 ± 0	186.6 ± 19.3

Aerosol distributions with MMADs of 1 and 12 µm produced by the Collison nebuliser and FFAG respectively were used to assess infection kinetics. Differential deposition was observed in the murine respiratory tract for each pathogen dependent on the size of the inhaled aerosol particles. Significantly greater deposition in the lungs was observed for the 1-3 µm particle aerosol produced by the Collison nebuliser compared to the nasal passages for all bacterial species investigated. In contrast, the bacteria incorporated within the 12 µm particle aerosol preferentially deposited in the nasal passages.

The differences in deposition profiles manifested as differences in infection kinetics. The median lethal dose and mean time to death were significantly greater for those animals that inhaled 12 µm particles (Table 2). The infection caused by inhalation of the 1-3 µm particle aerosols initiated in the alveoli or local lung lymph nodes before dissemination to visceral organs via the bloodstream. Although, the infections caused by inhalation of large particle aerosols initiated in the nasal cavity, subtle differences in progression of pathology and infected tissues were observed between the pathogens investigated (Thomas *et al* 2009b; Thomas *et al* 2010). Ultimately, the terminal stage involved dissemination via the bloodstream to visceral organs.

Table 2. Effect of particle size on infection kinetics in murine inhalational models. cfu = colony forming unit

Particle size	Median lethal dose (cfu)		Mean time to death (h)	
	1 µm	12 µm	1 µm	12 µm
Bacillus anthracis	2432	7656	101.6 ± 10.4	161.0 ± 16.1
Yersinia pestis	601	2951	72.0 ± 0	90 ± 11.5
Burkholderia pseudomallei	4	12	73.8 ± 11.3	174.7 ± 14.9

For the first time, assessments were made of the efficacy of therapeutics against both small and large particle inhalational infections of *B. anthracis*, *Y. pestis* and *B. pseudomallei*.

Conclusion: Aerosol particle size affects the site of deposition within the murine respiratory tract and influences disease progression. Ultimately, therapeutics must be geared towards providing protection against the complete spectrum of infections that may result from an inhalational challenge.

Anthrax Aerosols and Drums

A.M. Bennett[1],T. Pottage [1] and S. Parks[1]

[1]Microbiology Services Division, Health Protection Agency, Porton Down, Wiltshire, SP4 0JG, UK

Keywords: Bioaerosols, Health aspects of aerosols, Aerosol generation.
Presenting author email: allan.bennett@hpa.org.uk

Bacillus anthracis is a spore forming micro-organism that is the causative agent of anthrax. Anthrax has three main forms of infection: cutaneous, ingestional and inhalational. The latter is commonly fatal if untreated. In recent years, there have been two fatal cases of inhalational anthrax in the UK associated with African drums which were investigated by the Health Protection Agency (Riley 2007, Anaraki et al 2008). Other cases have also been identified in the US (Centers for Disease Control and Prevention 2000). In all these cases drums and skins have been recovered which have been shown to be contaminated with *B. anthracis* spores. The hypothesised route of infection in these cases was through the generation of an inhalable aerosol through either playing or manufacturing drums made from contaminated goatskins.

In order to investigate this route of infection a study was designed in order to measure the generation of microbial aerosols from artificially contaminated drums during playing and to measure the surface contamination of the drum over time.

Two drums were obtained for this study (Figure 1). The first drum was a small bongo was a holiday souvenir from West Africa, provided by a colleague. This drum had not been shaved. The second drum was a Djembe donated by a drum maker associated with one of the fatal cases. This drum had a shaved surface. Both drums were contaminated with spores of *Bacillus atrophaeus*, a commonly used surrogate of *B. anthracis*, generated from a DeVilbis No 40 nebuliser held close to the surface.. After drying, and at regular intervals over a period of three months, swab samples were taken of 1 cm^2 areas of the drum surface and assayed on TSA plates to measure the surface contamination on the drum.

Figures 1. Bongo Drum (left) and Djembe used in study.

The drums were placed in a 0.85m^3 volume safety cabinet with the following three microbial air samples: an Andersen 6-stage sampler (A6S), a Porton All glass Impinger (AGI) and a Casella slit sampler (CSS). Sampling was undertaken for 5 minutes period during which the drums were played for the initial two minutes. Results were expressed as percentage of total measured surface contamination aerosolised.

It was found that the surface contamination of the Bongo reduced by less than one log over the three month period in which it was played on 9 occasions while the contamination on the Djembe dropped nearly 2 logs during this time period when it was played 8 times.

The average % aerosol generated as percentage of surface contamination from the Djembe drumming was 0.010 measured by the A6S, 0.20 from the AGI and 9 x 10^{-3} from the CSS. The average particle size (A6S) was 1.9 microns. The Djembe results were 3.4 x 10^{-3} (A6S), 7.3 x 10^{-3}(AGI) and 3.1 x 10^{-3}(CSS) with an average particle size of 8.2 microns.

Since the magnitude of surface contamination found on drums associated with the cases of inhalational anthrax were far lower than those used in these experiments it would appear that the generation of anthrax aerosols from naturally contaminated drums would only occur sporadically at a very low level. Since the inhalational dose of anthrax is postulated to be in the range 8,000-10,000 spores it appears that these cases maybe due to the coincidence of a sporadic aerosolisation event with a highly susceptible individual.

Session 5E: Health Effects of Nanoparticles

Antibacterial activity by nanosilver ions and particles

G. A. Sotiriou and S. E. Pratsinis

Particle Technology Laboratory, Institute of Process Engineering, Department of Mechanical and Process Engineering, ETH Zurich, Sonneggstrasse 3, CH-8092, Zurich, Switzerland
Keywords: silver nanoparticles, antibacterial activity, *E. coli*, surface area concentration.
Presenting author email: sotiriou@ptl.mavt.ethz.ch

Nanosilver is used in heterogeneous catalysis and has promising applications in textiles[1], biomedical applications, biodegradable polymer films for food packaging[2], biological labeling, photonics, coloristic (plasmon)[3], optoelectronics and surface enhanced Raman scattering (SERS)[4]. At the same time, the use of nanosilver raises concerns for its toxicity against aquatic micro-organisms when disposed and therefore draws public attention[5]. In fact, nanosilver is one of the first nanomaterials to be regarded toxic and petitions had been filed to the U. S. Environmental Protection Agency (EPA) to regulate it as pesticide[6]. Therefore to safely employ nanosilver, correct risk and dose relations assessments need to be made.

There are several studies on the antibacterial activity of nanosilver made by wet-methods[7,8], co-condensation[9], electro-exploding wire[10] and flame spray pyrolysis[11,12]. Smaller nanosilver particles are more toxic than larger ones[8] especially when oxidized[8,11]. Additionally, even though silver metal is practically insoluble in water[13], when present in nanometer size range Ag^+ ions are released (leached)[11,14,15] from its surface. It has been shown recently[12] that the antibacterial activity of small (<10 nm) nanosilver particles is dominated by Ag^+ ions, while for larger ones (>15 nm) the antibacterial contribution by Ag^+ ions and particles is comparable. Such a behavior implies a surface area dependency of the antibacterial activity especially for small nanosilver sizes since the Ag^+ ion release is proportional to the exposed nanosilver surface area[12]. Additionally, when a nanothin silica coating on the surface of nanosilver is applied, this antibacterial activity can be minimized[16].

Here, the antibacterial activity of nanosilver against Gram negative *Escherichia coli* bacteria is investigated by immobilizing nanosilver on nanostructured silica particles and closely controlling Ag content and size. These Ag/SiO_2 nanoparticles were characterized by S/TEM, EDX spectroscopy, X-ray diffraction and, most notably, the exposed Ag surface area was measured by O_2 chemisorption. Furthermore, the fraction of dissolved nanosilver was determined by measuring the released (leached) Ag^+ ion concentration in aqueous suspensions of such Ag/SiO_2 particles. The antibacterial effect of Ag^+ ions was distinguished from that of nanosilver particles by monitoring the growth of *E. coli* populations in the presence and absence of Ag/SiO_2 particles. The antibacterial activity of nanosilver was dominated by Ag^+ ions when fine Ag nanoparticles (less than about 10 nm in average diameter) were employed that release high concentrations of Ag^+ ions. In contrast, when relatively larger Ag nanoparticles were used, the concentration of the released Ag^+ ions was lower. Then the antibacterial activity of the released Ag^+ ions and nanosilver particles was comparable.

Financial support by the Swiss National Science Foundation (No. 200020-126694) is kindly acknowledged.

Keywords: engineered nanoparticles, hygroscopic growth, adsorption

The first wetting layer of solid nanoparticles matters. Engineered nanoparticles can be exposed to water vapor in industrial processes, technological applications, and in the atmosphere. Water vapor produces films on the surface of the nanoparticles with a thickness that is determined by the relative humidity and interaction forces between the surface and the adsorbed water molecules (Thiel 1987). Recently, much attention has been paid to the impacts of atmospheric nanoparticles on cloud formation and climate (Laaksonen et al., 2004). Here we want to pay attention to understanding the environmental and climate impacts of directly emitted engineered nanoparticles. That question is highly topical and an early-stage evaluation of engineered nanoparticle exposure to the atmosphere, water and soil has been made (Mueller and Nowack, 2008).

The nanoaerosol is generated from aqueous silica suspension by an atomizer (TSI, 3076). Hygroscopic growth is measured using the nano-H-TDMA (Hygroscopicity Tandem Differential Mobility Analyzer). The size and density of size-selected nanoparticles are studied with the scanning mobility particle sizer (SMPS) and a DMA coupled with electrical low pressure impactor (ELPI). Particle morphology is studied using off-line electron microscopy analysis. The experimental results from water uptake are compared to the adsorption isotherm FHH-theory.

We observed that the smallest detected particles (selected mobility diameter of 8 or 10 nm) were spherical with the silica bulk density (2.2. g cm^{-3}) (Figure 1a) and larger particles were agglomerated (Figure 2b). The effective density of these particles decreased with size, from 1.7 g cm^{-3} at the smallest measured diameters (20 nm) to 0.8 g cm^{-3} at 150 nm (Figure 1c). From Figure 2 we see that a few (2-3) adsorbed water layers in these subsaturated conditions (RH from 50 to 90 %) were observed for the smallest size-selected particles (8- 10 nm). These observations agreed also well with fitted FHH isotherm. However, slightly larger nanoparticles at 15 and 20 nm in diameter had higher amounts of adsorbed water (Figure 2). Particles at this size range could include dense agglomerates with a few primary particles, whereby water adsorption is enhanced by the capillary effect. These adsorbed water layers can have consequential affect on the uptake of water soluble substances on these nanoparticles in atmosphere as well in their post-processing in engineered applications.

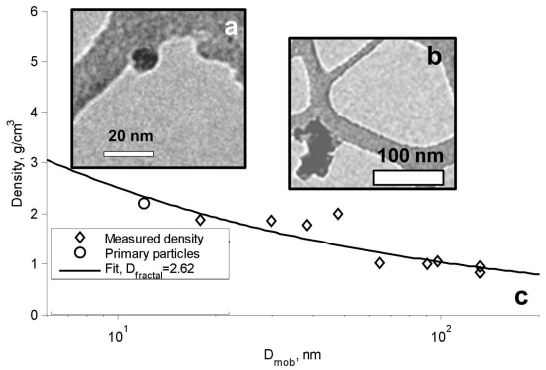

Figure 1 (a) TEM images of smaller spherical and (b) larger agglomerated fumed SiO2 nanoparticles. (c) Measured effective density versus particle size of atomized SiO2 nanoparticles and fitted density profile with Df= 2.62 (solid line).

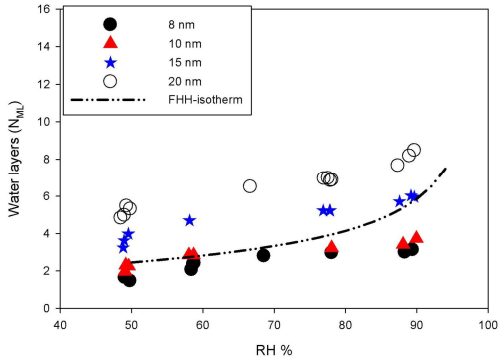

Figure 2 Number of the water layers versus RH at selected dry particle diameters for atomized fumed SiO2 and the fitted FHH-isotherm.

Presenting author email: christian.svensson@design.lth.se

Awareness of health effects due to nanoparticle exposure has continuously increased over the last decade. The primary route of exposure is by air, as particles deposit in the respiratory tract. Due to the special properties of nanoparticles, such as a high surface area to mass/volume ratio, concern has been raised with regards to their potential effects in biological systems.

In recent years the particles interaction with biomolecules has been acknowledged as crucial for the understanding of particle toxicity (Lynch, 2009). When biomolecules bind to the particle surface a dynamic protein/biomolecule corona is created (Cedervall, 2007). The protein corona is dependent on the surface chemical properties, the size and morphology of the particles. The protein corona is believed to be important for the biological effects of nanoparticles.

In this work we present a method to investigate the composition of the biomolecule/protein corona on model nanoparticles in two different physiological fluids, porcine serum and porcine lung fluid. Gold nanoparticle (AuNP) agglomerates (Geometric mean diameter GMD 70 nm) were generated by spark discharge (SDG) and high temperature evaporation condensation (HT). The agglomerates where sintered to spherical shapes, at 400°C, and characterized online by tandem differential mobility analysis (T-DMA) and aerosol particle mass analysis (DMA-APM) (Ehara, 1995). The sintered AuNPs (GMD 45 nm) were deposited onto solutions of bovine serum albumin (BSA) and homocysteine using an electrostatic precipitator (ESP). The BSA and homocysteine have thiol groups known to form bonds with gold particles. AuNPs in suspension with BSA and homocysteine were identified with dynamic light scattering (DLS) on selected time-intervals (h to days). AuNPs in solution were mixed with porcine serum or porcine lung fluid. Using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) the protein corona was determined for AuNPs mixed with the physiological fluids.

DLS data indicate that particle-biomolecule complexes had formed in suspension for AuNP depositions in both BSA and homocysteine. The DLS signal could be observed over the course of several days (Table 1).

Table 1. DLS measurements performed on AuNPs deposited in homocysteine solution.

AuNP + Homocysteine	d. (nm)
Day 1	165,5
Day 2	122,2
Day 7	107,8

Results from SDS-PAGE indicate that the protein corona is similar regardless of surfactant biomolecule, BSA or homocysteine (Figure 1). It also shows that the corona is different between particles mixed with porcine lung fluid or porcine blood serum.

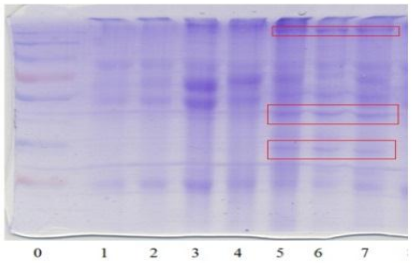

Figure 1. Results from SDS PAGE for gold nanoparticles mixed with porcine blood serum and lung fluid. 1, 2, 3, and 4 are samples of particles mixed with blood serum while 5, 6, and 7 are particle samples mixed with lung fluid. Red marks indicate unique protein bands for the protein corona in lung fluid.

In conclusion: We have shown that the protein / biomolecule corona can be studied using model particles generated in the aerosol phase and stabilized with BSA and homocysteine in suspension. Also, the observed corona is different between particles administered to porcine blood serum and lung fluid.

This study presents exposure assessment for nanoparticles (NPs) during synthesis and packing. The measurements were carried out at two different occupations where the first was a pilot plant and another was a TiO_2 factory. We measured particle size distributions with a Grimm sectional mobility particle sizer and a Grimm Dust monitor 1.109. NPs were discriminated from background particles from the size sectioned particle concentration difference during process and before process. Regional minute lung deposition rates was defined for NPs (IRCP, 1995) and in dose calculation was used respirator assigned protection factor (APF) (European standard: EN529) and by measuring respirator work place protection factor with condensation particle counter (TSI), electronic low pressure impactor (Dekati), and nanoparticle surface area monitor (TSI).

Figures 1 and 2 shows the particle size distribution time series during the NP synthesis with liquid flame spray (LFS) process and packing of TiO_2 nanomaterial. Three different LFS processes were conducted in a ventilated chamber or under hood (processes 1 to 3 in Table 1). Table 1 shows that in NP synthesis, minute particle number lung deposition was dominated by NPs during synthesis 1 and 2 ($f_{NP,\dot{n}} > 99\%$), and partly in synthesis 3. NPs influence on minute mass deposition rate was negligible ($f_{NP,\dot{m}} < 0.11\%$). However, in TiO_2 nanomaterial packing the NPs' affected on particle minute deposition rate only 5% but in mass 99%. Regional deposition rate shows that mass was deposited on head airways (70%) and particle number in alveolar region (70%). In NP synthesis workers used a TH2 type powered respirator where the particle penetration was 2% according to the standard EN529. However, the particle penetration was less than 10^{-6} % according to the CPC and less than 10^{-4} % according to the ELPI. This study shows that the metrics to describe exposure to NPs depend on the process (i.e. synthesis or post-process) and by using the respirator APF may overestimate significantly the calculated dose.

This work was performed as a part of Nanohealth, Nanoturva, and Nanodevice research programmes.

Release-ability of nano fillers from different nanomaterials

L.Golanski[1], A.Guiot[1], M.Pras[2] and F.Tardif[1]

[1]LITEN, CEA-Grenoble, Grenoble, Rhone Alpes, F38054 Cedex9, France
[2]IMP, INSA-Lyon, Villeurbanne, Rhone Alpes, 69621, France
Keywords: nanoparticle release, abrasion, sanding, nanomaterials

Presenting author email: luana.golanski@cea.fr

The nanoparticles (NP) are finding new industrial applications every day in fields as diverse as electronics, biomedicine, pharmaceutics, cosmetology, chemical catalysis, new materials and others. We are about to witness the advent of a new era in the industrial history of nanoparticles. Nevertheless, this new industry can develop dynamically only if the safety issues are solved during all along the life cycle of the nano products: from fabrication to the end of life through usage.

Due to the complexity of the nano toxicology, it will probably take decades to identify the dangerous nanoparticles and even a longer time to declare some of the nanoparticles as benign. One of the pragmatic ways to secure the nanomaterials today consists in reducing the exposure to nanoparticles of potentially exposed workers, consumers and the Environment close to zero.

Standard methods for investigating the wear resistance to abrasion induced by domestic use in dry and wet environments are used by manufacturers. However, these methods have to be adapted today for materials containing NP in order to measure if these NP could be released by the abrasion process or not. Very few data concerning NP release from nanomaterials in the air by abrasion are available: Guiot *et al* (2008), Vorbau *et al* (2009), Golanski *et al* (2010). The objective of developing such measurement techniques is double: to be able to optimize the "hooking" of the nanoparticles in the matrix and perhaps one day, to qualify the nano products before market introduction.

In this paper, the different steps necessary to setup the methods are summarized and the results obtained on paints, fabrics and polymers containing nano fillers discussed. Standard abrasion conditions in dry and wet environments were simulated. The aging effect induced by a mechanical friction like sanding were simulated as well. Different instruments were used for measuring the number size distribution of the abraded particles in the liquid solution and in the air. The advantage of each instrument is pointed out. These granulometers give no information about the type of NP measured. To address this issue the NP were deposited on a substrate for Scanning Electron Microscopy (SEM) or Transmission Electron Microscopy (TEM) analysis. In this way the nanoparticles released were analyzed in terms of their type: NP in agglomerate or free form or moreover NP embedded in the paint matrix.

Abrasion of the paints is found to produce submicrometric and micrometric particles in the air but no nanoparticles. Moreover, very few particles are released from paint coatings whatever the composition of the paint and whatever the tool used for abrasion. No free or agglomerated nanoparticles were observed. TiO_2 nanoparticles (~ 30nm) seem to remain embedded in the paint matrix (see on figure 1).

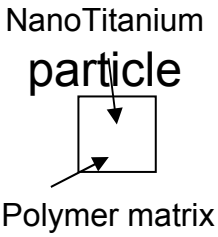

Figure 1. SEM image of the paint with nanoTiO_2: image of a TiO_2 nanoparticle embedded in a polymer matrix

Abrasion of the polymer coatings and textiles is found to induce nanometric particle release. The released nanoparticle number from investigated polymers depends on the abrasion tool type and composition of the material. Adding 5% wt of CNT (Carbone Nanotubes) to the reference material (polymer without CNT), induces hundred times more nanometric particle release from the nanomaterial by comparison with the reference. The influence of the fabrication process of the polymer on nanoparticles release was investigated as well. SEM measurements on abraded particles showed that no CNT were released from polymers containing up to 5% wt. For these polymers, the fabrication process was well controlled: eg. hooking of the CNT in the matrix.

Keywords: nanoparticles, aerosol emission, particle deposition, lung/particle interaction.
Presenting author email: robert.grass@chem.ethz.ch

The rapidly increasing production of engineered nanoparticles has raised questions regarding their environmental impact and their mobility to overcome biological important barriers. Nanoparticles were found to cross different mammalian barriers, which is summarized under the term translocation. The present work investigates the uptake and translocation of cerium dioxide nanoparticles in maize plants as one of the major agricultural crops.

In order to simulate the gas-phase exposure of maize plants to nanoparticles, flame spray pyrolysis (FSP) was utilized to directly synthesize a cerium oxide comprising aerosol. (Birbaum et al. 2010) The aerosol was produced in an enclosed cabinet (glove box, 2 m^3, see Figure 1) in which the maize plants were cultivated. After digestion of the maize leaves, the cerium concentrations were measured by a sector field inductively coupled mass spectrometer (ICP-SF-MS), allowing a detection limit of less than 1 ng of cerium per gram of leaf. (< 1 ppb mass/mass). The plant leaves were analysed for the cerium content directly after exposure and 12 weeks post exposure in order to measure the cerium translocation within the plant.

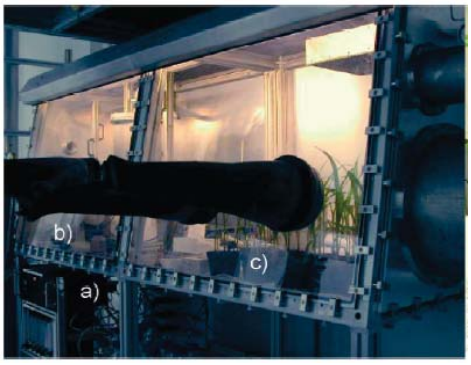

Figure 1. Exposure of maize plants to a cerium oxide aerosol in an enclosed cabinet (glove-box).

Element analysis results showed that cerium oxide nanoparticles were present on/in the maize leaves after the aerosol exposure. While it was not possible to discriminate between particles taken up by the plant cells and particles adsorbed to the surface of the leaves, the deposited nanoparticles could not be washed off with water (simulating rainfall). Examination of the concentrations in the leaves 3 months after the exposure

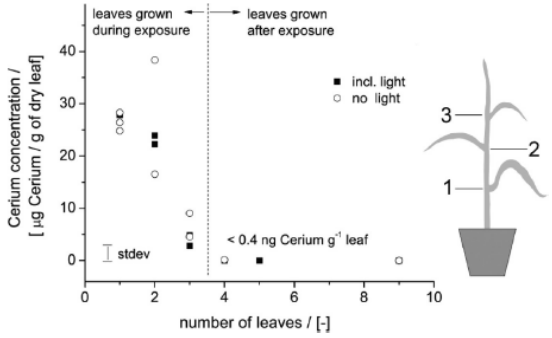

Figure 2. Cerium concentrations in plant leaves 3 months post nanoparticle exposure. Leaves 1-3 were directly exposed during the exposure, leaves 4-9 grew following the exposure.

experiments revealed that the cerium oxide nanoparticles did not translocate into newly formed leaves. No cerium oxide (detection limit of 0.4 ng cerium / g leaf) could be measured in the leaves grown during the three months post exposure period.

The presentation will further show the influence of light (exposure under light and dark for open and closed stomata) and results on the suspension exposure of maize plants (via the soil). The results of the maize plant exposure will be discussed and compared with *in vitro* lung cell exposure experiments (Rothen-Ruthishauser et al. 2010, Raemy et al. 2011) performed under the same exposure conditions.

In this work a liquid flame spray process called nHALO® (hot aerosol layering operation) producing engineered nanoparticles (ENPs) used for coating and surface modification of materials was studied. The process reagents, which are usually nitrate salts and water or alcohol as carrier, are vaporised in a hydrogen-oxygen flame. In the flame, particles nucleate and grow via condensation and coagulation into nanosized particulate matter. The produced particles may be metal, metal oxide or multicomponent. The process was installed inside an enclosure to minimise particle emissions into the surroundings. The focus of the research was to characterise the particles inside the enclosure, in the surroundings and at the exit points of the enclosure where the workers may be exposed to the engineered particles.

Particle number concentration was measured with a TSI 3022 CPC and number size distribution with a TSI 3080 electrostatic classifier with a TSI 3085 Nano-DMA connected with a TSI 3775 CPC and controlled by the SMPS software and with an ELPI. Mass concentration was measured with a TEOM 1400a. Individual particle samples for electron microscopy (EM) analyses were collected with an aspiration EM sampler.

Average particle number concentration inside the enclosure varied from $1.0 \cdot 10^4$ to $2.1 \cdot 10^5$ 1/cm^3 and average mass concentration from 1.2 to 2.6 mg/m^3 during process operation. The highest particle concentration was observed when the furnace was heated and when the flame was on. The high peaks in the number concentration levelled out rapidly indicating a batch-type process and efficient ventilation inside the process enclosure (Fig. 1a). It should be noted that the process enclosure was not occupied by the workers.

Particle number concentration in the surroundings was typically $6.0\text{-}8.0 \cdot 10^3$ 1/cm^3, and average mass concentration 66 µg/m^3. It is noteworthy, that after the door opening at around 14:40 (scaled time), the particle number concentration stayed at higher level than before the door opening (white line in Fig. 1a). This was probably caused by the opening of the door to the enclosure at 14:56, 15:05 and 15:55 (Leppänen, et al.).

Comparing the number and mass concentration in the surroundings to the enclosure concentrations during the nHALO® process it was evident that the ventilated enclosure worked well in isolating the particle source from the surroundings.

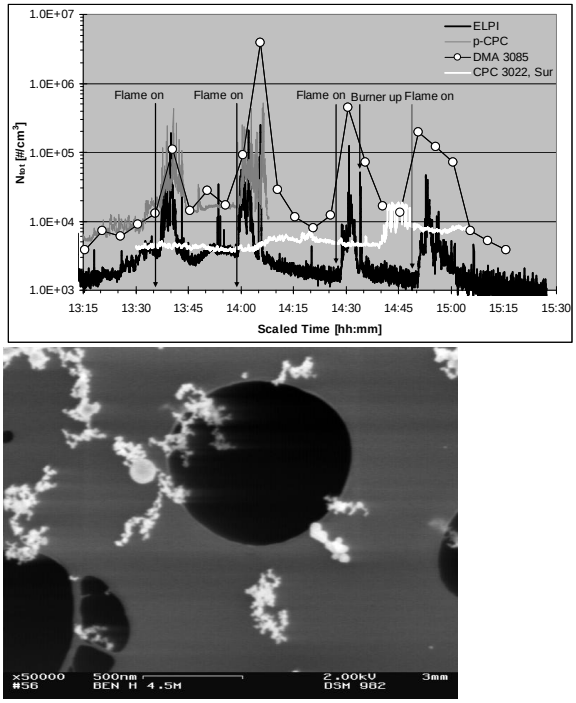

Figure 1: a) Particle number concentration for nHALO® inside the process enclosure and in the surroundings (white curve, scaled time) b) A scanning electron microscope (SEM) micrograph of the collected nanoscale particles from inside the enclosure. Particles were mainly aggregates, primary particle size approximately 20-30 nm.

Session 5F: Aerosols in Turbulent Flows 1

Distribution of relative velocities in turbulent aerosols

K. Gustavsson[1], B. Mehlig[2]
[1]Department of Physics, Gothenburg University, 41296 Gothenburg, Sweden
Keywords: turbulent aerosols, caustics, relative velocities.
Presenting author email: Bernhard.Mehlig@physics.gu.se

Collision velocities of particles in randomly mixing or turbulent flows ('turbulent aerosols') have been studied intensively for several decades. This is an important topic because the stability of turbulent aerosols is determined by collisions between the suspended particles.

Direct numerical simulations of particles in turbulent flows (Sundaram & Collins, 2007; Wang *et al.*, 2000) show that collision velocities (and thus the collision rate) increase precipitously as the 'Stokes number' St is varied beyond a threshold. This dimensionless parameter, $\mathrm{St} = (\gamma\tau)^{-1}$, is defined in terms of the particle damping rate γ and the relevant correlation time τ of the flow.

In (Wilkinson *et al.*, 2006) (see also Falkovich *et al.* (2002)) this steep increase was attributed to the fact that singularities in the particle dynamics result in large relative velocities at small separations. These singularities occur when phase-space manifolds (describing the dependence of particle velocity upon particle position) fold over. In the fold region, the velocity field at a given point in space becomes multi-valued, giving rise to finite velocity differences between particles at the same position in configuration space.

The boundaries of the folding region are referred to as caustics (Wilkinson & Mehlig, 2003, 2005). In the absence of such singularities, in a single-valued smooth particle-velocity field, the relative velocity of two particles tends to zero as they approach each other. In the presence of caustics, by contrast, the relative velocity of two particles may remain finite. When a singularity is created, the particle-velocity gradient diverges, $\partial v/\partial x \to -\infty$ (here x is the particle position and v its velocity). In (Duncan *et al.*, 2005; Wilkinson & Mehlig, 2005; Wilkinson *et al.*, 2006) it was shown that the frequency at which these singularities occur along a particle trajectory exhibits an activated St-behaviour, $\exp(-A/\mathrm{St})$.

Wilkinson *et al.* (2006) have suggested an interpolation formula accounting for both smooth and singular contributions to the collision rate and to the relative collision speed. But a theory for the distribution of relative velocities in turbulent aerosols at small and intermediate values of St is still lacking (a theory for collision velocities in turbulent flows at very large Stokes and Reynolds numbers was developed in (Gustavsson *et al.*, 2008), it is of interest in astrophysical contexts).

Here we compute the distribution of relative velocities for a one-dimensional model of heavy particles suspended in a turbulent flow, quantifying the caustic contribution to the moments of relative velocities (Gustavsson & Mehlig, 2010). We argue that the same principles determine the corresponding caustic contribution in two and three spatial dimensions. Our conclusions are in excellent agreement with numerical simulations of particles suspended in a randomly mixing flow in two dimensions, and in quantitative agreement with published data on direct numerical simulations of particles in turbulent flows (Bec *et al.*, 2010).

This work was supported by Vetenskapsrådet, the Gören Gustafsson Stiftelse, and the platform 'Nanoparticles in an interactive environment' at Gothenburg University.

Statistical properties of particle segregation in homogeneous isotropic turbulence

E. Meneguz, M. W. Reeks
School of Mechanical and Systems Engineering, Newcastle University, Newcastle upon Tyne, NE1 7RU, UK
Keywords: segregation, inertial particles, random uncorrelated motion, singularities.
Presenting author email: Mike.Reeks@ncl.ac.uk

The study of the kinematic of particles/droplets dispersed in turbulent flows is crucial for a wide range of natural and engineering applications. In this theoretical and numerical work, we focus on a two phase flow constituted by heavy particles and incompressible flow and we exploit a Full Lagrangian method to quantify the average segregation of particles. While doing so, we are able to analyse some particular features of this ongoing process, and in particular to study the statistics of the singularities of the particle velocity field and of the recently observed Random Uncorrelated Motion (RUM): the velocity of particles with large inertia brought into close proximity may be strongly decorrelated not only with the flow but one with another.

In our recent work (IJzermans *et al*, 2009 and 2010), we have studied the segregation of heavy particles in turbulence by calculating the rate-of-compression of the particle phase in a kinematic simulation. Particles are advected by Stokes drag in a flow field composed of 200 random Fourier modes. The volume occupied by the particles centred around a position x at time t is denoted by $J = det(J_{ij})$, where $J_{ij} = \partial x_i(x_0)/\partial x_{0,j}$, where x_0 denotes the initial position of the particle. The particle-averaged compressibility, $\mathscr{C} = d < ln|J| > /dt$, gives a measure for the change of the total volume occupied by the particle phase. Numerical results showed that the particle-averaged rate-of-compression decreases continuously if the value of the Stokes number (the dimensionless particle relaxation time) is below a threshold value, St_{cr}, indicating that the segregation of these particles continues indefinitely. We find that the probability density function of $ln|J|$, the compression, tends to a Gaussian distribution for $St \sim 1$ when $t \to \infty$. We believe the explanation for Gaussianity is similar to that for the occurrence of a Gaussian distribution of displacement (Taylor, 1922), with $\mathscr{C}'(t)$, the fluctuating value of $\mathscr{C}(t)$ about its mean. However, we find that that such PDF shows a significant skewness towards negative compression (segregation), i.e. singularities in the flow are likely to play a significant role in determining the statistics of the segregation in these long term limits.

By counting events for which $|J(t)| = 0$, we can calculate the distribution of singularities over a fixed interval of time respectively for a set of St numbers. As shown in Figure 1 for $St = 1$, excluding the influence of an initial transient when no singularities are observed, the histogram that represents the discrete probability distribution is well approximated by a Poisson distribution that describes the probability of the occurrence of an event (singularity) in a specified time span $[0, \triangle t]$ as $\sim \lambda \triangle t = \Lambda$; λ is the rate constant for the occurrence of singularities. The Poisson process implies that starting from some initial fully mixed equilibrium distribution, the decay in the number of particles that have not experienced a singularity is $\sim exp(-\lambda t)$.

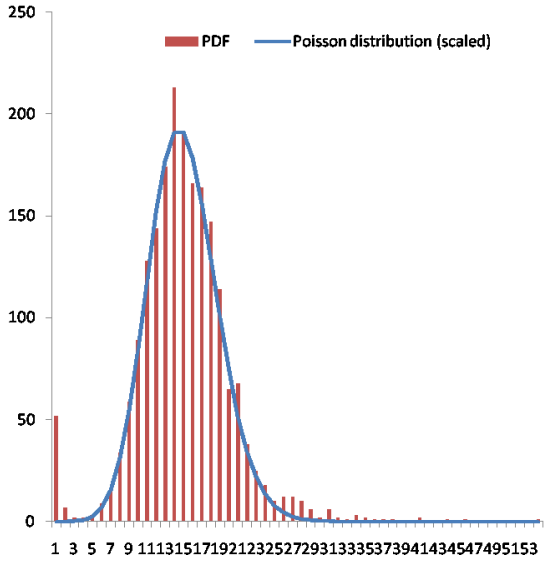

Figure 1: This is a comparison between theory and experimental data.

Finally, we discuss our work in relation to the one of Falkovic & Pumir, 2007 and Wilkinson *et al*, 2007 and we conclude that the occurrence of singularities is related to the formation of caustics and sling effect respectively, since it corresponds to the folding of the particle velocity field in phase space. We believe that RUM and singularities are intrinsically related and we are currently working to find a suitable way to demonstrate such theory from a mathematical and numerical point of view.

Particle and droplet transport in turbulence and inertial effects

R. Skartlien[1]
[1]Institute for Energy Technology, N2027, Kjeller, Norway
Presenting author email: roar.skartlien@ife.no

Turbulent flow with solid particles or droplets is encountered in both natural processes and in industrial applications. A challenge is to predict the distribution of the dispersed phase with account for particle inertia and turbulence inhomogeneity. Recent advances in Eulerian modelling have become possible due to kinetic methods based on an underlying Boltzmann type equation where the usual collision term is replaced by an interaction between particles and the turbulent medium (e.g., Reeks 1992, Swailes and Darbyshire 1999, Simonin 2000, Zaichik & Alipchenkov 2005).

The kinetic framework can be applied to turbulent diffusion and transport with inertial effects, such as for raindrops and aerosols in the atmosphere. Recent applications of the theory for solid particles and droplets in gas is presented, in the context of strongly inhomogeneous turbulence in pipe flow. The most valuable ingredient that emerges from the theory is a generalized diffusivity tensor, valid for a very large range of particle properties (material density, diameter and Stokes numbers).

In many applications it is common practise to use an over-simplified phenomenological diffusion equation for the mass flux density $\mathscr{F}_m$, of the form

$$\mathscr{F}_m = -\varepsilon\nabla\rho + \rho\mathbf{v}_d. \tag{1}$$

This diffusion equation may provide a solution for the density of particles ρ, once the drift velocity $\mathbf{v}_d$ and the particle diffusivity ε is given. In the absence of better estimates, the diffusivity is often set equal to the scalar eddy diffusivity of the fluid turbulence. For intertial particles, such as droplets, it is evident that this simple form breaks down, since the particles do not follow the fluid motion. The general form of the diffusion equation from kinetic theory is (Reeks 1992)

$$\begin{aligned}\rho\overline{v_i} &= -\varepsilon_{ik}\partial_k\rho - \rho\tau_p\partial_k(\overline{v_k'v_i'} + \overline{\lambda}_{ki}) \\ &+ \rho\tau_p(\overline{F}_i - \overline{\gamma}_i) - \tau_p\rho\frac{D\overline{v_i}}{Dt},\end{aligned} \tag{2}$$

where $D/Dt = \partial_t + \overline{v_k}\partial_k$, and $\overline{\mathbf{F}}$ is the mean aerodynamic force. The diffusive contribution to the mass flux is now

$$\mathscr{F}_i^d = -\varepsilon_{ik}\partial_k\rho, \tag{3}$$

where the generalized *diffusivity tensor* is

$$\varepsilon_{ik} = \tau_p(\overline{v_k'v_i'} + \overline{\lambda}_{ki}), \tag{4}$$

which is a tensorial quantity depending on the particle Stokes number via the inertial relaxation time τ_p. The kinetic stress tensor for the particles is $\overline{v_k'v_i'}$, and the dispersion tensor $\overline{\lambda}_{ki}$ is ultimately controlled by the fluid Reynolds stresses. For large Stokes number it is $\tau_p(\overline{v_k'v_i'})$ that controls the diffusivity, and for low Stokes number it is $\tau_p\overline{\lambda}_{ki}$. Figure 1 compares these contributions with the eddy diffusivity, for a distribution of inertial droplets in horizontal pipe flow.

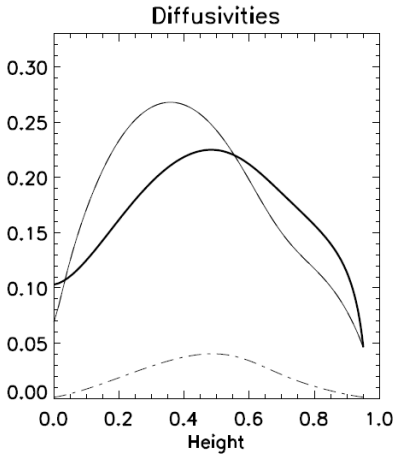

Figure 1: **Diffusivity** for a droplet size 1.2 times the average size in strongly inhomogeneous gas turbulence above a liquid layer in a horizontal pipe. The plot shows the total diffusivity $\tau_p(\overline{v_y'v_y'} + \overline{\lambda}_{yy})$ (thick line), the fluid contribution $\tau_p\overline{\lambda}_{yy}$ (dashed line) and the eddy diffusivity ν_T (thin full line). The deviation between the total diffusivity and the eddy diffusivity is due to inertia, and the fluid contribution $\tau_p\overline{\lambda}_{yy}$ is small compared to the kinetic part $\tau_p\overline{v_y'v_y'}$.

Full motion measurement of finite-size neutrally buoyant particles together with the turbulent flow field carrying them

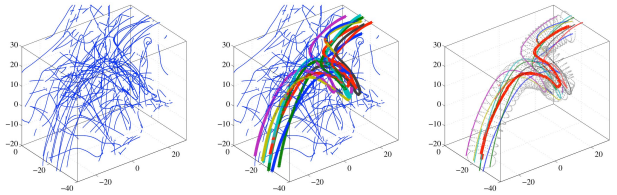
M. Gibert[1,2], S. Klein[1] and E. bodenschatz[1,2]
[1]Max Planck Institute for Dynamics and Self Organization, Göttingen, 37073, Germany, EU,
[2]International Collaboration for Turbulence Research
Keywords: Turbulence, Insoluble particles, Measurements.
Presenting author email: mathieu.gibert@ds.mpg.de

The motion of inertial particles in a turbulent flow is of interest in many applications ranging from mixing in industrial processes to dispersion in oceans or in the atmosphere. The case of small (compared to the Kolmogorov size η) but heavy particles is extremely well studied experimentally (Gibert *et al.* (2010)) as well as numerically (for an extensive review see Toschi *et al.* (2009)). In this case, the flow around the particle is smooth, which facilitate the writing of the equation of motion that couples the particle trajectory to the underlying turbulent flow field. In the case of finite-size particles (diameter $d_p > \eta$), the equation of motion is still unknown. Therefore, only a few numerical studies are available today (Homann *et al.* (2010)), and are limited to very small Reynolds numbers because of the complexity of the problem. This leads to the conclusion that only an experimental approach can help to discover and characterize the complex coupling between these big particles and the turbulent flow carrying them. Nevertheless, this is a very challenging task since it requires the measurement of the full trajectory of the particles (translation and rotation) together with the flow field that surrounds them, in a highly turbulent flow. In the following section, we present the most advanced measurement technique in the field that we have developed in order to acquire all these information.

Measurement technique and results

We studied particles made out of super-absorbent polymer. These particles initially dry have a diameter of $1mm$, once immersed underwater they grow until having a diameter of about $1cm$. Therefore, these solid particles are made out of more than 99% of water and inherit water properties : same optical index and same density (they are invisible in water). To follow their trajectories, we inject them with small fluorescent particles of $100\mu m$ in diameter. Since the big particles are invisible in the water von Kármán flow we use to generate the turbulence, we can use the same fluorescent tracer particles to track the fluid velocity (see Fig. 1 for more detail).

The experiments are conducted in a von Kármán swirling water flow (two counter-rotative coaxial propellers facing each other) at Taylor microscale Reynolds numbers up to 400 (the apparatus is described in Gibert *et al.* (2010)). At these Reynolds numbers, the energy injection length scale L is about $10cm$ and the dissipative length scale η is close to $100\mu m$. Therefore, the diameter of the big particles d_p lies in the inertial range ($d_p/\eta \approx 100$ and $d_p/L \approx 0.1$). We report data on the statistics of the velocity differences between the big particles and the surrounding turbulent flow. Our results show a strong correlation between the fluid and the particle velocity in the close vicinity of the big particles, but also that the particles perturb the flow by generating a wake behind them. This work provides the first quantitative data on the flow around large particles in turbulent flows and shows that in modeling, two-way coupling will need to be considered which is not present in the case of small inertial particles.



(a) (b) (c)

Figure 1: The measurement technique. (a)(b)(c) The axes are in *mm*, these plots correspond to a subset of $0.3s$ of measurements done at $3kHz$. (a) Three-dimensional plot of the fluorescent particles trajectories measured by Lagrangian Particle Tracking (LPT). (b) Identification of the particles tracks that do not separate from one another along their trajectories (they correspond to the tracks of the fluorescent particles embedded at the surface of the big particles). (c) Three-dimensional plot of the reconstructed big particle trajectory (the center of the particle is represented in red). The fluid particles trajectories have been removed from the figure for clarity, but we still have this information.

Aerosol Coagulation & Break-up in Homogeneous Isotropic Turbulent Flows

M.L. Eggersdorfer[1], D. Kadau[2], H.J. Herrmann[2] and S.E. Pratsinis[1]

[1]Particle Technology Laboratory, Institute of Process Engineering, Department of Mechanical and Process Engineering, ETH Zurich, Sonneggstrasse 3, CH-8092 Zürich, Switzerland.
[2]Computational Physics of Engineering Materials, Institute of Building Materials, Department of Civil, Environmental and Geomatic Engineering, ETH Zurich, Schafmattstrasse 6, CH-8093 Zürich, Switzerland.
Keywords: Aerosol dynamics, size distribution, Coagulation, Turbulence.
Presenting author email: meggers@ptl.mavt.ethz.ch

Turbulent mixing is present in many different processes in nature, e.g. formation of raindrops (Saffman & Turner, 1956), and in industry, e.g. aerosol synthesis of nanoparticles like carbon blacks and oxide powders (silica, titania; Xiong & Pratsinis, 1991). There, particles are produced at high temperatures and pressures with Reynolds numbers up to 10^6. Primary particles grow by gas and surface reaction, coagulation and sintering. The primary particles are too small to be affected by turbulence. Nevertheless coagulation leads to soft- or hard-agglomerates which can reach the size of the Kolmogorov scale η, the smallest scale of turbulence. These agglomerates experience the high frequency fluctuations and undergo turbulence-induced coagulation, restructuring or even fragmentation preventing gelation, which can occur in aerosols at high effective volume fractions (Sorensen et al., 1998).

Particle coagulation by Brownian motion or shear in flows at low Reynolds numbers is fairly well understood (Friedlander, 2000). The effects of turbulence on agglomerate formation and break-up are only partially understood. Uncertainties are in the fundamental theory of turbulence, the motion of small particles in close proximity in turbulence as well as the restructuring and break-up.

Ernst and Pratsinis (2006) showed by population balance simulations that turbulent-induced coagulation lead to pseudo self-preserving distributions that end to gelation in the absence of restructuring or fragmentation in the viscous regime (particle diameter d_p much smaller than η). Heine and Pratsinis (2006) investigated aerosol dynamics at high solid concentrations found typically in industrial scale manufacture of fine particles. Enhanced Brownian and shear-induced coagulation could lead to rapid soft-agglomerate growth and again gelation. However, restructuring and shear-induced fragmentation should slow and stop soft-agglomerate growth in industrial flow reactors.

Higashitani et al. (2001) investigated the break-up of soft-agglomerates in linear shear and elongational flows and proposed a power law relation between asymptotic fragment mass and shear stress for both flow fields. They found that the elongational flow field is more efficient to break-up agglomerates than the linear shear field.

In the present work the agglomeration and break-up of monodisperse particles in a homogeneous isotropic turbulent flow field are investigated. A discrete element method (DEM) is used for the particle dynamics and stochastic differential equations (SDE) are solved for the time evolution of the velocity and accelerations of the fluid. The evolution of the agglomerate number, mass and size (radius of gyration) with time is discussed for different Reynolds numbers. Equilibrium between coagulation and break-up is found, resulting in steady state agglomerate mass distributions (Fig. 1). Furthermore the agglomerate structure is characterized with an effective fractal dimension.

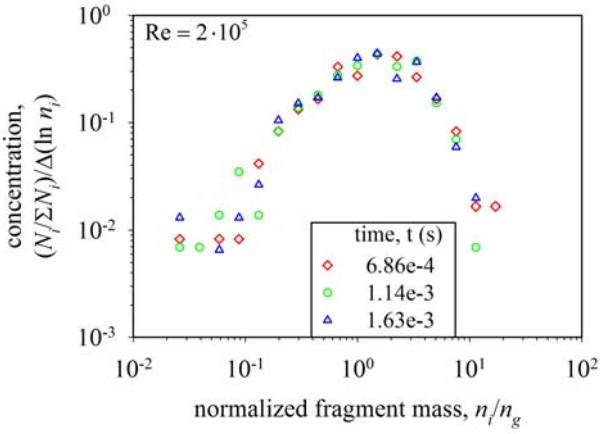

Figure 1. Steady state agglomerate mass distribution at three different simulation times. An equilibrium between coagulation and break-up is reached.

Keywords: resuspension, turbulent flow, multilayer deposit, severe accident

The work presented is concerned with the way small particles attached to a surface are resuspended when exposed to a turbulent flow. The process is important in a number of environmental and industrial processes. Of particular concern to this work is the release of radioactive particles from the primary circuit of an LWR as a consequence of a loss of coolant accident (LOCA). In this particular case the focus is on small particles < 5 microns in size, where the principal force holding the particle onto a surface is derived from van der Waals inter molecular forces. In general even for nominally very smooth adhering surfaces there exists a very broad spread in the adhesive forces. Here we develop and assess an improved version of the Rock'n'Roll model [Reeks & Hall, 2001] based on a statistical approach to resuspension which gives rise to a resuspension rate constant for the release of particles from a potential well due the action of the fluctuating aerodynamic force du to the turbulence. The analogy is with desorption of molecules from a surface in which the variance of the fluctuating aerodynamic force is the analogue of temperature. In this work we improve on the model by using measurements of the statistical fluctuations of both the stream wise fluid velocity and acceleration close to the wall from both LES and DNS of turbulent channel flow, translating those measurements into the statistical moment of the drag force acting on the particle attached to the surface. The original model assumes that aerodynamic forces and their time derivative are uncorrelated and have a Gaussian distribution. Here we examine the influence of non-Gaussian forces on the resuspension rate.

The ultimate model is a hybrid development of R'n'R model adapted for application to multilayer deposits based on the Friess and Yadigaroglu multilayer model [Friess & Yadigaroglu, 2001]. The particle size distribution is considered in the model in order to study the coveragent effect of the deposit layers. The model results are compared to the STORM SR11 test [Castelo *et al.*, 1999] (Figure 1) and BISE experiment [Alloul-Marmor, 2002] (Figure 2).

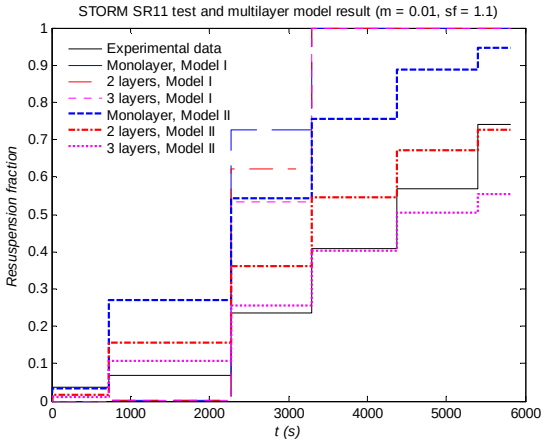

Figure 1. Models results and STORM SR11 test

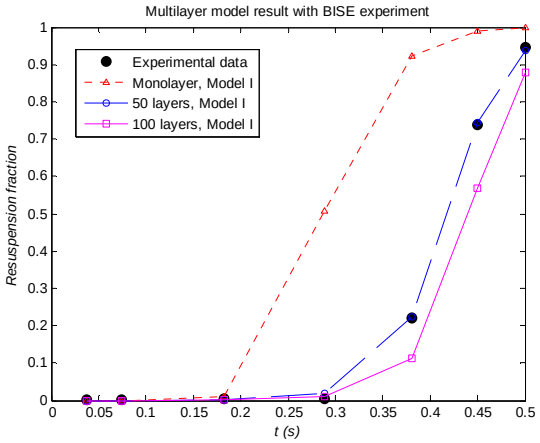

Figure 2. Model results and BISE experiment

As a general conclusion, the results showed that the models with small adhesive spreads give better comparison with the resuspension measured in the two experiments.

Aerosol nucleation is potentially important to climate because it is, along with primary particle emissions, a major source of new particles to the atmosphere. Nucleated particles can ultimately act as CCN and contribute to the indirect effect if they grow to larger sizes. Ultrafine particles are highly mobile within the human body and may be especially harmful to human health. To correctly predict the relative contribution of nucleation to total aerosol number concentration, air quality and climate models need to be able to correctly simulate ultrafine particle dynamics and chemistry.

In this work, we study the effect of nucleation on aerosol number concentrations in Europe with the regional 3-D chemical transport model PMCAMx-UF (Jung *et al.*, 2010). We use three different schemes to simulate new particle formation; i) a ternary H_2SO_4-NH_3-H_2O nucleation parameterization, ii) an activation mechanism with a linear dependence on the sulfuric acid concentration, and iii) a kinetic mechanism with a squared dependence on the sulfuric acid concentration. We evaluate the model predictions for the European domain against field observations collected during the EUCAARI campaign in May 2008 and February/March 2009.

PMCAMx-UF is a version of PMCAMx focusing on ultrafine particles simulating both the aerosol number distribution and the aerosol mass/composition distribution. It uses the TwO-Moment Aerosol Sectional (TOMAS) algorithm (Adams and Seinfeld, 2002) to simulate both the aerosol number and mass distributions. The aerosol size distribution in PMCAMx-UF is discretized in 41 sections from 0.8 nm to 10 μm. From 10 μm to 40 μm, two additional size sections are used for the description of cloud chemistry. PMCAMx-UF tracks the mass distributions for 13 aerosol species including SOA components, POA, EC, crustal material, water, chloride, sodium, ammonium, nitrate, and sulfate. The modeling domain covers a 5400 × 5832 × 6 km region in Europe with 36 × 36 km grid resolution. A new size-resolved Pan-European anthropogenic Particle Number (PN) emission inventory was developed for the first time and the extracted aerosol number emissions were used as inputs for PMCAMx-UF.

Figure 1 shows the PMCAMx-UF average predictions over the period of 1-29 May 2008 for total aerosol number concentration above 1 nm using the 1st order in sulfuric acid nucleation parameterization.

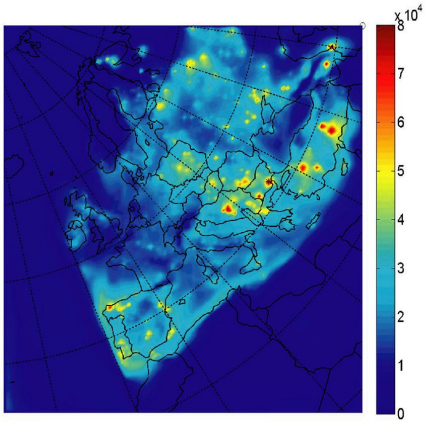

Figure 1. Predicted average number concentration (cm^{-3}) at the ground level above 1 nm during May 2008.

The model was found to perform reasonably well in both capturing the levels of particle number concentrations and size distributions at various sites, as well as their temporal variation in both diurnal as well as longer time scales.

The sensitivity of the predicted particle number concentrations above 1, 3, 50 and 100 nm to emissions of 1) SO_2, 2) Biogenic VOCs, and 3) particle mass is studied and the results will be discussed.

This work was supported by the European Integrated project on Aerosol Cloud Climate and Air Quality Interactions (EUCAARI).

Computational studies of atmospheric sulfur oxidation mechanisms

Presenting author email: theo.kurten@helsinki.fi

The global climate impact of the atmospheric sulfur cycle on a per-kilogram basis is enormous compared to that of most other biogeochemical cycles due to the ability of oxidized sulfur compounds such as sulfuric acid to form aerosol particles. For example, according to the emission inventories and radiative forcings in the 4th IPCC assessment report (Solomon *et al*., 2007) the short-term cooling associated with a kilogram of sulfur emitted as SO_2 is estimated to be 10^4 to 10^5 times larger in magnitude than the corresponding warming associated with a kilogram of carbon emitted as CO_2. Natural sulfur emissions have also been speculated to play a role in the global climate system. Specifically, temperature-driven variations in the emissions of biogenic sulfur compounds have been suggested to modulate cloudiness and thus act as a negative feedback in the climate system

Despite the importance of atmospheric sulfur chemistry, many key reactions of anthropogenic and especially biogenic sulfur compounds present in the atmosphere are still largely unknown. Oxidation reactions involving the OH radical are fairly well characterized, but the reaction rates of other oxidants such as NO_3, O_3, peroxyradicals or carbonyl oxides with many sulfur compounds are highly uncertain. Recent calculations (Kurtén *et al.*, 2010) indicate that night-time NO_3 oxidation may actually form the main sink for some organosulfur compounds such as DMSO (dimethyl sulfide oxide).

Another open question is the role of water catalysis in the sulfur cycle. It has been suggested (Jørgensen and Kjaergaard, 2010) that a single water molecule is able to catalyze some of the OH oxidation reactions of reduced biogenic sulfur compounds such as DMSO. On the other hand, recent calculations indicate that water catalysis does not significantly enhance the OH - oxidation of partially oxidized sulfur compounds such as methane sulfenic, methane sulfinic and methane sulfonic acid (CH_3SOH, $CH_3S(O)OH$ and $CH_3S(O_2)OH$).

Recent experiments (Sipilä et al., 2010) have demonstrated that H_2SO_4 is the only SO_2 oxidation product needed to explain laboratory observations of sulfuric acid – water nucleation, though stabilizing third compounds such as ammonia or amines are still likely required. However, this does not rule out the possible existence of other gas-phase oxidation mechanisms by which SO_2 can be converted into H_2SO_4 without OH. Such pathways might play a role in the sulfur cycle at night, when OH levels are extremely low.

We have computationally investigated the oxidation of SO_2 into SO_3 by several atmospheric oxidants. Both nitrate radicals and peroxyradicals are predicted to react very slowly with SO_2. Catalysis by water molecules is not able to enhance these reactions. In contrast, carbonyl oxides (Criegee Intermediates) were found to oxidize SO_2 rapidly, in agreement with very recent results by Jiang et al (2010). However, the atmospheric relevance of this finding is dependent on the highly uncertain atmospheric lifetime of the carbonyl oxides.

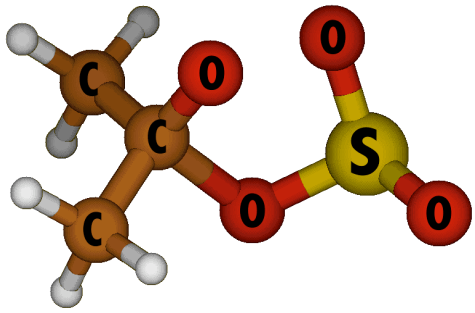

Figure 1. Transition state for the oxidation of SO_2 by 2-propyl carbonyl oxide.

The formation of new nanometer sized particles during so called new particle formation events is ubiquitous in the atmosphere. After condensational growth to sizes relevant for cloud droplet formation, the nanoparticles have a potential to influence the global radiation balance of the atmosphere (Merikanto, et al., 2009).

The number of ground based background stations in Europe where measurements of the size-dependent concentration of neutral or charged nanoparticles take place is becoming higher and higher. However, even if we have a satisfactory characterization of the formation events at these sites, we lack the information where and when these events take place over areas not covered by the network of stations. For example, in favourable regions we expect "hot-spots" with a higher frequency of these events and conversely "cold-spots" where gaseous precursor emissions necessary for the formation are low.

Fortunately, the information about how often particle formation take place over a larger regional area is possible to attain. We explain shortly a method of how this is done.

During new particle formation, particles of around 2 nm diameter are formed and these continuously grow by condensation. The growth can be followed by tracking the geometric mean diameter of the so called nucleation mode. After several hours, the geometric mean diameter can reach sizes around 10 nm or higher. Hence, if we observe particles at a particular site during an event with geometric mean diameters larger than 10 nm, we know they have been formed elsewhere.

Since we know the rate at which these particles grew until they were larger than 10 nm diameter, we also know at which time their size was 2 nm in diameter (growth rate calculations can be found in e.g. Dal Maso et al., 2005; Kulmala et al., 2007). By combining this information with back trajectories, we are able to find out where the actual conception of the 2 nm diameter particles took place. An example of this method can be viewed in Figure 1, where we see that particles detected as 20 nm diameter at evening time at the Vavihill site in southern Sweden, are formed as 2 nm diameter particles 13 hours earlier over the Skagerrak sea.

Conversely, on other days when we fail to observe formation events at our particular site, we get a "no-count" along the back trajectory.

Completing this characterization for all Nordic sites, we get a complete mapping of where these events take place over the Nordic area. Results from this mapping will be presented during the EAC conference.

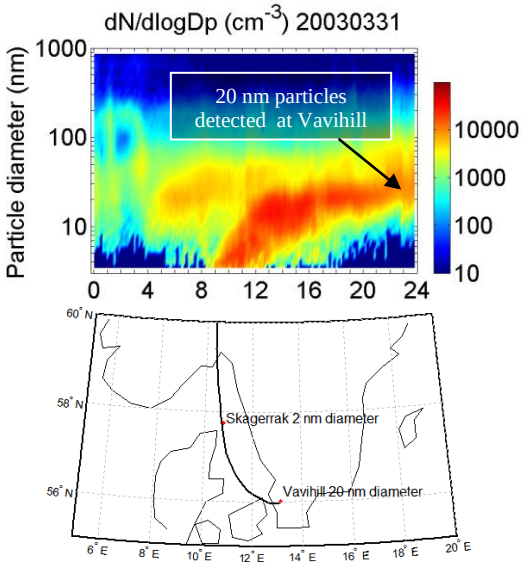

Figure 1. The observed particle number size distribution March 31, 2003 during a formation event at the Vavihill site (upper panel). The detected 20 nm diameter particles at Vavihill around 23:00 hours can be traced back to the time when they were formed as 2 nm particles 13 hours earlier over the Skagerrak sea (lower panel showing the 100 m back trajectory arriving to Vavihill at 23:00).

Presenting author email: ismael.ortegacolomer@helsinki.fi

Climate change is currently one of the central scientific issues in the world, and the ability to reliably forecast climate is crucial for making political decisions that affect the lives of billions of people. According to the Intergovernmental Panel on Climate Change, aerosols remain the dominant uncertainty in predicting radiative forcing and climate change.

According to current best estimates (Merikanto et al. 2009) roughly 20-80% of atmospheric particles are formed from condensable vapours by gas-to-particle nucleation. While new-particle formation is observed everywhere in Earth's atmosphere (Kulmala et al. 2004) the actual birth mechanism of the particles is still unknown.

In terms of the molecular species participating in nucleation, the only thing known for certain is that sulphuric acid is somehow involved in the process. On the other hand, sulphuric acid alone cannot explain the observed particle formation, and several other candidates, both organic and inorganic, have been proposed to participate. These include base molecules such as ammonia or amines and semivolatile organic compounds such as dicarboxylic acids, and organosulphates.

Nucleating clusters in atmospheric conditions are small, consisting of only a few or a few tens of molecules. These clusters are therefore well below present detection limits if they are electrically neutral. Several theoretical methods have tried to describe those clusters, but probably the most successfully has been quantum mechanical calculations. The aim of our work is to use quantum mechanical calculations to improve our knowledge about the molecular mechanisms behind atmospheric nucleation.

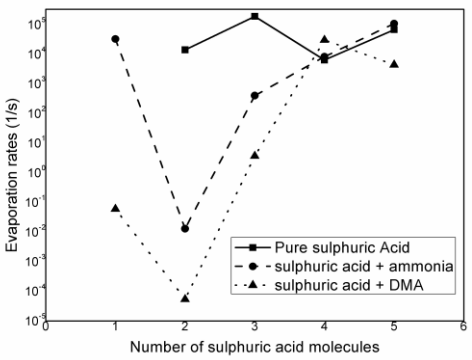

Figure 1. Evaporation rates of different clusters versus number of sulphuric acid molecules in the cluster

We have used a cost-effective multi-step method to study the stability of sulphuric acid clusters containing ammonia, and different amines. Using the calculated formation free energies we have estimated the evaporation rates of each cluster. As can be seen from figure 1, the evaporation rates of clusters containing dimethylamine is smaller compared to pure sulphuric acid clusters and ammonia-containing clusters when there are three or less sulphuric acid molecules. On the other hand, for larger clusters, the presence of just one base molecule does not seem to be enough to stabilize the cluster with respect to acid evaporation.

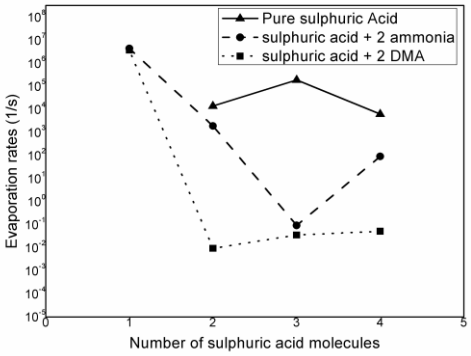

Figure 2. Evaporation rates of clusters containing two base molecules, versus number of sulphuric acid molecules in the cluster

Figure 2 shows how the addition of a second base molecule in the cluster allows the stabilization of larger clusters. In the case of clusters with two dimethylamine clusters, the cluster with two sulphuric acids seems to be the most stable. In contrast, the cluster with three sulphuric acids is the most stable of the clusters containing two ammonia molecules.

These results show how neutral sulphuric acid clusters in the atmosphere require the presence of various base molecules in order to have long enough lifetimes for growth to be possible.

Growth of Particles via Organic Condensation: Is Gas-Phase Chemistry Enough?

There is ample evidence that ultrafine particles often grow much more rapidly than can be explained by condensation of effectively non-volatile constituents such as sulfuric acid. Organic vapors are natural candidates to fill this gap because organics comprise a very large fraction of the total sub-micron aerosol mass, and because organics are often abundant in regions where new-particle formation and growth is observed. The mechanism behind this contribution is another story.

The flux of an organic, i, to a unit surface area can be written as:

$$\phi_i = A\,[C_i^v - a_i C_i^o] = A\,C_i^o\,[S_i - a_i \exp(D_K/D_p)]$$

A is a prefactor describing the velocity normal to the surface and containing any relevant conversions. For condensational growth the useful flux units are $nm\,s^{-1}$ or $nm\,hr^{-1}$. C_i^o is the saturation concentration of i (the saturation vapor pressure converted to mass concentration units in $\mu g\,m^{-3}$). S_i is the saturation ratio, $S_i = C_i^v/C_i^o$. Finally, a_i is the activity of i and $K(D_P) = \exp(D_K/D_p)$ is the Kelvin effect.

Whatever the exact value of the saturation gradient $[S_i - a_i \exp(D_K/D_P)]$, the flux will scale with $A\,C_i^o$. A depends on the mean normal speed ($s^{\perp} = 44\,m\,s^{-1}$ for $M_i = 0.200\,\mathrm{kg\,mole^{-1}}$ at 300 K). For $\rho = 1.4\,\mathrm{g\,cm^{-3}}$:

$$A = 44\,m\,s^{-1} \times \frac{10^{-3}}{\rho} = 0.031\,\frac{nm\,s^{-1}}{\mu g\,m^{-3}} = 113\,\frac{nm\,hr^{-1}}{\mu g\,m^{-3}}$$

Given observed 1-10 $nm\,hr^{-1}$ growth rate of nanoparticles during new-particle formation events, with 3 $nm\,hr^{-1}$ as typical, there must be an excess concentration of about $0.03\,\mu g\,m^{-3}$ to drive the observed growth.

Compounds that are too volatile will drive growth rates that are far too fast if they are supersaturated; however for $C^o = 10^{-2}\,\mu g\,m^{-3}$ the characteristic growth rate is 1 $nm\,hr^{-1}$ for $S = 1$. A deposition rate *slower* than 10 $nm\,hr^{-1}$ for $C^o \geq 0.1\,\mu g\,m^{-3}$ is unlikely, and the observed rates of 2-10 $nm\,hr^{-1}$ would be difficult to maintain (we should see periods with much, much larger growth).

We can constrain the production rate of condensible vapors by assuming a steady state: $P_i \simeq C_i^{ss}(S-1)/CS$, and $C_i^{ss} \simeq 0.03\,\mu g\,m^{-3}$. For $CS \simeq 1 - 10\,hr^{-1}$, $P \simeq 0.03 - 0.3\,\mu g\,m^{-3} hr^{-1}$. At this production rate material in $C^o = 0.01\,\mu g\,m^{-1}$ will have $S > 1$ and material in $C^o = 0.001\,\mu g\,m^{-1}$ will have $S \gg 1$, so we will generate supersaturation much more rapidly than the condensational sink will be able to eliminate it. That is the circumstance where condensational growth will appear to be "kinetic" – the steady-state vapor concentration, which drives condensational growth, will be well above its equilibrium value, so the growth will resemble "non-volatile" uptake.

All of this production must wind up in the condensed phase, and it is near the *maximum* rate for generation of condensible organics under typical new-particle formation conditions; the net production of SOA *mass* must be larger. There will almost certainly be production of semivolatiles with $0.1 \leq C^o \leq 1\,\mu g\,m^{-3}$, and we can only form a few $\mu g\,m^{-3}$ over the 10 or so hours it takes to grow the nanoparticles via condensation. In addition, essentially all of the vapors in the range $10^{-3} \leq C^o \leq 1\,\mu g\,m^{-3}$ need to be produced via gas-phase chemistry. It is plausible that compounds in this range can be produced from vapors with $C^o > 1\,\mu g\,m^{-3}$, but lower volatility is improbable – one generation of gas-phase chemistry can drop volatility by 1-4 decades. Consequently, it seems reasonable that of order 25% of the total SOA formation could be in the range needed to drive nanoparticle growth.

The Kelvin term deserves some attention. As we have written it, $K = \exp(D_K/D_p)$, where $D_K \simeq 7\,nm$ for $\sigma \simeq 0.03\,N\,m^{-1}$. In practice, this shows that we need to generate larger supersaturations to grow the very smallest particles, with $S = e^2 = 7.4$ required to condense onto 3.5 nm particles. For larger $C^o \geq 0.1\,\mu g\,m^{-3}$ it is simply impossible to generate such a large supersaturation in the face of the existing condensational sink. For $C^o \leq 10^{-3}\,\mu g\,m^{-3}$ it is trivial to generate the supersaturation if we can find the chemical source term. Only the $C^o = 10^{-2}\,\mu g\,m^{-3}$ bin will be strongly influenced by the Kelvin term, and the signature would be accelerating growth for $D_p \simeq 7\,nm$. This is exactly what is observed.

Consequently, if a large but not implausible fraction of condensible organic vapors are formed with intrinsic volatilities $10^{-3} \leq C^o \leq 0.01\,\mu g\,m^{-3}$, it is possible for gas-phase oxidation chemistry of organics to drive condensational growth of nanoparticles in new-particle formation events. This narrow window of volatilities is bounded by plausible gas-phase production mechanisms on the low end and the observed particle growth rates on the high end, and even the effect of surface-tension on the smallest particles via the Kelvin effect is consistent with observed growth-rate trends. This does not prove that gas-phase formation of low-volatility compounds alone drives nanoparticle growth, but it does show it almost certainly can.

How accurate are the nucleation event analysis tools?

According to current knowledge, atmospheric nucleation events initiate at a particle diameter of ~1.5 nm. However, until very recently, most field instruments measuring the aerosol size distribution have had a low-end cut-off at ~3 nm. Therefore, several mathematical approaches have been developed in order to quantify nucleation rates at the initial cluster size as well as nucleation mechanisms from the measured distribution data (e.g., Sihto et al., 2006; Kuang et al., 2008).

We have evaluated these analysis tools with over 1200 numerical nucleation events for which the nucleation mechanism and formation rates are known exactly. We have tested the performance of different formulations of the tools as well as the sensitivity of the results to the various assumptions that have to be made in the analysis. In order to resemble the atmospheric measurement data as closely as possible, the model output was regridded into typical size channels of a DMPS instrument with 10-minute time intervals.

We find that calculating the growth rate of sub-3 nm clusters from the time delay between the diurnal curves of H_2SO_4 and 3-6 nm particle concentration can overestimate the growth rate during strong nucleation events. This is because of coagulation scavenging of the clusters to the earlier formed nucleation mode, which can under some conditions lead to apparent negative time delays. However, the cases in which the time delay remains positive but is shortened compared to time delay corresponding to the actual growth rate are more problematic for the analysis.

In general, the particle formation rate at 3 nm (J_3) is captured reasonably well by the analysis tools with 43-97% of the events falling within a factor-of-two accuracy from the actual simulated value. However, the accuracy of the analysed values show clear sensitivity to the specific form of the analysis equations used and assumptions made about the initial size of nucleating clusters. On the other hand, the estimates of the actual nucleation rate at 1.5 nm were clearly less accurate with only 37-59% of the events within a factor-of-two accuracy. The main reason for the large errors is that the analysis methods do not take into account the size-dependence of particle growth rates below 3 nm. Moreover, the results are also sensitive to the assumption made about initial cluster size.

The poor estimates of $J_{1.5}$ can lead to fairly large uncertainties in the nucleation prefactors (i.e. constant P in nucleation equation $J_{1.5} = P \times [H_2SO_4]^k$). However, all the analysis set-ups tested in this study resulted to an order-of-magnitude accuracy for almost 90% of the simulated events. This can be considered reasonable since the coefficients derived from atmospheric data typically exhibit a variation of 1-3 orders of magnitude. This indicates that the high variation of observed nucleation prefactors is not a consequence of inaccuracies in the analysis methods, but a real phenomenon caused by (so far unknown) environmental factors.

Large uncertainties were found also when the analysis tools were used to determine the nucleation mechanism in terms of the number of H_2SO_4 molecules in a critical cluster (i.e. exponent k in previous equation). Although our results suggest that in general the analysis tools tend to overestimate the number of H_2SO_4 molecules in the critical cluster, also significant underestimation was found in up to 41% of the cases. This indicates that one cannot automatically rule out more than 2 sulphuric acid molecules in a critical cluster even if field data shows nucleation exponents in the range 1-2. Our analysis also suggests that combining data from several new particle formation events to scatter plots of H_2SO_4 vs formation rates ($J_{1.5}$ or J_3) and determining the slope of the regression line may not give reliable information about the nucleation mechanism.

The atmospheric processing of soot aerosols leads to a transformation of the agglomerated structure to droplets/crystals with an elemental carbon core due to coating processes (Zhang *et al.* 2008). This affects global climate by transforming net-heating light absorbing hydrophobic black carbon into particles with increasing light scattering cross section and hygroscopicity. The health effects are also expected to vary between the fresh and processed soot. Secondary Organic Aerosols (SOA) contributes to a large fraction of the material that condenses onto soot. A group of important SOA precursors are the light aromatic Volatile Organic Compounds (VOCs). The time scales for the transformation of soot with its corresponding changes in optical and Cloud Condensation Nuclei (CCN) properties are not well known. The aim of this work is to quantify the timescales in processing of soot aerosols using photo-oxidation studies of engine exhaust from light duty diesel vehicles in a smog chamber set-up.

The experiments were conducted in a 6 m^3 Teflon (FEP) smog chamber as described in Nordin *et al.* (2011). Diesel exhaust was injected by a heated ejector dilutor and heated inlet (120 °C), the vehicle used in the experiments was a VW Passat 1.9 TDI (1998). Emissions from the warm idling car or a flame soot generator were then sampled to the smog chamber giving an initial concentration of about 10 µg/m^3 and a size distribution with a geometric mean diameter (GMD) of 80-90 nm. The aromatic precursors Toluene and m-Xylene were injected by evaporation into the smog chamber and after a 30-40 min stabilization period UV lights were turned on. The soot morphology was investigated using a Differential Mobility Analyzer (model 3071, TSI) - Thermodenuder (Custom built) - Aerosol Particle Mass Analyzer (model 3600, Kanomax) (DMA-TD-APM) system which had been calibrated with spherical PSL particles (100, 240 and 350 nm). Particles with mobility diameters between 90 and 300 nm were selected by the DMA. The mass of the fresh (m_{fresh}) and coated soot particles (m_{coated}) were then measured by two adjacent runs, where the TD was set to 300°C to evaporate the organics. From this, the mass growth factor (*Gfm*), defined as the ratio of m_{coated} and m_{fresh} (Pagels *et al.* 2009) was calculated. This together with a Scanning Mobility Particle Sizer (SMPS) provides assessments of the size dependent organic carbon- (OC) and elemental carbon (EC) mass. The light scattering and the CCN properties were measured by a Nephelometer (model Aurora 3000, Ecotech) and a Cloud Condensation Nuclei Counter (model CCN-100, DMT), respectively.

Preliminary results show that a mass increase (growth factor) of about 3-15 (figure 1) due to condensation of organics is necessary for transformation of 90-300 nm soot aggregates into spheres with an effective density of about 1.4 g/cm^3. This transformation decreases the water vapor supersaturation required for CCN activation of 150 nm particles from larger than 2% (fresh soot) to 0.2 % (soot coated with 80% SOA).

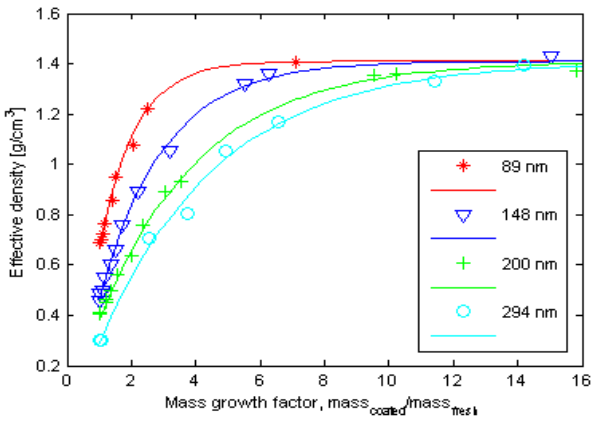

Figure 1. The measured and fitted curve for the effective density as a function of the mass growth factor (*Gfm*). The following fit was used $\rho_{eff}(d_{me}) = \rho_{fresh}(d_{me}) + \left(1.4 - \rho_{fresh}(d_{me})\right)(1 - exp((Gfm - 1)/a(d\_me)))$

The results suggests that particles with a mobility diameter less than 300 nm, which dominate the number concentration, become spheres with a significant increase in hygroscopicity during the experiment time of four hours. The growth factor is used to calculate the OC- and EC-mass which can be utilized as a normalization factor for light scattering cross section and a reference mass for the Soot Particle-Aerosol Mass Spectrometer (SP-AMS).

Presenting author email: thomas@kemi.ku.dk

Humic-Like Substances (HULIS) have been proven to comprise a significant fraction of the organics in various environments. HULIS have attracted a lot of attention because of their ability to efficiently lower surface tension of water solutions and thereby influence hygroscopic growth and cloud condensation nuclei (CCN) activity. However direct measurements are still scarce and the reported hygroscopicity for HULIS samples varies significantly.

This study focuses on elucidating the hygroscopicity of HULIS by applying the same extraction protocol of HULIS to particulate matter (PM) sampled in three very different environments. Filter samples from the rural continental background site Melpitz ($PM_{2.5}$), from a street canyon in Copenhagen (PM_{10}) and from Storm Peak Laboratory (SPL) located 3.2 km asl in Colorado ($PM_{2.5}$) were selected. Here results from the latter are presented.

The extraction of HULIS was carried out by applying the one-step protocol described by (Varga et al, 2001) with minor modifications to facilitate extraction of large amounts of HULIS. Hygroscopic growth was measured with LACIS-mobile. The experimental setup and procedure is very similar to that described by Ziese et al, (2008). A refractive index of 1.63 was assumed for HULIS in the data analysis. The CCN-activity was derived from fitting a sigmoidal function to the activated fraction of particles vs electrical mobility particle diameter where doubly charged particles are accounted for. The CCN-concentration was measured with a DMT CCN-counter and the total particle concentration [CN] was measured with a CPC 3010.

Preliminary results for hygroscopic growth of 200nm HULIS particles originating from SPL are presented in fig. 1. The growth factors (GF) are smaller compared to results for HULIS from Budapest. In fig. 2 the preliminary results for the CCN-activity of the SPL HULIS are depicted. In this case the results are comparable to the results of Ziese et al (2008). Closure between the results for sub- and supersaturated conditions respectively can be obtained assuming a surface tension lower than that of pure water for the wetted HULIS particles, which is in line with what would be expected (Ziese et al, 2008). Based upon the physiographic location of SPL it can be speculated that the SPL-HULIS would resemble HULIS originating from aged biomass burning aerosol (Dinar et al, 2006) – however the results do not indicate that. It could be due to differences in HULIS extraction protocols.

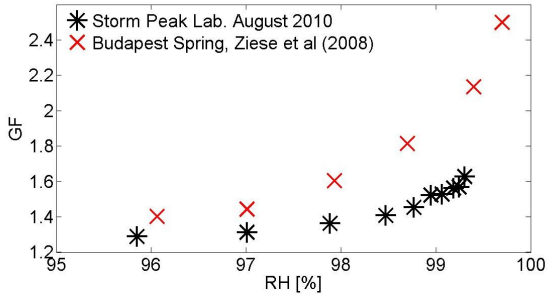

Figure 1. A comparison of growth factors (GF) for HULIS from SPL and Budapest, spring (Ziese et al, 2008).

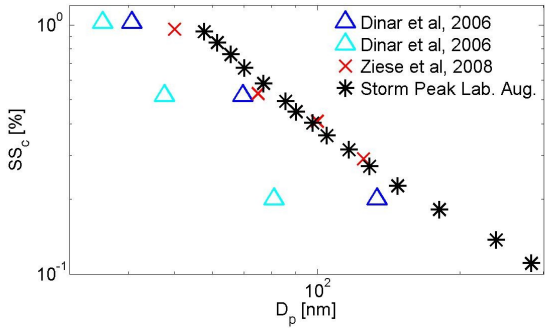

Figure 2. The CCN-activity of HULIS from SPL and from Budapest is comparable (Ziese et al, 2008). The CCN-activity is higher for HULIS originating from biomass burning (blue triangles) and significantly higher for aged biomass burning aerosol (cyan triangles).

Presenting author email: wolfgang.junkermann@Kit.edu

During recent airborne experiments on several occasions very high numbers of ultrafine particles were observed in plumes of fossil fuel burning industrial installations. The high numbers of particles observed might have an impact on the regional production of cloud condensation nuclei concentrations and thus contribute to significant regional cloud microphysics modifications. This has a subsequent effect on the spatial distribution and on the intensity distribution of precipitation. Such precipitation modifications would have a severe impact in pristine semiarid areas with already low total annual precipitation.

We are presenting results from airborne measurements of ultrafine particles in different moderately polluted or pristine areas of the world, also from semiarid areas which are prone to desertification and show how precipitation is affected by increasing CCN numbers. Measured size distributions together with meteorological data are used to calculate source strengths and budgets of ultrafine particles.

We compare source strength of natural and anthropogenic CCN precursor sources and discuss the importance of anthropogenic ultrafine particle emissions based on our experimental results.

Based on the experimental results a significant impact of ultrafine anthropogenic particles on regional climate can be derived, less important on the radiation balance, and with a main effect on the regional water budget.

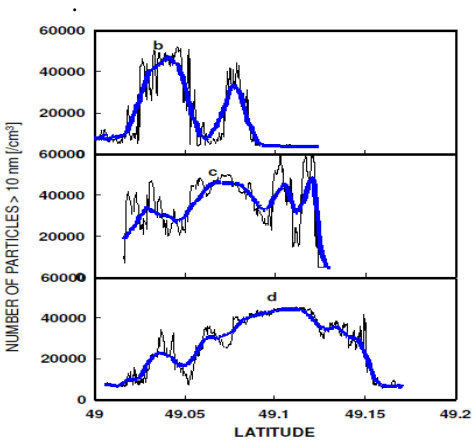

Figure 1. Plume cross sections after 5, 15 and 35 km in a combine power plant / refinery plume (Junkermann et al., 2011).

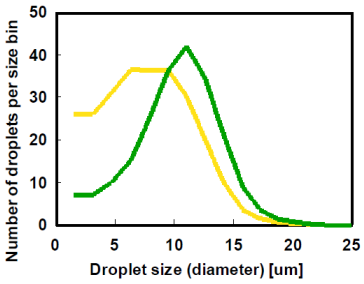

Fig. 2, cloud droplet size distributions in nonprecipitating stratocumulus clouds under low (green) and slightly enhanced CCN number concentrations (Junkermann et al., 2009)

We also show how new cleaning technology for flue gases affects the emissions of fossil fuel burning industries and how this modifies the importance of anthropogenic emissions to the regional CCN budget.

Cloud droplet number concentrations (CDNC) prediction in global climate models (GCMs) is a challenging step for quantifying the cloud radiative properties as large uncertainty is associated with it. In an attempt to elucidate and disentangle one of the reasons for the spread of the shortwave (SW) cloud radiative forcing (CRF) estimated by the GCMs, its sensitivity to cloud droplet parameterization used is assessed under three different meteorological fields using present day emissions.

The sensitivities are computed with the NASA Global Modeling Initiative (GMI). GMI is a global 3D chemical-transport model specifically developed for impact assessment studies that allows easy interchange of different model components while maintaining all others identical. The common modeling framework allows a direct intercomparison of results obtained between alternate representations of aerosol, chemistry and transport processes, without the uncertainties typically associated with comparison of output from different GCMs.

CDNC is computed with the empirical correlation of Boucher and Lohmann - BL (1995), and the physically-based parameterizations of Abdul-Razzak and Ghan - AG (2000), and Fountoukis and Nenes - FN (2005). Sensitivities are examined under three different meteorological fields from the NASA GEOS4 finite volume GCM (FVGCM), the NASA GEOS1-STRAT (GEOS) and the NASA GISS II' GCM (GISS). Computed CDNC is used to calculate the effective radius. The CLIRAD-SW solar radiative transfer model is used online to calculate the cloud optical depth (COD) and the shortwave fluxes from the surface to the top of the atmosphere (TOA). COD is calculated as a function of the effective radius. Evaluation of modeling results (i.e., cloud droplet effective radius, cloud optical depth) is performed against satellite products from Moderate Resolution Imaging Spectroradiometer (MODIS) platform.

Depending on the meteorological fields and droplet parameterization used the annual mean CDNC ranges from 75 to 146 cm^{-3} (Figure 1) with larger differences seen over the heavily polluted regions of the globe (e.g., Europe, China, NE USA), regions affected by long range transport of pollution plumes (e.g., Atlantic Ocean) and regions affected by biomass burning (e.g., S. Africa, S. America). The results for the SW CRF are quite similar across the modeling experiments and, in the global mean. These estimates compare reasonably well with the results derived from the Earth Radiation Budget Experiment (ERBE) analysis.

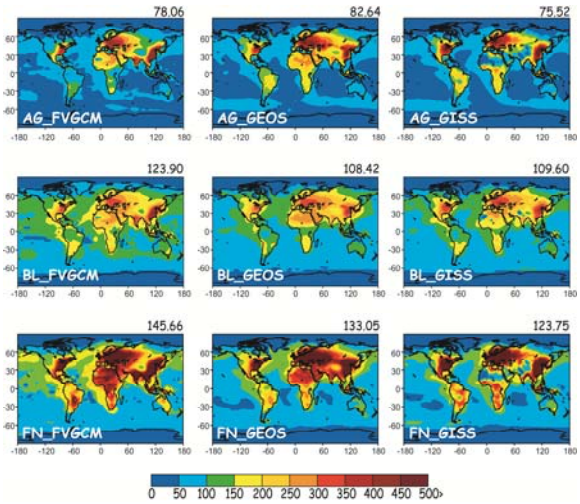

Figure 1. Simulated annual mean cloud droplet number concentrations (cm^{-3}) for all droplet schemes considered and meteorological data sets from FVGCM, GEOS and GISS GCMs. Global annual averages are shown in the upper right hand corner of each panel

Presenting author email: helmuth.horvath@univie.ac.at

Photophoretic forces act on a particle which has an inhomogeneous surface, especially with respect to the accommodation coefficient. Gas molecules incident on it leave the surface after more or less accommodation, resulting in a force and torque on the particle. Due to Brownian rotation of the particle the net force is zero. If the particle is also exposed to an orientating torque, the photophoretic force points in a preferred direction resulting in net photoporetic force. The orienting torque can be caused by gravity or by the earth magnetic field. Photophoretic forces are important if the mean free path of the gas molecules is larger than the size of the particles. This is the case for almost all particles found in the stratosphere and mesosphere. The direction of the photophoretic force can be opposite to gravity and it can exceed the weight of the particle. In that case the particle is lifted upwards, until it reaches conditions where the two forces are equal.

The photophoreic force is influenced by the mean free path of the air molecules, the solar and infrared irradiance, the light absorption of the particle, the orientating torque (which could be magnetic or gravitational) and the variation of the accommodation coefficient on the surface of the particle.

Laboratory observations of photophoresis are available in the literature, obviously for the laboratory conditions (Rohatschek, 1985).. In order to apply these results to the atmosphere, the temperature profile of the atmosphere, the incoming solar flux density, the emitted terrestrial infrared radiation, was determined at each location and at each day of the year and applied to various types of particles.

The equality of the average gravito-photophotetic force and gravity force has been taken as the main condition of layer formation. This requirement has been supplemented by the condition of mechanical stability, that ensures return of the particle to the equilibrium position when an accidental shift in altitude occurs (Cheremisin et al, 2002). It has been assumed that the combination of these two factors creates favourable conditions for accumulation of particles of certain types and sizes at corresponding altitudes, resulting in aerosol layers.

The following classes of particles have been studied: (1) Particles strongly absorbing both solar radiation of visible and terrestrial IR radiation (soot-like particles) (2) Particles strongly absorbing only terrestrial IR radiation (similar to sulfate containing aerosols). Particles with and without a magnetic moment were considered.

Photophoresis can be responsible for aerosol layer formation at altitudes of 20, 30, 50, 70 and 85 km. The layers form in specific geographic regions and at certain seasons An example for time dependent locations where particles will be in a stable position is shown in figure 1.

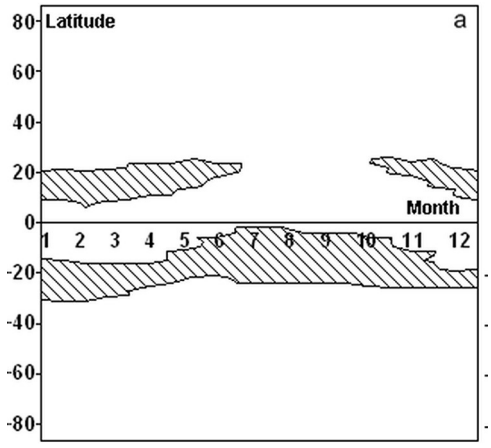

Figure 1. Seasonal-latitudinal map of stratospheric levitation areas for strongly absorbing IR radiation particles

Session 6C: Smog Chamber Experiments and SOA 2

Simulating secondary organic aerosol (SOA) formation over Europe using the volatility basis-set approach (VBS) in the online coupled model COSMO-ART

Eleni Athanasopoulou[1], Heike Vogel[1], Max Bangert[1], Christoph Knote[2], Bernhard Vogel[1], Ben Murphy[3], Alexandra Tsimpidi[4], Spyros Pandis[3,4]

Keywords: SOA (Second. Organic Aerosols), aerosol modeling, volatility basis-set.
Presenting author email: eleni.athanasopoulou@kit.edu

COSMO-ART is a recently developed regional model that couples meteorological and air quality processes online (Vogel et al., 2009). Comparisons of aerosol predictions against measurements suggested an underestimation of the total aerosol mass, which was attributed mainly to low organic aerosol (OA) predictions (Knote et al., 2010). This finding became the stimulation for revising SOA treatment within COSMO-ART, presented in the current study.

Previous research suggests that the models' inability to reach OA observations is strongly related to gas-particle partitioning of all (thousands) organics emitted and formed into the atmosphere, but not in simulations. An efficient way to incorporate this chemical evolution of organics into modelling (aging), is their group treatment by saturation concentrations (VBS) (Donahue et al., 2006).

Recent model applications using VBS confirm model's improved efficiency in predicting OA mass (Murphy and Pandis, 2009; Tsimpidi et al., 2010 etc). According to their results, SOA can represent more than 50% of total OA mass, while their absolute values can reach more than 5μgm^{-3}, which seems promising for improving COSMO-ART performance (Fig. 1).

In the framework of this study, COSMO-ART is modified to include the VBS treatment of SOA. Nine biogenic and anthropogenic SOA precursors (higher alkanes and alkenes, terpenes, isoprene) are grouped into 4 surrogate species with effective saturation concentrations of 1, 10, 100, 1000 μgm^{-3}, modified according to the spatial-temporal variation of temperature (Clausius-Clapeyron eq.). Aerosol yields after each precursor's oxidation to OH, O_3 and NO_3^- alter with its condensation effectiveness and are a combination of the low and high NOx mass yields used in Murphy and Pandis (2009). Further oxidation of surrogate species decreases their saturation concentration by 1 order of magnitude (aging) and increases their mass by 7.5% (to account the oxygen added).

The VBS approach is then coupled with the existing gas-particle partitioning module and with the chemical mechanism RADMKA (Regional Acid Deposition Model Version Karlsruhe). The simulation domain covers Europe with an horizontal grid size of 14km and 40 vertical layers up to a height of 20km. The meteorological initial and boundary conditions are achieved from the IFS model of ECMWF for May 2008. COSMO-ART results by applying the prior (SORGAM) and the current (VBS) SOA module are inter-compared and evaluated against field measurements of OA collected during the EUCAARI campaign for selected stations.

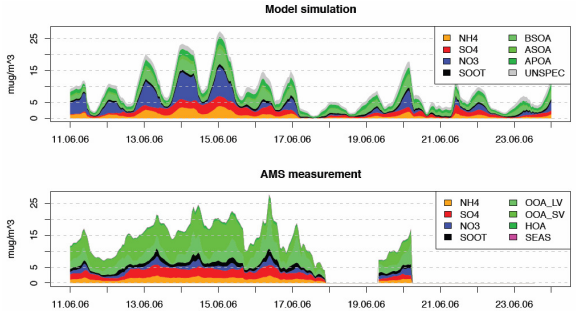

Figure 1. Evaluation of COSMO-ART aerosol composition AMS campaign measurement (PSI) in Payerne (CH) (Knote et al., 2010)

A similar grouping and aging approach used in global applications, showed an effect on CCN concentrations, due to the enhanced condensation and particle growth (Yu, 2011). The fully coupled approach used by COSMO-ART, gives to this study the opportunity to investigate the feedback of the VBS approach on cloud formation. Results will be presented during the conference.

Studies using photochemical "smog", or aerosol, chambers can provide valuable insights into the complex multiphase processes leading to the formation and transformation of atmospheric particulates. As part of the Aerosol Coupling in the Earth System (ACES) project, a series of novel experiments were carried out at the Manchester Aerosol Chamber in order to investigate the chemistry and microphysics of the formation and transformation of biogenic secondary aerosols under realistic conditions. A selection of compounds covering a wide range of reactivity including isoprene (C_5H_8), monoterpenes (isomeric formula $C_{10}H_{16}$), sesquiterpenes (isomeric formula $C_{15}H_{24}$) and oxygenated VOCs have been studied in detail.

The chemical composition of the formed SOA was measured on-line using an Aerodyne Time-of-Flight Aerosol Mass Spectrometer (ToF-AMS). A hygroscopicity tandem differential mobility analyser (HTDMA) and a cloud condensation nuclei (CCN) counter were used to probe the hygroscopic properties and of the aerosols in the sub- and super-saturated regimes, respectively. A proton transfer mass spectrometer was used to study the evolution of the gas phase oxidation products.

This paper presents a comprehensive overview of the chemical composition, hygroscopicity and cloud condensation nuclei (CCN) properties secondary organic aerosols formed from five structurally different biogenic VOCs (β-caryophyllene, limonene, myrcene, linalool, α-pinene), and compares them to those of SOA formed from the photooxidation of real plant emissions (Silver Birch). A discussion of results of the use of organic (Hamilton et al., 2010) and inorganic seed will be presented and compared to those obtained from nucleation experiments.

Results obtained using the ToF-AMS showed that SOA formed from the above precursors have a wide range of chemical properties, as expressed by the fraction of mass fragment 44 (a typical marker for highly oxygenated organic molecules) and 43 (a possible marker for less oxygenated organic molecules) to the total organic signal. Furthermore, the effect of photochemical ageing on those properties was not uniform across all five precursors. A link of these results to the findings of the hygroscopic properties of the same SOA particles and their CCN behavior will be presented and discussed.

This work was supported by the UK Natural Environment Research Council (NERC) through the Aerosol Properties, PRocesses And InfluenceS on the Earth's climate (APPRAISE) programme. M. Rami Alfarra is supported by NERC's National Centre for Atmospheric Science (NCAS).

In order to properly represent and predict effects of aerosols in climate systems, an accurate description of their formation and properties is needed. Volatile Organic Compounds (VOC) acting as aerosol precursors and forming secondary organic aerosol (SOA) can originate from both biogenic and anthropogenic emissions. A lot of emphasis has been to understand these systems separately (Hallquist 2009) but in the atmosphere it will be a more complex situation where the anthropogenic emissions will be subjected to oxidation and transformation also after being mixed with biogenic emission.

During spring/summer 2010 two campaigns in Forschungszentrum Jülich, Germany were conducted with focus on Anthropogenic - Biogenic Secondary Organic Aerosol (ABSOA). The measurement campaigns took place in the JPAC (Jülich Plant Aerosol Chamber) and SAPHIR (Simulation of Atmospheric PHotochemistry In a large Reaction chamber) facilities with the objective to clarify how interactions of biogenic and anthropogenic trace gases influence SOA formation with regard to mass, number, composition and properties. In the JPAC chamber the biogenic emissions originated from real boreal plant emissions (Mentel 2009) and the anthropogenic emissions were represented by toluene and xylene. The large outdoor SAPHIR chamber enables studies of tropospheric chemistry and photochemical models under natural conditions (Rohrer 2005) and here the BVOCs were represented by limonene and α-pinene and AVOC by benzene, toluene and xylene. The systems were investigated individually (BSOA, ASOA) and mixed (ABSOA).

Several instruments were used for both physical and chemical characterisation of aerosol e.g; Aerosol Mass Spectrometer (ToF-AMS), Volatility Tandem Differential Mobility Analyser (VTDMA), Hygroscopicity Tandem Differential Mobility Analyser (HTDMA), Cloud Condensation Nuclei Counter (CCN-C) and Scanning Mobility Particle Sizer (SMPS) systems. In the SAPHIR campaign aerosol filter samples were collected for offline analysis with respect to tracer molecules. In addition the gas phase chemistry and partitioning was monitored using ozone and NO_X analyzers together with PTR-MS.

Example of the characterisation was the volatility measurements, using the VTDMA system. The VTDMA comprises: an initial Differential Mobility Analyser (DMA) where a size fraction of the aerosol particles is selected; the oven unit where the evaporation and adsorption of the volatile fraction occurs and a final SMPS system where the residual particle number distribution is measured. A less volatile SOA gives a larger residual particle size distribution compared to a more volatile SOA. (Jonsson 2007).

Generally, the aerosol thermal characteristics were comparable in the SAPHIR and the JPAC experiments and the induced aging produced less volatile aerosol particles for all investigated systems. However, the two system are rather different in aging characteristics where the JPAC aerosol were produced in a flow system with residence time around an hour while the SAPHIR aerosol were aged during several hours/days.

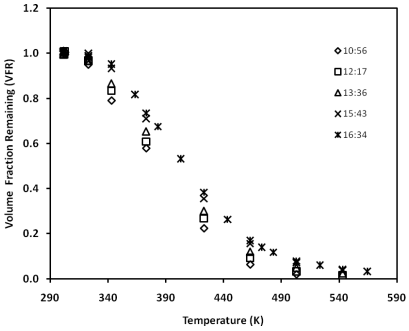

Figure 1. Volatility of ageing (UTC hh:mm) of SOA from mixed anthropogenic and biogenic volatile organic compounds in the SAPHIR camber.

In the frame of the EUCAARI (European integrated project on Aerosol Cloud Climate Air Quality Interactions) project, organic aerosol characterization and source apportionment were carried out during nine intensive observation periods (Table 1) by means of proton-Nuclear Magnetic Resonance (^{1}H-NMR) spectroscopy. Analogously to more established methodologies employing mass spectrometric techniques, we exploit factor analysis for the identification of a small number of recurrent chemical classes. In particular, NMR analysis provides a categorization of water-soluble organic aerosols based on spectral fingerprints and characteristic functional groups distributions.

Table 1. Summary of the EUCAARI intensive observation periods (IOPs) providing NMR datasets

Factor analysis of NMR spectral datasets is already widely used for the analysis of complex organic matrices in several scientific fields, from pharmaceutics to food chemistry and medical chemistry. Deconvolution of main spectral profiles within each time series of ^{1}H-NMR spectra of submicron aerosol samples was conducted using non-negative factor analysis techniques, such as Positive Matrix Factorization (PMF), Non-negative Matrix Factorization (NMF), and Multivariate Curve Resolution (MCR).

The interpretation of the spectral profiles and their attribution to specific sources (i.e., anthropogenic and biogenic SOA, biomass burning POA) of water-soluble organic particles in the atmosphere is based on the comparison with a unique library of reference spectra recorded during laboratory studies or in the field at near-source stations.

Some recurrent profiles were identified in different IOPs of EUCAARI project and their contribution to the total mass of OA were quantified. In particular the principal recurrent spectral profiles isolated were: (a) biogenic Secondary Organic Aerosol (SOA); (b) wood burning aerosols; (c) HUmic Like Substances (HULIS); (d) other complex aromatic and aliphatic oxidized compounds enriched in aliphatic chains; (e) MetanSulfonicAcid (MSA) and (f) low-molecular weight amines.

The results of this statistical analysis were compared to those of existing methodologies of factor analysis applied to atmospheric aerosol spectroscopic datasets (AMS) collected in the same period for each measurement campaign.

Our findings indicate that factor analysis applied to NMR atmospheric datasets can efficiently complement AMS in lumping the complex oxidized organic mixtures into chemical classes characterized by specific sources or ageing states. More specifically, NMR spectroscopy provides a better discrimination between aromatic and aliphatic structures, which is critical for the quantification of biomass burning products, and for the discrimination between biogenic and anthropogenic SOA.

Secondary organic aerosol (SOA) comprises a major fraction of the submicron aerosol mass (Hallquist *et al*, 2009). It consists of thousands of different compounds, and undergoes permanent chemical evolution during the atmospheric aging process, resulting in an increasingly oxidized aerosol (Jimenez *et al* 2009). As a result of this, chemical features of SOA (such as unit mass spectra from aerosol mass spectrometry) become increasingly similar with increasing aging time. This is good news for modeling purposes, as the specific SOA source becomes less important for the quantification of the SOA impact e.g. on climate. However, this also means that it is difficult to perform an apportionment of the SOA to its various sources, e.g., by positive matrix factorization (Lanz *et al* 2007).

We have investigated SOA formation from a variety of sources, including both wood combustion and diesel exhaust, with either the full exhaust or only the gaseous precursors (Chirico *et al* 2010; Heringa *et al* 2011), using the setup shown in Figure 1. In addition, SOA formation from anthropogenic and biogenic model precursors such as trimethylbenzene and α-pinene was investigated. All experiments were performed at the PSI smog chamber (Paulsen *et al* 2005).

We characterized the formed SOA using a high resolution time-of-flight aerosol mass spectrometer. The various fragments obtained from the high-resolution spectra were tested for characteristic differences using a variety of methods. The results will be discussed along with a comparison to high-resolution aerosol mass spectra from ambient samples.

Understanding particle formation by alkene-ozone reactions: Experimental studies and theoretical simulations

Presenting author email: bonn@iau.uni-frankfurt.de

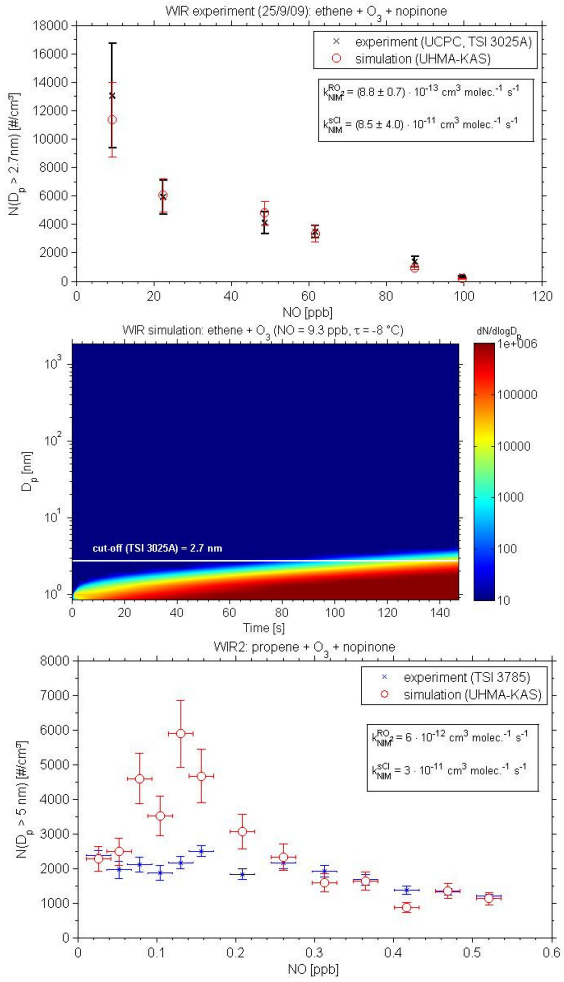
Abstract
The formation of secondary organic aerosol particles is one of the most progressing aspects with respect to composition and the increase of knowledge about heterogeneous processes. Besides partitioning and ageing effects, the exact mechanistic understanding of the formation process needs to be unravelled. From previous studies on the suppressive influence of water vapour we can assume the start of the nucleation process by so-called secondary ozonides. These are expected to be activated as clusters by large organic peroxy radicals (RO_2). In order to learn about the exact role of different radicals, i.e. RO_2 and HO_2 as well as Criegee biradicals (sCI), we conducted flowtube experiments with simple alkenes in the presence of ozone and nopinone and varied the nitrogen oxide (NO) concentration. NO increased nucleation at very low values while acting suppressive at intermediate and higher concentrations. The observed total particle number concentration was simulated by an aerosol dynamics model with implemented gas-phase chemistry and nucleation hypotheses. With this set-up we were able to reproduce the observed particle number concentration in different systems, i.e. alkenes and concentration levels. This allowed the set-up of a new mechanistic nucleation pathway, including the interaction of RO_2 and sCI radicals in order to form new detectable particles capable in explaining the suppressive effect of isoprene on nucleation. From these studies it seems likely that an organic nucleation might be an atmospheric phenomenon too, depending on the concentration and structure of present VOCs.

Methods
(Experimental) Particle formation has been studied in a vertical flow chamber with a constant temperature at 24°C. Mixtures of alkenes and NO were performed a priori in stainless steel bottles and used thereafter. Ozone was produced online by a pen-ray lamp and nopinone added by a permeation oven. Particles were detected by two different counters: WCPC (TSI 3085, cut off = 5 nm) and UCPC (TSI 3025A, cut off = 2.7 nm). The concentrations of the gases were either calculated by mixing volume (ethene) or measured by PTR-MS as well as ozone and NO_x analysers.
(Theoretical) Based on the University of Helsinki Multicomponent Aerosol model (UHMA, Korhonen et al., 2004) the detailed chemistry of propene and ethene was calculated and initiated by the measured values.

Findings
A new particle formation mechanism was implemented and two unknown rate constants fitted:

(a) RO_2 + SOZ: $k_a = (0.9\text{-}3)\times10^{-12}$ cm^3 molec.$^{-1}$ s^{-1}
(b) sCI + SOZ: $k_b = (6\text{-}8.5)\times10^{-11}$ cm^3 molec.$^{-1}$ s^{-1}

Taking into account the difference in structure of propene- and ethene sCIs, both constants agree well and a nucleation occurs using both radicals in turn.



.
Fig. 1: Ethene measurements and simulations (top and centre) as well as propene measurements (bottom).

Conclusions
It was obtained that NO and HO_2 radicals act suppressive, with a competition of individual radical reactions especially with RO_2. The production of more water-soluble compounds by HO_2 is not supportive.

Ammonium nitrate aerosol exhibits highly scattering properties across the solar spectrum. Further to this, it displays hygroscopic tendencies (Tang, 1996), allowing enhanced water uptake for a given relative humidity. Consequently, its ability to scatter incident solar radiation is increased leading to an enhancement of the aerosol direct radiative forcing. Anticipated reductions in sulphur dioxide in polluted regions will result in an increase in the availability of ammonia to form ammonium nitrate as opposed to ammonium sulphate. Consequently, the relative importance of ammonium nitrate to the aerosol burden is likely to increase.

This paper presents an assessment of the contribution, properties and impact of ammonium nitrate upon the European aerosol burden. In-situ measurements of aerosol properties made onboard the UK Facility for Airborne Atmospheric Measurements (FAAM) BAe-146 aircraft will be presented. The aircraft employs a suite of aerosol instruments, which resolve the chemical composition, number size distribution, optical and hygroscopic properties of the in-situ aerosol population. This includes an Aerodyne Aerosol Mass Spectrometer (AMS) which measures the size resolved chemical composition of both volatile and semi-volatile particulate matter (Canagaratna *et al.*, 2007). The measurements were conducted as part of the EUCAARI-LONGREX (European Integrated Project on Aerosol Cloud Climate Air Quality Interactions–LONG Range EXperiment) and APPRAISE-ADIENT (Aerosol Properties, Processes and influences on the Earth's climate – Appraising the aerosol direct impact on climate) campaigns. Science flights were conducted across Europe, during predominantly clear sky conditions during 2008.

Ammonium nitrate was found to dominate in North-Western Europe during episodes of high pollution, reflecting the enhanced NO_x and ammonia sources in this region. Ammonium nitrate and organic matter were often observed to increase with altitude in the atmospheric boundary layer. This was attributed to partitioning of semi-volatile gas phase species to the particle phase at reduced temperature and enhanced relative humidity. Increased ammonium nitrate concentrations in particular were found to strongly increase the ambient scattering potential of the aerosol burden. During particularly polluted conditions, increases in boundary layer aerosol optical depth of 50-100% were estimated to occur due to the observed increase in secondary aerosol mass with altitude and associated water uptake. These enhancements significantly increase the direct aerosol radiative forcing. Such increases have major ramifications for regional climate predictions as semi-volatile components are often not included in aerosol models.

Our observations over North-Western Europe indicate that failure to include the semi-volatile behaviour of ammonium nitrate will result in significant errors in predicted aerosol direct forcing.

The ability of a sophisticated regional aerosol transport model to represent the complex spatial distribution of ammonium nitrate will be explored. This will include the observed horizontal spatial gradients in North-Western Europe and in particular the vertical distribution of the aerosol.

Keywords: anthropogenic aerosols, optical properties, ADIENT, direct effect.
Presenting author email: e.j.highwood@reading.ac.uk

The direct effect and radiative forcing of atmospheric aerosols depends crucially on their so-called optical properties, such as extinction co-efficient, single scattering albedo and asymmetry parameter. These in turn depend on microphysical properties of the aerosols specifically size and composition. The complexity of atmospheric aerosols requires synergistic use of models and measurements in order to provide this information for use in climate models.

The ADIENT and EUCAARI projects have provided a new body of measurements of aerosol composition, microphysical and optical properties within anthropogenically perturbed air masses across western Europe. In particular, co-incident measurements of aerosol composition and radiative properties were made onboard the Met Office/ NERC Facility for Airborne Atmospheric Measurements BAe146.

In this talk, aerosol composition as seen by an CTOF-AMS (Drewnick et al, 2007) and black carbon mass as seen by an SP2 (Schwarz et al, 2006; McMeeking et al, 2010) will be used together with best estimates of refractive indices, measured size distributions and a Mie scattering code will be used to model the optical properties of aerosol from a number of flights during the ADIENT and EUCAARI projects. The resulting scattering and absorption will be compared against co-incident measurements from a nephelometer and Particle Soot Absorption photometer. The degree to which "optical closure" can be achieved and the influence of uncertainty in assumed refractive index of various aerosol components will be discussed (illustrated in Figure 1).

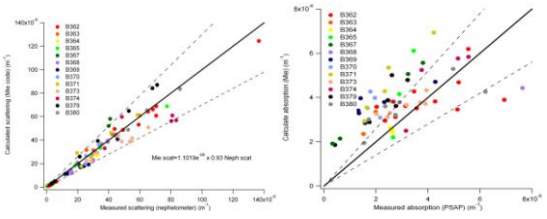

Figure 1. The closure obtained between a) scattering and b) absorption modelled using assumed refractive indices, measured size and composition and observations from the nephelometer/PSAP

Additionally, the variation of single scattering albedo and aerosol optical depth across Europe from the FAAM EUCAARI-LONGREX flights (Morgan et al, 2010; McMeeking et al, 2010; Hamburger et al 2010) and ADIENT flights around the UK will be presented. The hygroscopicity of the aerosol encountered will also be discussed.

ADIENT satellite based aerosol direct radiative forcing

G.E. Thomas[1], N. Chalmers[2], B. Harris[2], E.J. Highwood[2] and R.G. Grainger[1]

[1]Atmospheric, Oceanic and Planetary Physics, University of Oxford, Oxford, OX1 3PU, UK
[2]Department of Meteorology, University of Reading, Reading, RG6 6BB, UK
Keywords: ADIENT, aerosol direct effect, radiative forcing, GlobAEROSOL.
Presenting author email: gthomas@atm.ox.ac.uk

Atmospheric aerosols play an important role in determining the radiative balance of the atmosphere, both directly (Yue et al., 2006) and through their interactions with clouds (Lohmann and Feichter, 2005). However our knowledge of the radiative impact of aerosol on over a long term, global scale remains very uncertain, due to the variable nature of aerosol loading and composition. Thus, aerosols remain one of the primary uncertainties in our understanding of the climate system (IPCC, 2007).

As part of the ADIENT project, new regional estimates of the radiative forcing due to the direct radiative effects of aerosols have been generated, based on the GlobAEROSOL dataset (Portela et al. 2009). GlobAEROSOL provides a range of global datasets of aerosol properties derived from European satellite sensors, running from 1995—2008. Data from the Advanced Along Track Scanning Radiometer (AATSR), processed using the Oxford-RAL Aerosol and Cloud (ORAC) retrieval (Thomas et al. 2009), have been used in this project.

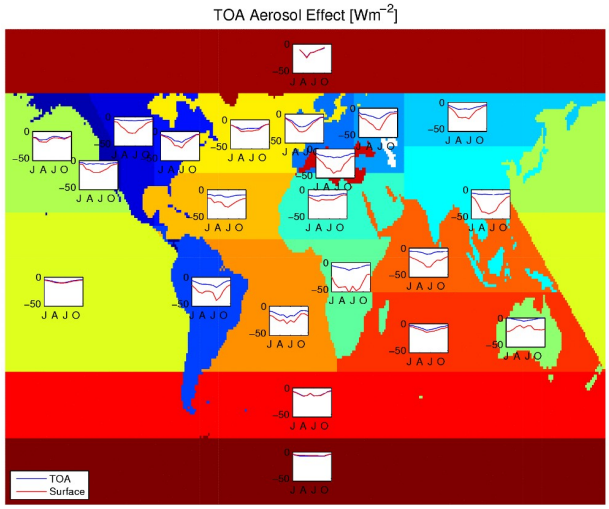

Figure 1. Monthly radiative effect of aerosol for each region at the top and bottom of the atmosphere.

Monthly radiative transfer calculations have been performed with the Edwards and Slingo (1996) RTM across 22 regions covering the globe (11 land, 9 ocean and 2 polar regions) for the year 2006. An extensive error characterisation has been performed for each of these regions, by comparison of the GlobAEROSOL aerosol optical depth with AERONET and by testing the sensitivity of the radiative transfer to model parameters (e.g. aerosol properties, surface albedo). Additionally, high spatial (1x1°) resolution and daily calculations have been performed to characterise the effects of temporal and spatial averaging. These errors have been propagated through the radiative transfer calculations to provide 1-σ uncertainty estimates for the resulting radiative forcings.

This talk will present the results of this analysis for the first time, and compare them with other estimates of the direct aerosol radiative forcing; both measurement and model based.

ADIENT is a UK Natural Environment Research Council project (grant number NE/EO11187/1) under the Aerosol Properties Processes and Influences on the Earth's Climate (APPRAISE) programme.

Testing methods to derive top of the atmosphere reflected shortwave fluxes in the presence of aerosol during the ADIENT campaign: application to GERB and SEVIRI

H.E Brindley, A.P. Georgiadis, and J.E. Russell

Department of Physics, Imperial College, London, SW7 2AZ, UK
Keywords: satellites, shortwave fluxes, aerosol radiative effect
Presenting author email: h.brindley@imperial.ac.uk

Due to their fifteen minute temporal resolution, the combination of the narrowband Spinning Enhanced Visible and InfraRed Imager (SEVIRI) and the Geostationary Earth Radiation Budget (GERB) instruments on the Meteosat Second Generation series of satellites offers an unprecedented opportunity to track the evolution of both natural and anthropogenic aerosol and assess their associated radiative impact over the approximate 60°S-60°N,60°E-60°W region viewed by the instruments. However, as noted in previous studies (Brindley and Ignatov, 2006), the aerosol retrieval algorithm used to generate optical depths in the standard GERB products uses one fixed aerosol model which may not be appropriate for specific aerosol events. In addition, fluxes are typically derived from satellite observed radiances via the application of an angular distribution model (ADM) selected according to scene type. At present, shortwave (SW) fluxes derived from the observed GERB radiances do not contain a treatment to account for the impact of aerosol on the anisotropy of the radiance field, an omission which will result in angle dependent SW flux biases (Brindley and Russell, 2008).

In this paper we first seek to evaluate two methodologies that have been proposed to correct for these SW flux biases. The first, introduced by Loeb et al. (2003), involves the application of a theoretical correction to clear-sky ADMs derived from the Clouds and the Earth's Radiant Energy System (CERES) instrument to account for the presence of aerosol. The second, developed by Zhang *et al.* (2005), again uses CERES observations, in this case building ADMs as an explicit function of near surface wind speed and aerosol optical depth.

To perform the analysis we focus on periods and locations sampled under the auspices of the Appraising the Direct Impacts of AErosol oN ClimaTe (ADIENT)/European Integrated Project on Aerosol Cloud Climate Air Quality Interactions (EUCAARI) projects. We apply both methods to co-located GERB and SEVIRI data and see a significant reduction in the instantaneous direct radiative efficiency of aerosol calculated using the GERB observations as they stand, and after application of the new ADMs (Figure 1). By considering the homogeneity of the derived fluxes as a function of solar and viewing geometry we also conclude that for the conditions sampled here, the aerosol correction method developed by Loeb et al. gives the most reliable results.

We then focus on a specific flight off south-eastern England during May 2008 to assess whether radiative closure can be achieved using the recommended flux conversion and the observed aircraft data. Whilst a limited closure is possible, the aerosol optical depths retrieved using aerosol optical properties inferred from the aircraft tend to be somewhat smaller than those recorded by nearby Aerosol Robotic Network (AERONET) stations. Better agreement on this wider spatial scale is obtained using the standard fixed aerosol model. The results highlight the effect of small scale inhomogeneities in aerosol composition on satellite derived aerosol fields, and the implications for calculations of their associated direct radiative effect.

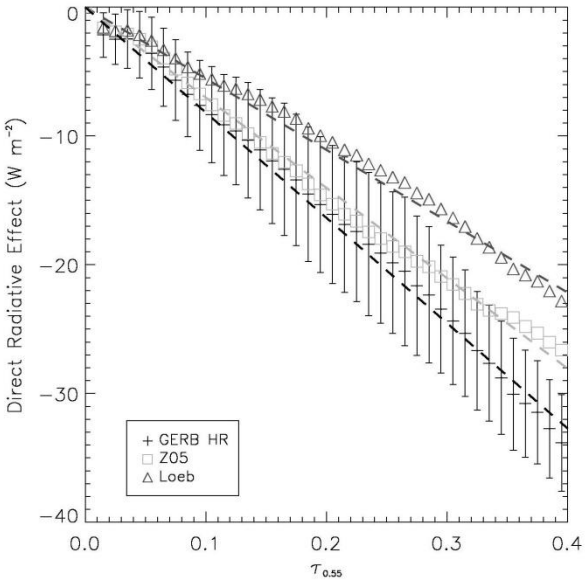

Figure 1. SW Direct Radiative Effect as a function of aerosol optical depth at 0.55 microns (τ_{055}). GERB HR indicates the original GERB fluxes, Z05 and Loeb are fluxes obtained using the Zhang *et al* ADMs and Loeb *et al* aerosol correction method respectively

Keywords: nanoparticle, sizing, photon correlation, LDA
Presenting author email: pjani@sunserv.kfki.hu

First nanoparticle measurements were performed with serial manufacture photon correlation Laser Doppler Anemometer (Nano-LDA). The system was developed to monitor the number concentration and individual velocity and size of nanoparticles simultaneously. Using a backscattering arrangement there is no need for high precision alignment procedure.

The high collection efficiency combined with high QE single photon counting makes it possible to reach the nanometer size range. Photon correlation technique was used for data processing of single photon count events to generate the cumulative autocorrelation function and its FFT. This data contains the mean velocity of the measured aerosol flow. However the special technique for burst selecting and burst processing opens the way for the data processing of individual particles. By this way the particle concentration, velocity and size histogram can be calculated too. The size estimation is based on the amplitude technique combined with a model-based iterative parametric method (Vámos 2010).

After the first functional tests of the system (Jani 2010), measurements on monodisperse paraffin particles were performed below 2µm. The particles generated by PALAS AGF 2.0 iP have ca. 250nm average diameter with approximately lognormal size distribution.
The particle flow was diluted with filtered air and lead through a Differential Mobility Analyser (http). The separated particles were lead to the measurement volume of the LDA system.

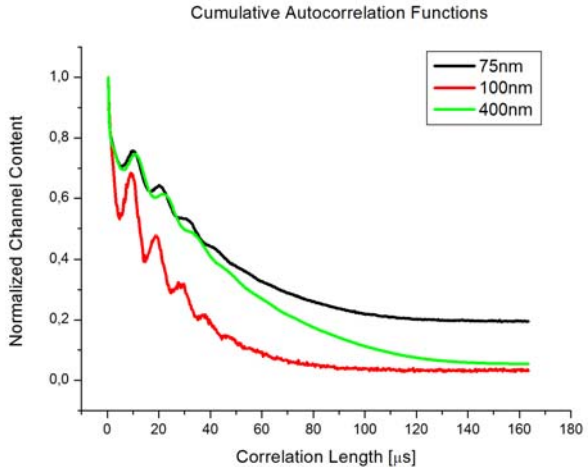

Figure 1. Normalized autocorrelation function curves from paraffin particles separated by DMA

For the high dynamic range of the scattered intensity neutral density filter range is incorporated in the Nano-LDA permitting to select illumination intensity with 1:10^5 ratio.

Successful measurements were carried out for mean particle sizes 75nm, 100nm, 200nm, 300nm, 400nm and 500nm. Obtained autocorrelation functions are plotted on Figure 1 normalized to zero channel content. For lower particle sizes the scattered intensity decreases with the sixth power of the particle diameter. By this way the SNR for the 75nm particles decreases as it can be seen in the graph.

The FFT of the cumulative autocorrelation function is calculated and smoothed with the well-known parabolic interpolation method to reach the 1% velocity measurement accuracy (Figure 2).

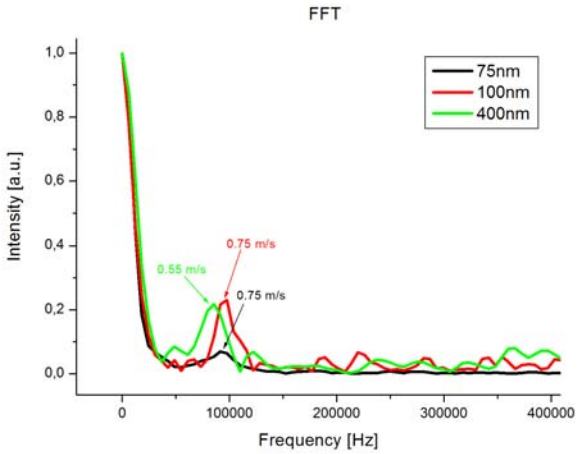

Figure 2. Normalized FFT curves from paraffin particles separated by DMA

Conclusion

The Nano-LDA proved itself to be sensitive for particles down to 75 nm. The recorded ACF curves show high modulation depth with tolerable SNR even for 75nm particles. It is not presently clear whether the aerosol generator has outputs in the even lower size ranges.

In consequence of the small measurement volume 10^7 particle/cm^3 concentration can be reached.

There is considerable uncertainty regarding the effects of soot containing aerosols on climate and human health. Investigating these effects is complicated by the fact that airborne soot is notoriously difficult to quantify. This is partly due to the ambiguity of 'soot'. Various techniques exist which utilize the effective light absorption or low volatility as means of quantification of airborne soot. The operationally defined quantities measured by these techniques are not necessarily comparable. Furthermore, it is desirable to measure soot as one chemical category among others rather than as a stand alone parameter.

Aerosol Mass Spectrometry has recently emerged as a powerful technique for on-line measurements of particulate composition. The most widely used device, the Aerodyne Aerosol Mass Spectrometer (AMS), operates by means of flash vaporization due to impaction on a heated (600 C) surface. The low volatility of soot makes it a refractory species, i.e. it is not measured by the standard AMS. In order to address this problem a Soot Particle (SP) module was developed, which vaporizes soot by means of a 1064 nm Nd-YAG laser.

In this study an SP-AMS was used to measure soot in diesel exhaust from a light duty vehicle. The exhaust was artificially aged by adding SOA precursors such as toluene and m-xylene and exposing the mixture to UV irradiation in a 6 m^3 smog chamber (Nordin et al 2011) for five hours. The resulting SOA condensation enabled investigations into the difference in instrumental response between fresh and aged soot. Soot particles produced by means of a diffusion flame propane soot generator were also included in the study, to determine the suitability of these as substitute for exhaust particles.

Two complementary techniques were used to validate the measured soot content of the aerosol, Particulate Soot Absorption Photometer (PSAP 3λ, Radiance Research and PSAP 1 λ, custom built) and Aerosol Particle Mass Analyser (APM, model 3600, Kanomax). The PSAP measures light absorption of a filter onto which particles are deposited. From this quantity a mass loading of soot is inferred, taking into account light scattering simultaneously measured with a Nephelometer (Ecotech, Aurora 3000, 3 λ). With an APM one determines the mass of charged aerosol particles through balancing centrifugal and electrostatic forces. In these experiments a Differential Mobility Analyzer (DMA, TSI, model 3071) and thermo-denuder (TD, custom built) were used in combination with the APM. By denuding the sampled aerosol at 300 C, the mass fraction of soot in particles can be deduced.

Throughout the campaign, the SP-AMS was used with both the standard vaporization device and the soot vaporisation module present. The laser was typically engaged in five minute intervals separated by an hour, while the standard device was engaged continuously. This is a compromise which enables soot mass measurements while retaining the capabilities of a normal AMS, producing data which is comparable with that of other studies. The soot and SOA signal generated were qualitatively similar to PSAP and APM signals.

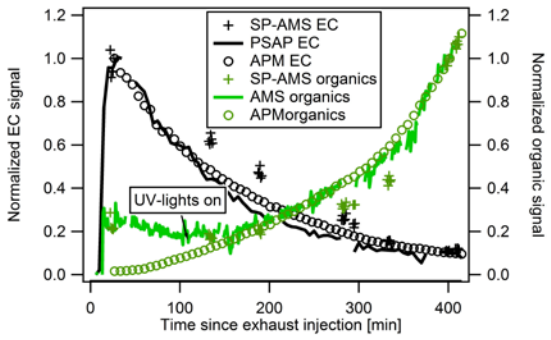

Figure 1. Soot and organic signal during an experiment were diesel exhaust spiked with toluene and m-Xylene was irradiated with UV.

When quantifying chemical species by AMS, one needs to determine their ionization efficiency (IE). This aspect of data analysis is to our knowledge not investigated for soot. There are two key differences from conventional AMS, the molecular structure of the soot, and the mode of vaporization. Preliminary results indicate that the IE of soot is low compared to that of non-refractory species. This has important implications for soot quantification. In the data plotted above, it results in an over prediction of soot mass loading by ~120% at t=400 (where TD-DMA-APM indicates 90% of particulate mass is SOA) if one fails to account for pure C_n fragments formed by the SOA, even though these contribute <3% of SOA signal.

Aerosol particle phase state measurement technique using a low pressure impactor

E. Saukko[1], H. Kuuluvainen[1] and A. Virtanen[1]

The phase state of aerosols – primarily whether particles are solid or liquid – has impact on the behavior of atmospheric as well as on industrial aerosols. According to the recently published results, the atmospheric biogenic SOA particles can adopt amorphous solid phase (Virtanen et al, 2010). The phase change of particles can be induced by temperature change, absorption of water or other solvent or by chemical aging. Existing methods to resolve the phase state, such as tandem differential mobility analysis rely on the size change of particles related to the water uptake or release related to deliquescence and efflorescence.

To address the need to study phase change induced by size-preserving and nearly size-preserving processes a new method has been developed. The method relies on the physical impaction of particles on a smooth substrate and subsequent counting of bounced particles by condensation particle counter (CPC).

To evaluate the performance of this method, the phase state of laboratory aerosols in the presence of water vapor was studied. The results show a marked difference in particle bouncing probability between crystalline and amorphous solids - not only at the deliquescence relative humidity level, but also on the slope of the bouncing probability with respect to humidity.

The schematic of the measurement system is described in Figure 1. The system consists of a size classification DMA, humidity control unit, a single Berner-type impactor stage and a batch sampling system to acquire a sample, repressurize it and measure with a CPC.

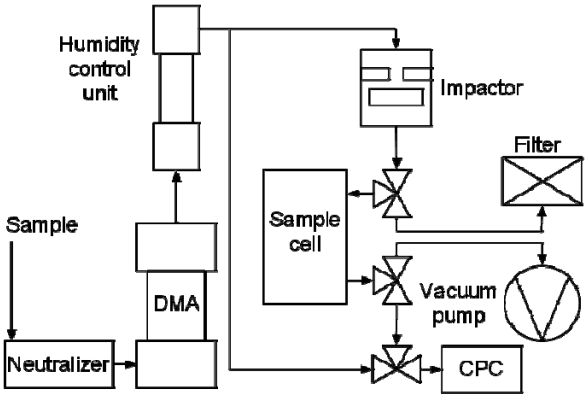

Figure 1 Schematic representation of measurement system

An example of bounce probability with varying relative humidity is given in figure 2. An ammonium sulphate aerosol, size selected for 91nm was cycled through the system and an almost step-like transition was seen on the bounce probability at around 80% relative humidity. This corresponds well with the known deliquescence relative humidity (DRH) of 80% (Mikhailov et al 2009)

The bounce probability can not at present be quantitatively linked to mechanical properties of particles, but it is qualitatively informative. The method has been applied on nebulised laboratory aerosols as well as on secondary organic aerosols.

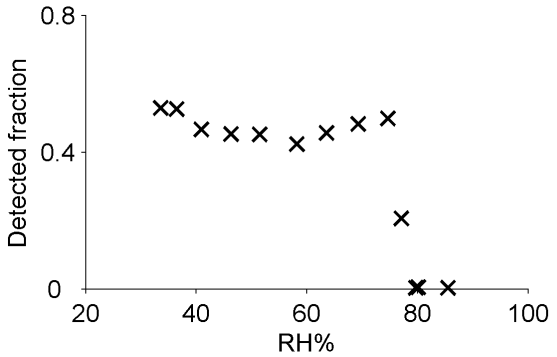

Figure 2 Fraction of 91nm ammonium sulfate particles detected after impaction with varying humidity

Rapid measurements of single aerosol droplets in conditions far from equilibrium using an electrodynamic balance

J.F. Davies[1], A.E. Haddrell[1], J.B. Wills[1] and J.P. Reid[1*]

[1]School of Chemistry, University of Bristol, Bristol, BS8 1TS, United Kingdom
Keywords: heat and mass transfer, instrumentation, levitation, evaporation
Presenting author email: james.davies@bristol.ac.uk

Rapid processes, such as evaporation and water uptake, occurring in aerosol droplets on the millisecond timescale have important implications in atmospheric chemistry, industrial spray techniques, aerosol combustion and drug delivery to the lungs.

A new electrodynamic balance (EDB) to study rapid processes in single aerosol droplets (Heinisch, 2009), consisting of four cylindrical, electrically isolated electrodes with a gas channel through the central cylinder for delivery of a gas flow, has been constructed (fig. 1). The benefit of this geometry over others comes from the strength of the trapping field combined with 360^{O} lateral optical access. The stability of trapped droplets permits the application of a high velocity on-axis gas flow through the inner cylindrical electrode directly over the surface of the droplet, allowing rapid processes in a gas flow to be studied. The droplet is illuminated with laser light and a characteristic fringe pattern is formed from the interference between reflected and doubly refracted rays. The fringe pattern is imaged with a camera and an approximation to Mie theory is applied (Glantschnig, 1981) to size the droplet in real-time at rates of well over 100 s^{-1}.

Figure1. Cylindrical electrodynamic balance. Side view (left) and top-down view (right) of electrodes.

Droplets are introduced into the trap with a piezoelectric droplet-on-demand dispenser of 30 μm orifice producing droplets of diameter 30 - 40 μm (approx.) and at speeds of around 2 m s^{-1}. The droplet travels the horizontal distance to the trap centre in ~20 ms.

The combination of droplets stability and high camera frame rates enables very fast dynamic measurements to be carried out, such as the evaporation of solvents (e.g. water) from atmospheric, medical and industrial aerosol droplets. These measurements provide an insight into the coupling of heat and mass transfer. The gas flow enables very fast changes in humidity to be introduced and droplets can be dried out in seconds leading to possible changes in the droplet phase such as the formation of gels or glassy phases.

Rapid uptake and growth of aerosol can also be studied. These are important processes in atmospheric chemistry, in terms of mass accommodation and cloud formation and growth, and in drug delivery via the lungs. The rapid humidity increase on inhalation of a medicinal aerosol can be effectively reproduced in this system to probe the lung penetration depth and hence the effectiveness of the aerosol as a drug delivery method.

Initial measurements of the evaporation of water from mixed component aerosol of varying composition have been carried out. Figure 2 shows the evaporation of mixed water / glycerol droplets (50:50) and the rapid water evaporation regime is clearly visible at a time resolution of 50 ms. A time resolution of much less than 10 ms is possible.

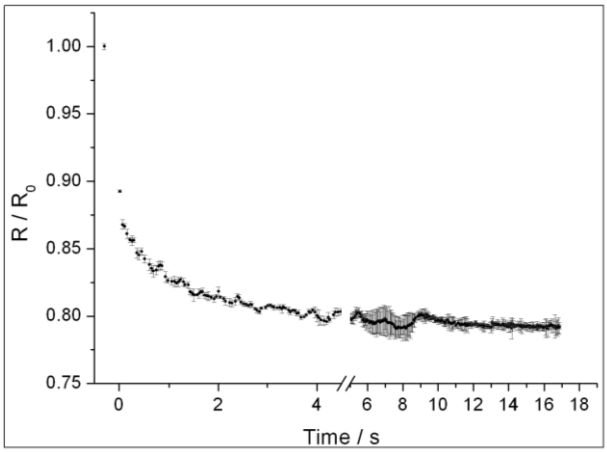

Figure 2. Water evaporation of 50:50 water / glycerol aerosol droplets in a dry gas flow (error bars indicate standard deviation of multiple droplets)

This technique provides the only method of measuring rapid changes in single aerosol droplets under a directed gas flow and offers a unique method of studying the effect of rapid changes in relative humidity.

Interferences in thermo-optical measurements of elemental and organic carbon caused by other aerosol constituents

R. Hitzenberger, E. Traxler, and B. Rosati
Faculty of Physics, University of Vienna, A-1090 Vienna, Austria
Keywords: elemental carbon (EC), organic carbon (OC), EC/OC split
Presenting author email: regina.hitzenberger@univie.ac.at

Elemental carbon (EC), which is produced by combustion processes, has come under intense study in recent years because of public health concerns (Kim et al., 2003) and climate change research. Despite intensive research efforts over the past nearly four decades, there still is no standard method to measure EC and there still is no scientific consensus of how to deal with interferences caused by refractory organic carbon ("brown carbon", e. g. Andreae and Gelencser, 2006) and possibly other aerosol constituents.

Numerous intercomparison (earlier studies summarized by Watson et al., 2005) performed over the years showed that total carbon (TC) measured with different methods usually agrees withic about 10%, but differences in EC up to factors of 7 are not too infrequent. For thermal methods, these differences are caused by the setting of the EC/OC split, usually depend on the aerosol type and sources present at the sampling site, and have so far not been resolved.

In the study by Hitzenberger et al. (2006), nearly all methods for EC and BC determination used in Europe at that time were compared for the urban aerosol un Vienna under summer conditions and gave no significant differences, so at least under these conditions (strong Diesel source, no space heating), the methods were found to perform more or less equally well. In winter time (Reisinger et al., 2008), however, differences of up to factors of about 4 were found especially on those days where a newly developed technique (Wonaschütz er al., 2009) showed a significant presence of biomass smoke. EC measured with a Sunset analyzer (Birch and Cary, 1996) always was lowest. As this thermo-optical method had not been available during the summer study, we cannot comment on its performance under summer conditions.

In the present study, the results of a laboratory investigation on the influence of various other inorganic and organic substances on the thermal behaviour of a diesel soot proxy (Elftex 124, Cabot Corp.) are presented. First results show that NaCl, which often is part of winter aerosols even at continental locations because of road salting, lowers the combustion temperature of EC and shifts the EC peak in the thermograms to lower temperatures. The EC/OC Split, however, is not influenced because combustion temperatures for EC are still high. Brown carbon proxies were found to influence the EC/OC split and to bias the EC concentration low. Other substances and substance mixtures are also investigated.

Presenting author email:sioutas@usc.edu

The association between adverse health effects and increased exposure to particulate matter (PM) has been of primary concern to public health organizations. To assess PM impact on health, particles are typically collected by filtration and impaction. More recently, PM collection by means of a concentrator-BioSampler tandem method has been adopted. However, a systematic evaluation of these techniques is currently unavailable. In this study, we compare the chemical and toxicological characteristics of concentration-enriched $PM_{2.5}$ samples simultaneously collected by a filter, a Nano-Micro Orifice Uniform Deposition Impactor (Nano-MOUDI) and a BioSampler.

Gravimetric measurements showed considerable agreement in PM collection efficiency for all three samplers. Accordingly, samples from the three collectors exhibited similar chemical compositions. The mass fractions of their inorganic ions, labile and non-labile, were comparable. Moreover, the organic carbon (OC) content of the BioSampler slurry was similar to that of the filter, while water-soluble OC levels of the filter and impactor samples were close to a 100% agreement. Lastly, linear regression analyses demonstrated that the water-soluble elements existed in similar mass ratios for the filter and impactor samples. Their respective total components were also in very good agreement. By contrast, the recoverable elements of the BioSampler slurry, determined by high resolution magnetic sector inductively coupled plasma mass spectrometry, were in good agreement with the water-soluble elements of the filter and impactor samples but not their corresponding total components.

In spite of the overall agreement among the $PM_{2.5}$ samples on their chemical composition, the oxidative potential of the filter and impactor substrate, assessed by abiotic and cellular assays, was similar yet substantially lower than that of the BioSampler slurry. Findings from a macrophage reactive oxygen species (ROS) assay showed that the mean activities of the filter and Nano-MOUDI water extracts were comparable but 0.46 and 0.31 times lower than the activity of the unfiltered BioSampler slurry, respectively (Figure 1). However, filtering the BioSampler slurry, i.e. removing insoluble PM-bound species, attenuated its ROS activity to about the same level as that of the filter and impactor substrate. These results demonstrate a significant contribution of insoluble species, which are unlikely to be recovered by water extraction, to the overall PM redox activity. Similarly, findings from a dithiothreitol (DTT) and a dihydroxybenzoate (DHBA) assay revealed that water extraction of the filter and impactor PM samples prior to toxicity tests did not recover potent PM-bound species, thereby leading to an underestimation of their redox activities.

Consequently, although commonly adopted for PM sampling, particle collection by filters and impactors for use in toxicological testing may be unsuitable. Alternatively, PM collection by the BioSampler, which circumvents the need for particle extraction, constitutes a more adequate approach for use in toxicity assays.

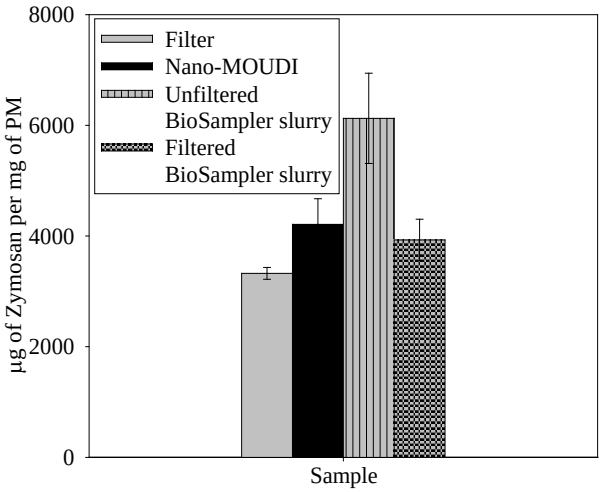

Figure 1. ROS response of the water extracts of the filter and Nano-MOUDI $PM_{2.5}$ samples as well as the unfiltered and filtered BioSampler $PM_{2.5}$ slurry. Error bars represent one standard error.

The authors would also like to thank Debra Schmitz and Emma Di Stefano for performing the DTT and DHBA assays.

Size selected nanoparticle quantification of deposited aerosol by GIXRF

H. Bresch[1], F. Reinhardt[2], U. Waldschläger[3], B. Pollakowski [2], B. Beckhoff[2], S. Seeger[1]

Presenting author email: harald.bresch@bam.de

Cascade impactors are widely used instruments in chemical aerosol characterization. There are several techniques for the chemical analysis of aerosol samples from cascade stages , e.g. EDX, GC-MS, Raman, XRF, etc., but none of them measures particle size and size distributions. Particle size resolved quantitative chemical analysis either requires the additional use of particle classifiers (e.g. SMPS) or the quantitative analysis of the deposits on cascade stages. The latter implies sample strengths above the lower threshold of the respective analytical method. Many environmental indoor or outdoor aerosols are polydisperse and consist of several chemical substances in different quantities. The quantification of one given chemical substance or a given element, hidden in the background of all the other contributions, and its assignment to a particle size class is therefore not always easy to achieve with the methods available.

Here we present a novel approach to use Gracing Incidence X-Ray Fluorescence Analysis (GIXRF) based on fundamental constants in order to determine size, quantity and chemistry of small nanoparticulate aerosol fractions within a poly-disperse aerosol.

The sampling was done with an electrostatic aerosol sampler (TSI 3089), using one square inch clean Si-wafers. We prepared monodisperse $ZnTiO_3$, TiO_2 nanoaerosol by use of an atomizer (Topas ATM 220) either with and without size selection by the Classifier and also a technical produced example of a polydisperse indoor aerosol.

For the experiments we used the PTB/BAM X-ray beamlines at BESSY II in Berlin at different excitation energies. High spectral resolution enables studies of the chemical state of the elements (Reinhardt et al., 2009) while the low divergence of the beam allows for dedicated geometries, such as a grazing incidence setup. Based on total-reflection X-ray fluorescence analysis (TXRF), which offers very low quantitative detection limits in the pg to fg range (Beckhoff et al., 2007), in GIXRF the incident angle of the excitation radiation is tuned between 0° and about threefold the critical angle of total-reflection. Thereby the position and strength of the maxima of the X-ray standing wave field (XSW) above the surface is modified. Particles with a given diameter deposited on a flat substrate will be exposed to excitation radiation of varying intensity depending on the angle of incidence and the particle size.

Hence the measured X-ray fluorescence signal contains information on the atomic composition of the particles and information on the deposited size fraction.

Based on fundamental constants we could use GIXRF measurements at BESSY II beamlines to determine the total amount of deposited nanoparticles of one size on a flat surface. Besides the absolute determination of the deposited nanoparticles, the measurement is independent of small contaminations of the substrate with other materials or polydisperse nanoparticles. This makes the GIXRF method a unique and very promising method for nanoparticle characterization, especially regarding poydisperse and inhomogenic environmental aerosols.

Session 6F: Aerosols in Turbulent Flows 2

Condensation and Turbulence

Charles Clement

15 Witan Way, Wantage, Oxon OX12 9EU, U.K.

Keywords: aerosol formation, turbulence, condensation, size distributions

Vapour condensation and turbulence both occur in the formation of clouds and their subsequent behaviour. There is still a lack of understanding of the interaction of these processes which strongly affects the size distributions of droplets in clouds and fluctuations in condensed water content which can lead to precipitation. Difficulties in a theoretical description arise from the necessity to include both molecular mass transfer by diffusion and heat transfer as well as turbulent motion. This paper addresses the basic microphysics involved including size scales and timescales needed. Condensation on an aerosol is a rapid process with timescales of the order of seconds. This may be seen in nature from the apparently stationary clouds which appear in fast airflows past escarpments or isolated peaks such as Table Mountain. A summary of theoretical work on mass transfer to aerosols was given by Clement (2008). Two key results are that "mean fields" for the vapour concentration, c, and the temperature, T, apply to volumes containing many droplets, and that the difference, $u = c - c_e(T)$, where the latter is its equilibrium value, obeys the general equation:

$$\partial u / \partial t + \mathbf{v}.\nabla u + \nabla.(- Du) = D\, c_e'' (\nabla T)^2 - (\partial p / \partial t - \nabla.\mathbf{q}) / (L\, Cn) - c_e' (1 - Le^{-1}) (\partial T / \partial t + \mathbf{v}.\nabla T) - (1 + Cn)^{-1} (d\rho_a/dt)/ \rho_d, \quad (1)$$

where c_e' is dc_e /dT, L is the latent heat of condensation, D is the vapour diffusivity, $\mathbf{q}$ is the radiation current interacting with the aerosol, Le, is the ratio of the thermometric conductivity to D, and Cn is the bulk condensation number:

$$Cn = k / (L\, D\, \rho\, c_e'(T)).$$

The LHS terms in (1) represent transport and diffusion so that it is the terms on the RHS which lead to possible supersaturation, with the final term being the actual transfer rate to the aerosol, density ρ_a which is itself proportional to $u = c - c_e$. The first term on the RHS is essentially positive and its nonlinearity gives rise to supersaturations in temperature gradients. The proportionality to $- \partial p / \partial t$ shows the effect of producing supersaturation pressure in rising air columns, and the radiative term can have either sign in adding or removing heat from the aerosol.

For water vapour in air, Le is about 0.85 and the sign of the nonzero term with Le depends on whether the temperature of the transported air at the point in question is rising or falling. In any mixing situation in the atmosphere, air packets will exist which have opposite signs. This could lead to highly local fluctuations in the water content of clouds as well as the evident fluctuations in the existence of the cloud which are seen at cloud edges. An example of the locality of the aerosol formation produced is seen in the calculations for cooled laminar flow in a tube performed by Barrett and Fissan (1989), but calculations for actual turbulent flows in the atmosphere are lacking.

Turbulence will produce fluctuations in temperature and water vapour content in the atmosphere, and lead to fluctuations in water vapour saturation. A calculation of distributions resulting from condensation on droplets passing through a realistic statistical set of saturation fluctuations does produce broad distributions (Kulmala *et al* 1997). It is possible to show from a representation of atmospheric turbulence by Sidin *et al* (2009) that dispersion of droplets occurs fast enough so that local distributions arise from uncorrelated fluctuations. We investigate further the dispersion in relation to the "mean field" volume containing droplets. The size range of this volume specified by diffusion is close to that of the dissipative turbulence. Local displacements of water vapour within the region from diffusion and turbulence are then similar so that both are important in calculating condensation. This implies that accurate calculations of condensation would need a very fine grid and small timesteps.

Intensive numerical calculations of condensation in simpler flow situations involving complete equations for heat and mass transfer and an aerosol size distribution have been carried out by Pyykonen and Garrick, but their extension to realistic clouds presents formidable difficulties. There is a continuing need for simpler models which include the important physics. An important aid to better understanding would be much more local measurements of fluctuations in water content and droplet size distributions in clouds.

In clouds the adiabatic cooling drives uprising air across the cloud point and hence causes nucleation of cloud droplets which subsequently coarsen and eventually lead to rain. In clouds nucleation is due to seeds (mostly small salt particles) such that droplets have to grow from a submicrometer to millimeter scale.

Surprisingly similar scenarios lead to precipitation in binary liquid mixtures subjected to a shallow temperature ramp (Auerhammer *et al*, 2005; Vollmer *et al*, 2007, Lapp *et al*, 2011). In that case, however, critical nuclei are two orders of magnitude smaller, and gravity becomes noticeable when droplets have grown to a size of tens of microns (Lapp *et al*, 2011). Consequently, the resulting "clouds" fit into test tubes with lateral dimensions of a few centimeters such that one can follow the evolution of the phase-separating mixtures for very long times under carefully controlled conditions. Upon slow cooling the mixtures repeatedly go through cycles of nucleation, coarsening and sedimentation.

We adopt a set of PDEs describing the evolution of the mixtures (Cates *et al*, 2003), and discuss its instability towards nucleation and convection (Vollmer, 2008; Trösemeier and Vollmer, 2011). This approach also provides a minimal model explaining the arising of the repeated rain formation. It can be described as Ostwald ripening, followed by a finite-time runaway growth of droplet sizes due to larger droplets sweeping up smaller ones (Lapp *et al*, 2011). The model predicts that he period Δt of the oscillations and the temperature sweep rate ξ are related by

$$\Delta t \sim \xi^{3/7}.$$

The predictions compare very well with our experimental results on iso-C4E1 droplets in water, which are obtained by analysing data on the time evolution of the droplet-size distribution and sedimentation velocities of a systems subjected to temperature ramps at different fixed ξ and sample geometry (see Figure 1).

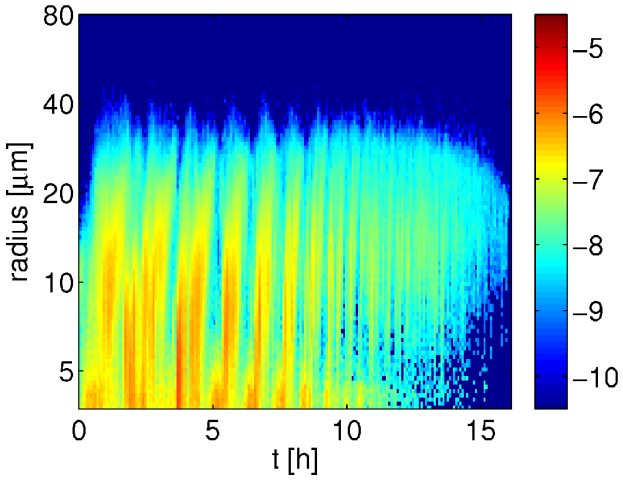

Figure 1. Temporal evolution of the droplet size distribution of iso-C4E1 droplets in water. A slow drift in temperature (25 K in 16 h) causes the system to oscillate.

We argue that the theoretical treatment is a benchmark model for rainfall, applicable to warm clouds in a stratified atmosphere.

Non-local closure model for particle dispersion tensors in a turbulent boundary layer

A. Bragg[1], D.C. Swailes[1]
[1]Department of Mechanical & Systems Engineering, Newcastle University, Tyne & Wear, NE1 7RU, U.K.
Presenting author email: andrew.bragg@ncl.ac.uk

Keywords: inhomogeneous turbulence, particle dispersion, pdf kinetic equation, non-local dispersion tensors

Probability density function (pdf) kinetic equations and their associated continuum equations provide a theoretically sound modelling approach for inertial particle dispersion in turbulent flows (Reeks (1991), Reeks (1992), Swailes *et al* (1997)).

$$\frac{\partial}{\partial t}p = -\frac{\partial}{\partial \mathrm{x}_i}p\mathrm{v}_i + \frac{\partial}{\partial \mathrm{v}_i}\left[p(F_i+\kappa_i)\right] + \frac{\partial}{\partial \mathrm{v}_i}\left[\frac{\partial}{\partial \mathrm{x}_j}p\lambda_{ji} + \frac{\partial}{\partial \mathrm{v}_j}p\mu_{ji}\right] \quad (1)$$

Equation (1) is the pdf kinetic equation, where $p(\mathbf{x},\mathbf{v},t)$ is the pdf for particle position and velocity at time t, $\mathbf{x}$ is a position phase-space variable, $\mathbf{v}$ is a velocity phase-space variable and $\boldsymbol{F}(\mathbf{x},\mathbf{v},t)$ is the mean force acting on the particle. The dispersion tensors $\boldsymbol{\lambda}(\mathbf{x},\mathbf{v},t)$, $\boldsymbol{\mu}(\mathbf{x},\mathbf{v},t)$ and $\boldsymbol{\kappa}(\mathbf{x},\mathbf{v},t)$ appearing in equation (1) represent integrals along particle paths describing the interaction between the fluid turbulence and the particles. In the continuum equations, it is the velocity averaged forms of the dispersion tensors that appear, and they require closure treatment.

For particle dispersion in a turbulent boundary layer where the turbulence is strongly inhomogeneous and anisotropic, the closure of the dispersion tensors is complex since the inhomogeneity and anisotropy of the turbulence experienced by the particle along their trajectories must be accounted for. Usually the approximation made is that the turbulence seen by the particles is 'locally homogeneous', that is, that within the time for which the turbulent field is correlated the particles experience a flow field which is approximately homogeneous (e.g. Swailes *et al* (1997)). However recent studies have shown that local homogeneous approximations to the dispersion tensors can be both qualitatively and quantitatively incorrect for particle dispersion in a turbulent boundary layer (Skartlien (2007)).

In addition to this there does not exist a general closure for $\boldsymbol{\kappa}$, the dispersion tensor describing a convective acceleration experienced by the particles due to the inhomogeneity of the fluid turbulence. Usually $\boldsymbol{\kappa}$ is approximated by using its known form in the limit of zero Stokes number particles (Skartlien (2007), Skartlien *et al* (2009)), and therefore does not account for the influence of particle inertia.

A new 'non-local' closure model will be presented which attempts to account for the effects of turbulence inhomogeneity (and anisotropy) and particle-boundary collisions on the dispersion tensors. The new closure model also provides a general closure for $\boldsymbol{\kappa}$, valid for small to large particles.

Tumbling in turbulence and irrational quantisation

Michael Wilkinson[1] and Alain Pumir[2]
[1]Department of Mathematics and Statistics, Open University, Milton Keynes, England, MK7 6AA.

Keywords: turbulence, aerosols, tumbling
Presenting author email: m.wilkinson@open.ac.uk

A non-spherical object (such as an ice crystal) in a turbulent flow will tumble randomly. This tumbling can be significant for understanding the aggregation, fragmentation and optical properties of non-spherical bodies. In this talk I will present the simplest model of random tumbling, which is an Ornstein-Uhlenbeck process describing motion of a vector $\mathbf{n}$ on the surface of a sphere, with angular velocity ω: the equations of motion are

$$\dot{\mathbf{n}} = \omega \wedge \mathbf{n}$$

$$\dot{\omega} = -\gamma\omega + \sqrt{2D}\eta(t)$$

where $\eta(t)$ is white noise. I will explain why, despite its simplicity, this can be a good model for the tumbling of microscopic particles in a turbulent flow.

The model has a single dimensionless parameter: the persistence angle $\beta = \sqrt{D/\gamma^3}$ is the typical angle through which the axis $\mathbf{n}$ of the body rotates during the correlation time of the angular velocity ω. In the limit $\beta \gg 1$ where the tumbling is weakly damped, the model has a very surprising structure: the corresponding Fokker-Planck equation is analysed using a radial Schrodinger equation in which the angular momentum quantum number j takes an *irrational* value, $j = (\sqrt{17}-1)/2$. I shall also discuss the two-dimensional case, which is excatly solvable, for all values of β.

I will also describe numerical studies of the motion of microscopic rod-like bodies in simulations of three-dimensional Navier-Stokes turbulence. There is a surprising feature which cannot be explained using the spherical Ornstein-Uhlenbeck model: we find that the direction vector $\mathbf{n}$ of rod-like bodies is preferentially aligned with the vorticity vector Ω of the velocity field, rather than with the principal eigenvector of the strain-rate tensor.

Motion of large particles in turbulent flows: rotational motion and lift.

Keywords: Motion of particles, spinning, lift.
Presenting author email: alain.pumir@ens-lyon.fr

The motion of a large, neutrally buoyant particle freely advected by a turbulent flow is studied experimentally. Thanks to new experimental techniques[1], the translational *and* rotational motion of the particles are simultaneously determined. The particles are investigated in a von Karman swirling flow, at a reynolds number $R_\lambda \approx 300$; the particles diameters are $D \sim 0.6 \times L_{int}$, where L_{int} is the integral length scale of the flow[2].

The experiments demonstrate that both the translational and angular accelerations exhibit very wide probability distribution functions, which can be viewed as a manifestation of intermittency.

The orientation of the angular velocity with respect to the trajectory, as well as the translational acceleration conditioned on the spinning velocity provide evidence of a lift force acting on the particle.

The orders of magnitude of the force and of the torque acting on the particles will be discussed, and the issues of size and Reynolds number dependence will be addressed.

This work was supported by Agence National pour la Recherche, under contract DSPET.

Particle Resuspension Modeling in Turbulent Flows

F. Zhang*, †, M. Reeks* and M. Kissane†

Keywords: resuspension, turbulent flow, multilayer deposit, severe accident

The work presented is concerned with the way small particles attached to a surface are resuspended when exposed to a turbulent flow. The process is important in a number of environmental and industrial processes. Of particular concern to this work is the release of radioactive particles from the primary circuit of an LWR as a consequence of a loss of coolant accident (LOCA). In this particular case the focus is on small particles < 5 microns in size, where the principal force holding the particle onto a surface is derived from van der Waals inter molecular forces. In general even for nominally very smooth adhering surfaces there exists a very broad spread in the adhesive forces. Here we develop and assess an improved version of the Rock'n'Roll model [Reeks & Hall, 2001] based on a statistical approach to resuspension which gives rise to a resuspension rate constant for the release of particles from a potential well due the action of the fluctuating aerodynamic force du to the turbulence. The analogy is with desorption of molecules from a surface in which the variance of the fluctuating aerodynamic force is the analogue of temperature. In this work we improve on the model by using measurements of the statistical fluctuations of both the stream wise fluid velocity and acceleration close to the wall from both LES and DNS of turbulent channel flow, translating those measurements into the statistical moment of the drag force acting on the particle attached to the surface. The original model assumes that aerodynamic forces and their time derivative are uncorrelated and have a Gaussian distribution. Here we examine the influence of non-Gaussian forces on the resuspension rate.

The ultimate model is a hybrid development of R'n'R model adapted for application to multilayer deposits based on the Friess and Yadigaroglu multilayer model [Friess & Yadigaroglu, 2001]. The particle size distribution is considered in the model in order to study the coveragent effect of the deposit layers. The model results are compared to the STORM SR11 test [Castelo *et al.*, 1999] (Figure 1) and BISE experiment [Alloul-Marmor, 2002] (Figure 2).

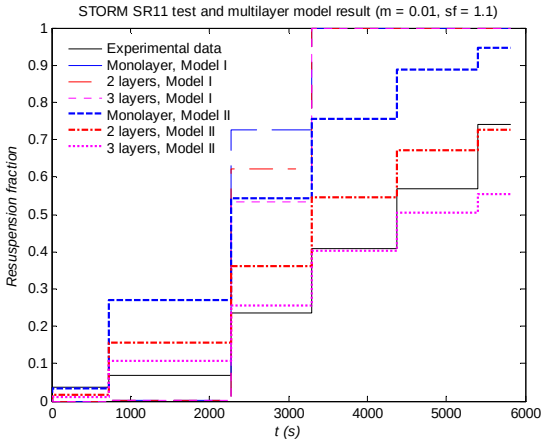

Figure 1. Models results and STORM SR11 test

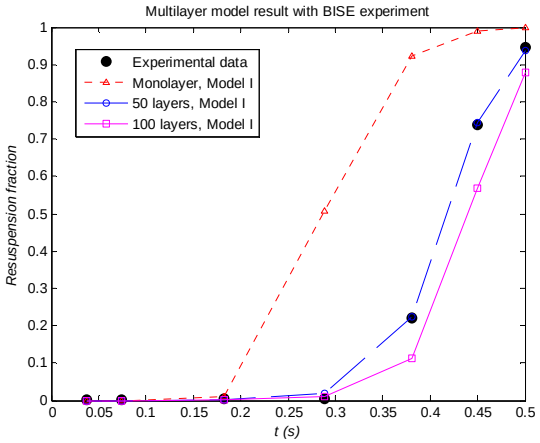

Figure 2. Model results and BISE experiment

As a general conclusion, the results showed that the models with small adhesive spreads give better comparison with the resuspension measured in the two experiments.

Behind CO_2, black carbon (BC) aerosol is the 2nd strongest contributor to current global warming (Ramanathan and Carmichael, 2008). Nonetheless there remain fundamental uncertainties regarding the ways in which coatings of nonrefractory material, formed by condensation and coagulation, affect BC's optical properties and hydrophilicity. While measurement of coating thickness can be made using Droplet Measurement Technology's Single Particle Soot Photometer (SP2), no instrument is currently capable of quantitatively measuring the composition of BC and its coatings, and this represents a limiting factor in our scientific understanding.

This work involves the use of a new instrument, the Soot Particle Aerosol Mass Spectrometer (SP-AMS), a modified version of the standard Aerodyne Aerosol Mass Spectrometer (AMS). The heater is removed and replaced by an Nd:YAG laser of the same type used in the SP2. This only vaporises particles containing BC, allowing for selective measurement of BC core and coating composition.

The SP-AMS was deployed alongside a suite of SP2s and several optical measurement systems (Aethalometer®, PhotoAcoustic Soot Spectrometer (PASS), Particle Soot Absorption Photometer (PSAP), Nephelometer and Cavity Ring-Down) as part of the SOOT11 campaign at the AIDA chamber, Karlsuhe, Germany, in November 2010. This allowed for measurement of well-characterised test particles in high concentrations. Fresh soot was generated using a CAST (Combustion Aerosol STandard) burner and coated by condensation of SOA (Secondary Organic Aerosol) due to α-pinene ozonolysis. In a reciprocal experiment, CAST soot was added to homogeneously-nucleated SOA and hence BC coating was achieved through coagulation. Similar experiments were carried out using BC generated from a diesel engine test bench.

We investigate changes in the aerosol as SOA was added, both in terms of chemical composition and optical properties. As fractal soot is coated in nonabsorbing SOA, it is restructured into a quasi-spherical core-shell system, which enhances absorption by a lensing effect effect (Schnaiter et al., 2005, Lack and Cappa, 2010). This phenomenon was observed as part of our experiments, as shown in Figure 1.

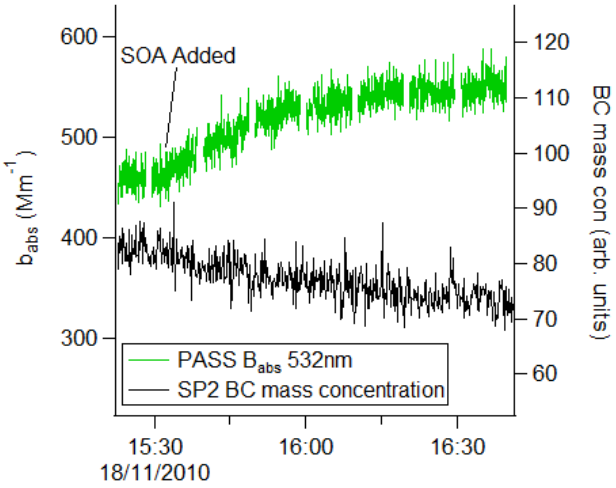

Figure 1 - Absorption enhancement due to coating of soot by SOA formed by ozonolysis of α-pinene.

Biogenic organic compounds are important constituents of ambient particulate matter (PM). To our knowledge, up to now little attention was paid to the quantity and distribution of single biogenic compounds in urban regions (Lewandowsky *et al* 2008). The aim of this project is to study the contribution of biogenic aerosol to PM_1 and PM_{10} concentrations and its spatial and temporal variation within the city of Berlin.

From Feb 2010 to Oct 2010, PM_{10} and PM_1 24 hrs samples were taken with a low volume sampler every 6th day at three different stations in Berlin, referred to as vegetation rich, traffic and urban background (only PM_{10}). For analysis with GC-MS, tracers for secondary oxidation products, biomass burning, primary biogenic and cooking emissions were chosen which might give valuable information about sources and transportation of biogenic PM in urban areas.

Levoglucosan, a suitable tracer for biomass burning showed highest PM_{10} median concentrations of all measured compounds between 41–45 ng m^{-3} at the three sites and 18 and 25 ng m^{-3} for the PM_1 fraction at the vegetation rich and traffic site, respectively. Highest PM_1 median concentration of 43 and 17 ng m^{-3} showed malic acid, assumedly an oxidation product of semi-volatile carboxylic acids (Kawamura and Gagosian, 1990). Lowest concentrations were found for the isoprene markers 2-methyltetrols with less than 1 ng m^{-3} for both fractions at all sites. Median concentrations for pinonic acid were between 9–12 ng m^{-3} for the PM_{10} and 8 and 11 ng m^{-3} for the PM_1 samples. It was found to be 3 to 8 times higher than its isomer pinic acid. The fatty acids (C_{14}–C_{18}) showed quite similar mean concentrations (2–8 ng m^{-3} and 1–5 ng m^{-3} for PM_{10} and PM_1, respectively).

Different types of seasonal trends were determined. Figure 1a shows a clear maximum in summer, which was found for all secondary oxidation products as well as for oleic and pentadecanoic acid. A nearly linear trend with decreasing and increasing concentrations from winter to autumn exist for some fatty acids and glucose (figure 1b and c). Only levoglucosan shows a clear minimum in summer (figure 1d).

Further, PM_1 of PM_{10} ratios were calculated. They vary strongly, between and within compounds, from 0 up to more than 100%. Latter causes still have to be clarified.

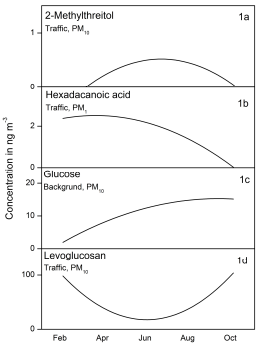

Figure 1: Different types of seasonal trends

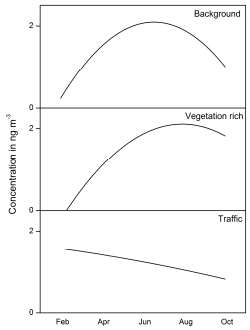

Figure 2: Seasonal trends of adipic acid (PM_{10}) at all sites

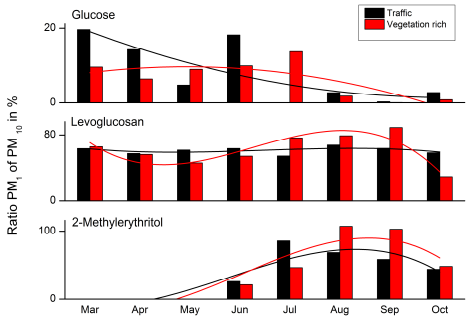

Figure 3: Variations of PM_1/PM_{10} ratios (given as monthly median) at the traffic and vegetation rich site

Only weak spatial variations of concentrations could be observed. However, spatial differences emerged by comparing the seasonal trends, where i.e. adipic acid shows a linear instead of a parabolic trend for PM_{10} samples at the traffic station (figure 2), indicating a specific local source. Further differences can be noticed in the PM_1/PM_{10} ratio. The ratio and partly its seasonal trend can differ between the stations as shown for glucose, levoglucosan and 2-Methylerythritol (figure 3).

The results present that the occurrence of biogenic compounds within the city of Berlin provides a great complexity in distribution, which can be described by concentration differences, seasonal behavior and the PM_1/PM_{10} ratio. Further investigations shall expand the knowledge i.e. by comparison with OC/EC data and ^{14}C-analysis.

Detailed measurements of the composition and properties of black carbon (BC) were made as part of CalNex, a major multi-platform field study in the Los Angeles (LA) area in the summer of 2010. The deployment took place at the Pasadena supersite inside the LA metropolitan area, and included a Single Particle Soot Photometer (SP2), 3-wavelength Photoacoustic Soot Spectrometer (PASS), 7-wavelength Aethalometer and a new Soot Particle Aerosol Mass Spectrometer (SP-AMS). A Cavity Enhanced Phase Shift (CAPS) instrument was also operated in parallel to measure the bulk extinction properties. The bulk composition was also compared with collocated online thermo-optical OC/EC measurements.

The combination of instruments was chosen to study the microphysical interplay between BC core and coating composition and the bulk optical properties of the aerosol. As well as the single particle BC mass quantification provided by the SP2, the SP-AMS was able to directly study the bulk composition of the BC and its coatings. This new instrument operates in a similar manner to a standard Aerodyne AMS but instead of a heated tungsten surface, an active cavity YAG laser (the same used by the SP2) selectively vaporizes BC-containing particles, including their cores. The PASS was used to derive bulk properties without any of the artifacts associated with filter-based methods and was able to derive Angstrom exponents, which were seen to vary in both the scattering and absorption channels.

To further investigate the effect of the coatings on the optical properties of the particles, the SP2, SP-AMS and PASS were run downstream of a thermal denuder. This operated on a continuously ramping program, which the instruments measured progressively removing the coatings from the BC. This work will help to provide a better quantitative link between the physiochemical modifications made to BC particles during atmospheric processing and the evolution in their optical properties.

Presenting author email: g.ayoko@qut.edu.au

The number of health and sensory effects linked to air pollutants continues to grow (see, e.g., Pope and Dockery, 2006). Due to their immature respiratory systems and faster breathing rates, children are particularly at risk (Zhang and Zhu, 2010). However, there have been limited published studies on the relationship between long term exposure to particles and adverse human effects in children. Additionally, the role of the chemical composition of particles in their biological effects has not been fully understood. To address this issue, a systematic study of the chemical composition of ambient air in the vicinity of selected schools in the greater Brisbane area is being undertaken. The study is a part of a large project aimed at gaining a holistic picture of the exposure of children to traffic related pollutants, and some of the preliminary results are described in this paper.

Airborne Particulate Matter (PM) with aerodynamic diameters equal to or less than 1.0 (PM1) and equal to or less than 2.5 micrometer (PM 2.5) were collected in 3 Schools (S01, S02 and S03). The sampling campaign at each school took place over one week. $PM_{2.5}$ was collected during school hours (8am to 5pm) for organic carbon (OC) and elemental carbon (EC). OC and EC were analysed at Chester Labnet according to the IMPROVE method and their fractions (OC1- OC4, PC and EC1-EC3) were determined. The $PM_{2.5}$ and PM_1 samples were both collected for 24 hours and analysed by Particle Induced X-ray Emission (PIXE) for their elemental compositions at ANSTO.

The average OC and EC results over the 5 days are tabulated in Table 1. The high OC/EC ratio suggests that vehicle emissions are not the dominant source of carbonaceous aerosols at the schools; secondary organic aerosols were also present (Giugliano et al. 2005). It can be seen that S02 has the highest EC concentration and lowest OC/EC, suggesting that the greatest influence of traffic emission especially from diesel vehicles occurred at this school. This is supported by the traffic data, which showed high traffic counts with more heavy duty vehicles passing through the school.

Si, P, S, Cl, K, Ca, Ti, Cr, Mn, Fe, Cu, Zn, Br, Sr, Pb and Cd were detected at the three schools while Al, Co, Ni and V were only detected at S02. Si, Cl, Fe and Pb were found mainly in the $PM_{2.5}$ samples at all three schools while Sr and Cd were found mostly in the PM_1 fraction at S01 and S02. The elemental profiles of S02 were distinctly different from those of S01 and S03.

Table 1: Average OC and EC results for each school

School ID	OC ($\mu g/m^3$)	EC ($\mu g/m^3$)	OC/EC ratio
S01	2.76 ± 0.34	0.23 ± 0.19	13.59
S02	4.05 ± 0.41	0.80 ± 0.80	5.14
S03	3.27 ± 0.38	0.26 ±0.17	13.38

S02 showed more influence from traffic emission with higher concentrations of traffic related elements such as Pb, Zn, Ni, Mn and Fe (Martuzevicius et al. 2004).

Multicriteria decision making methods, Preference Ranking Organisation METHods for Enrichment Evaluation (PROMETHEE) and Graphical Analysis for Interactive Assistance (GAIA) were applied to this data in order to determine the school with the least pollution. PROMETHEE is a ranking method which determines the preference of one object over another and GAIA is the visual representation of the influence of the variables in the form a biplot. PROMETHEE ranked S01 as the least polluted and S02 as the most polluted. In addition, three separate clusters were observed in the GAIA biplot, indicating that the aerosols in each of the schools have different chemical compositions.

The paper highlights the contributions of airborne soil as well as secondary organic and traffic- related aerosols to the air quality around the schools.

Soot (black carbon) particles are the most efficient light absorbing aerosol species and have pronounced direct, semi- and indirect climate effects in the atmosphere. These effects strongly depends on the mixing state of soot particles, e.g. the light absorbing capability of soot (related to direct radiative effects) can be enlarged by a factor of 1.5 up to 3 when soot is coated. From this aspect, understanding of soot mixing state and it evolution mechanism is an essential task for understanding the climate research. Unfortunately, there is very limited information about the evolution of soot mixing state in the atmosphere. Since there is nothing to compare with, the modeled soot mixing state remains a big source of uncertainties in our climate models.

In CAREBeijing 2006 campaign, we tried to address this issue by measuring soot mixing state in the megacity Beijing. A volatility tandem differential mobility analyzer (VTDMA) was implemented to determine the size-resolved mixing state of soot particles (7 sizes from 30 nm to 320 nm). Pronounced diurnal variations of soot mixing state were observed during the campaign and have been validated against aerosol hygroscopic mixing state (Figure 1, Su et al. 2010). For Aitken mode particles, the largest F_{in} (number fraction of internally mixed soot) was observed in 8:00 to 9:00 while for accumulation mode particles, the largest F_{in} were observed in 12:00 - 13:00.

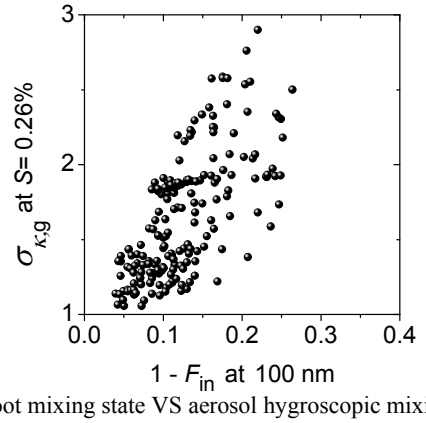

Fig. 1 Soot mixing state VS aerosol hygroscopic mixing state

The evolutions of accumulation mode particles can be well explained by competitions of fresh emission and coating processes. Given the soot emission rates, the profile of condensable vapor concentration p_{Cond}, can be constrained by the soot concentration and mixing state information. The parameter p_{Cond} shows a diurnal profile with high values during daytime, i.e. a peak around noon time, similar to oxidant or oxidative products (like O_3 and H_2SO_4). The coating rate (dF_{in}/dt) due to condensation growth could be extremely high in the measurement site with a maximum of ~ 100% h^{-1}(Fig. 2).

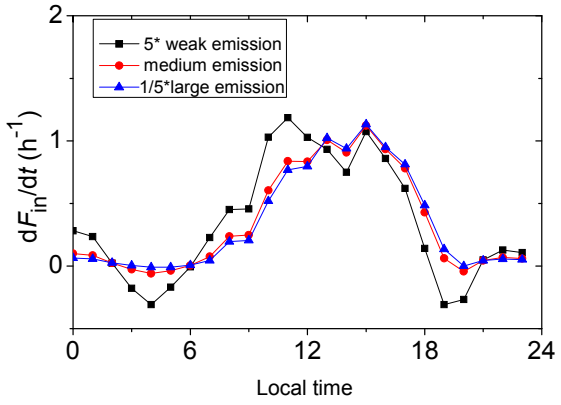

Fig. 2 Aging rate of soot particles due to condensation process

The evolution of soot mixing state was found to be strongly linked to the aging process of air masses. So we suggested parameterizing the soot mixing state at 150 nm by air mass aging indicators and calculating the soot mixing state of other accumulation mode particles from that at 150 nm. The simplicity and flexibility of this mechanism promise its use in time-consuming climate models though more evidences from other sites are also needed to verify the universality of our results. We also illustrate the importance of reporting the threshold value in the definition of soot mixing state and suggest using a distribution concept in future studies.

Does aerosol in London create an urban solar flux island?

C.L. Ryder[1] and R. Toumi[2]

[1]Department of Meteorology, University of Reading, Reading, Berkshire, RG6 6BB, UK
[2]Department of Physics, Imperial College London, Prince Consort Road, London, SW7 2BW, UK
Keywords: urban aerosols, PM, radiative properties, field measurements, indirect effect
Presenting author email: c.l.ryder@reading.ac.uk

Solar irradiance measurements from a new high density urban network in London are presented. We find that central London receives less solar irradiance at the surface compared to outer London, and attempt to attribute this difference to the direct effect of aerosol using a combination of ground based measurements of PM10 and PM2.5 and radiative transfer modelling.

Urban heat island effects have a significant effect on the energy balance of cities, due to the effects of building materials, sparsity of vegetation and anthropogenic heat sources (Grimmond et al., 2010). One additional contributor to differences in the urban energy balance compared to rural areas is the higher concentration of aerosols due to urban pollution, which scatter and absorb incoming solar radiation, thus reducing the total downwelling surface solar radiation (Oke, 1997), known as the direct aerosol radiative effect.

Studies in several other cities using point measurements comparisons between urban and rural sites have found total urban solar irradiance to be between 1 to 33% less than their rural counterparts (e.g. Hay, (1984) in Vancouver, East (1968) in Montreal and Jáuregui and Luyando (1999) in Mexico City). Due to the gradation in the amount of aerosol pollution which originates from city sources, there should be a corresponding gradation in the surface solar irradiance.

Variations in solar irradiance due to attenuation by aerosols on an urban scale have implications for the understanding of urban meteorology, urban energy balance models and for solar power generation. Despite this importance, no studies have examined the distribution of solar irradiance in urban areas on a sub-city scale.

Here we present measurements from a new, high density network of inexpensive solar irradiance sensors across London to determine the spatial distribution of solar irradiance across the city both in terms of the annual average and on a case study basis. For the case studies, we describe a new method to determine aerosol column loading solely using measurements of clear sky total solar irradiance. We examine the findings compared to ground-based particulate measurements across London and establish to what extent London's spatial aerosol distribution affects the downwelling surface solar irradiance.

Annual averages of solar irradiance demonstrate that central London receives 30 ± 10 Wm^{-2} less solar irradiance than outer London at midday, equivalent to 9 ± 3% less than the London average (see Figure 1). Particulate matter and AERONET measurements combined with radiative transfer modeling suggest that the direct aerosol radiative effect could explain 33 to 40% of the inner London deficit and a further 27 to 50% could be explained by increased cloud optical depth due to the aerosol indirect effect. These results have implications for solar power generation and urban energy balance models.

Presenting author email: kornelia@almos.uni-pannon.hu

For decades the air pollution has been considered as one of the most serious problems mainly in highly populated areas all over the world including Hungary. During winter months the PM10 concentration exceeds several times the health limit.

In Europe, monitoring of PM10 is regulated by CEN standard (EN 12341), the β-ray absorption and gravimetry are the most widely used. Gravimetry is the reference method in the PM10 measurements. This method gives information about the aerosol concentration only after 48h, while beta-attenuation method provides data in high time resolution. According to the regulations, the gravimetric mass measurements are carried out at RH=50±5% and T=20±1°C. In both cases the water vapour content of the air and consequently the absorbed water can cause positive artefact during the sampling. This is the result of the hygroscopicity and hysteresis of the aerosol particles. As it is well known, at higher RH the particles can absorb the water vapour, therefore their size and mass can grow. On the other hand, when RH decreases the particles begin to lose the absorbed water. In the most cases this weight loss is less than the previous mass growth, due to hysteresis.

The aim of this work is to study the effect of water vapour on the aerosol mass measurement by both methods. First we tested the gravimetric method. Each filter (Whatman) was weighted before and after sampling to determine the aerosol mass on the filter. The sampling was carried out by a Hi-vol (Digital DH-80) sampler and a FH 62 beta monitor. The experimental period was between 4 November 2008 and 18 March 2010 in a residential site in Budapest, Hungary. The hygroscopic behaviour of the aerosol particles were investigated in a chamber, where the RH was adjusted between RH=20% and RH=90%.

First we studied the water uptake of the aerosol particles from RH=50% to RH=90%. After the humidification, the RH was reduced back to 50%, and on the basis of the "remaining water mass" the effect of hysteresis was estimated.

Our results show that because of the hysteresis of the aerosol mass concentration can be overestimated by up to 16%. From these results we can conclude that the aerosol mass at RH=50% cannot be considered as dry mass. In order to verify it, the mass measurements were continued at lower (<20%) RH, this reduction resulted in further loss in the aerosol mass. The average aerosol mass deficit was 4.56%, while its maximum value reached 16.8%.

Finally, we concluded that the PM10 mass concentration measured at 50% RH can be overestimated by 2% to 17%. In Fig. 1 the degree of this overestimation is presented for the time interval of this study.

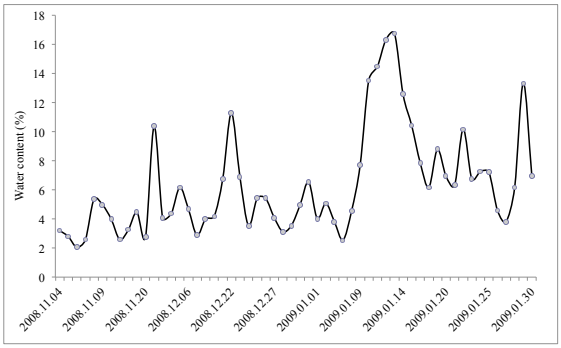

Figure 1. The water content of aerosol samples at RH=50% relative to RH=20%

Beta-attenuation is an online method and the sampling is usually carried out at ambient relative humidity. Therefore humidity correction should be applied on these data. The water uptake of the particles from the same period was measured between RH=20% and RH=95% and the mass growth factors were calculated ($GF=mass_{wet}/mass_{dry}$).

Applying the mass growth factors and considering ambient relative humidity we estimated the water contribution to the aerosol mass concentration measured by the online method. The humidity corrected data show that in many cases the PM10 concentration was lower than the air quality standard during the smog alert period as presented in Fig. 2.

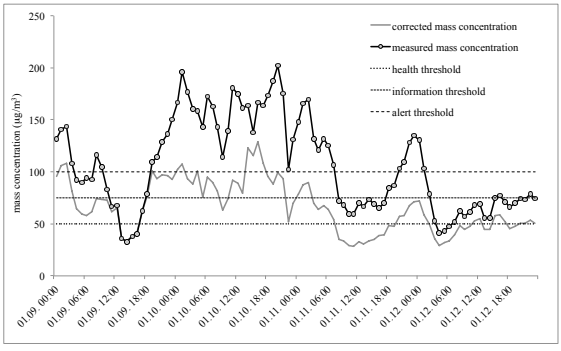

Figure 2. The measured and the humidity corrected mass concentration during the smog period in Budapest.

Clouds play a crucial role for physical and chemical processes in the atmosphere. Lagrangian-type field experiments where an orographic cloud is used as a natural flow-through reactor provide a basis for studying such processes. Several such hill cap cloud experiments were conducted in the past with the most recent ones being the FEBUKO campaigns in 2001 and 2002 at Mt. Schmücke in Thuringia, Germany (Herrmann et al., 2005).

In September/October 2010 another Lagrangian-type cloud experiment was conducted to study aerosol cloud interaction at Mt. Schmücke, with a special focus on highly time-resolved online instrumentation that was not available during the times of the previous studies.

Three measurement sites were installed: An upwind site, which served for the characterisation of incoming air masses, an in-cloud site on the Schmücke summit, and a downwind site, where under appropriate meteorological conditions air masses after their passage through a hill cap cloud could be studied. A scheme of the area with the 3 sites is given in Figure 1.

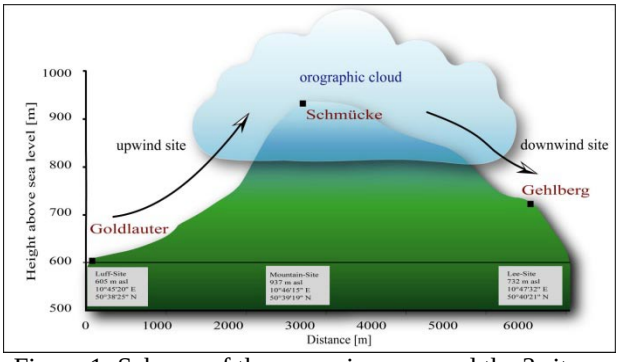

Figure 1: Scheme of the campaign area and the 3 sites.

The valley sites were equipped with a comprehensive suite of instrumentation, including gas monitors, VOC and OVOC samplers, PTR-MS, FAGE, SMPS, APS, HTDMA, CCNC, MAAP, CPC, mist chambers, filter samplers, impactors, MARGA, PILS, AMS, and a ceilometer, to determine the physical and chemical state of the aerosol upwind and downwind of the cloud. At the in-cloud site the cloud droplets were collected using bulk and multi-stage cloud water collectors. The HOx budget was determined by a FAGE and the interstitial and droplet (residual) phase were sampled behind an interstitial inlet and two CVIs applying SMPS, OPC, PSAP, aerosol mass spectrometry (AMS, ALABAMA), filters and OVOC samplers. The liquid water content was measured by a PVM and the droplet size distribution by a FSSP.

Samples from the discontinuous instruments (filters, impactors, cloud collectors, etc.) were analysed for their chemical composition, including among others: inorganic ions, OC/EC, WSOC, WSON, organic acids, sugars, organic carbonyl compounds, trace metals, and soluble metals in different oxidation states (Fe(II)/Fe(III)).

Tracer experiments were performed by releasing an inert chemical gas at the upwind site and studying its distribution in the Schmücke area within a reasonable time interval (1 hour). These data, together with an in-depth local and regional classification of the meteorological conditions during cloud events, allowed for an identification of time periods, where a connected air flow between the three sites can be assumed, i.e. representative air masses were sampled before, during, and after a cloud passage.

A comparison of the physical and chemical properties of the aerosol within these air masses, especially from the online instruments, led to interesting preliminary insights in various scientific areas such as aerosol processing through clouds, chemical cloud composition, or the influence of clouds on the radical oxidants budget. First results, especially from the chemical measurements, will be given in this contribution.

Presenting author email: johannes.schneider @mpic.de

Cloud and aerosol interactions in orographic cloud formation were studied during the field campaign Hill Cap Cloud Thuringia (HCCT) in September and October 2010 on a mountain site in Central Germany (Schmücke, 938 m a.s.l.).

The cloud droplet number concentration and size distribution was measured by a forward scattering spectrometer probe (FSSP) in a size range between 2 and 40 µm. Cloud droplets were sampled through a counterflow virtual impactor (CVI) and their residuals were analysed for non-refractory chemical composition by a compact time-of-flight aerosol mass spectrometer (C-ToF-AMS, size range 40 – 1000 nm). Interstitial particles were sampled by an interstitial inlet with a cut-off of 5 µm and analysed for non-refractory chemical composition by a high-resolution (HR)-ToF-AMS (size range 40 – 1000 nm), and for black carbon by a multiangle absorption photometer (MAAP). Size distributions of both the interstitial particles and the cloud droplet residuals was measured by optical particle counters (0.25 – 32 µm).

During the measurement period of the HCCT campaign (Sept. 19 until Oct. 25, 2010), the Schmücke field station was covered in clouds for 370 hours, corresponding to more than one third of the total measuring time.

Here we focus on the chemical composition of the activated and the non-activated particles. From the measured mass concentration of the interstitial and out-of-cloud aerosol particles, we calculate a chemically resolved activated mass fraction f_{mass} for the individual compounds that can be detected by the AMS (organics, sulphate, nitrate, ammonium, and chloride) by the following equation:

$$f_{mass} = \frac{\overline{C_{ooc}} - C(t)}{\overline{C_{ooc}}},$$

where $\overline{C_{ooc}}$ is the average mass concentration measured directly before and after the cloud event and $C(t)$ is the concentration of the interstitial aerosol during a cloud event.

Figure 1 displays the resulting activated mass fraction for a selection of cloud events on September 16. The upper panel shows the cloud droplet number concentration, the middle panel the measured particle mass concentration (out-of-cloud and interstitial), and the lower panel shows the activated mass fraction. While the inorganic species reach activated fraction of more than 90%, the organic activated mass fraction is significantly lower (on average by 10%) for all cloud events displayed here. Further investigation will clarify whether this effect is due to a higher fraction of organic mass in the smaller particle size range or if the effect is due to the lower hygroscopicity of organic particulate matter compared to inorganic material as ammonium sulphate or ammonium nitrate. The latter is connected to the O:C ratio of the organic particulate matter which increases with particle aging in the atmosphere, leading to an increase in hygroscopicity (Jimenez et al., 2009)

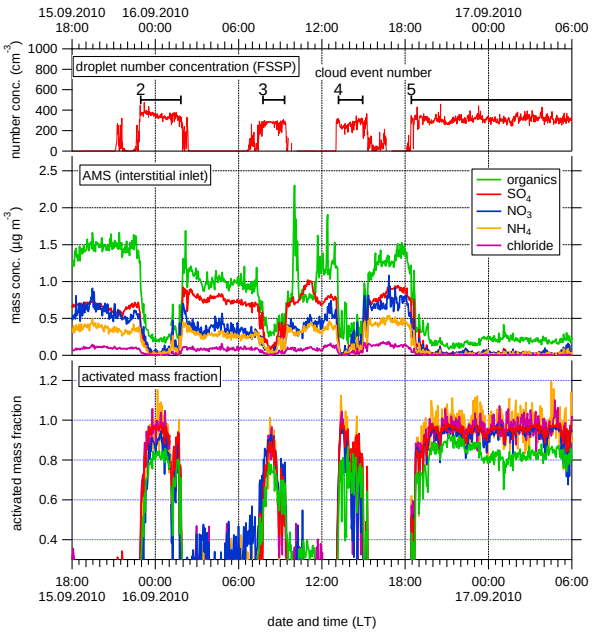

Figure 1. Example for the activated mass fraction analysis during selected cloud events. Upper panel: cloud droplet number concentration, middle panel: absolute mass concentrations (interstitial inlet), lower panel: activated mass fractions.

The AMS data will be further analysed for chemically resolved size distribution and organic O:C ratio. The analysis of the cloud residuals sampled through the CVI inlet and measured with the second AMS will complete the interpretation of the results.

Understanding phase transition and hygroscopic behavior of organic acid particles and their mixtures with ammonium sulfate by micro-Raman spectroscopy

M.C. Yeung[1] and C.K. Chan[2]

[1]Department of Chemical and Biomolecular Engineering, [2]Division of Environment,
Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, 852, Hong Kong
Keywords: deliquescence, crystallization, hygroscopic growth, Raman microscopy
Presenting author email: meiji@ust.hk

Hygroscopic particles can interact with water vapor and change in phase state, size, concentration and even chemical composition, all of which can influence optical properties, cloud condensation nuclei (CCN) activity as well as chemical reactivity. Laboratory investigation of the aerosol thermodynamic properties is therefore necessary to elucidate their impacts on global climate and tropospheric chemistry.

Organic components have been found as the major constituent of atmospheric aerosols and they are often mixed with inorganic species. In this study, we applied the micro-Raman spectroscopic technique to examine four organic particles, including malonic acid (MA), glutaric acid (GA), adipic acid (AA) and glyoxylic acid (GlyA), as well as their mixtures with ammonium sulfate (AS). Mirco-particles deposited on a hydrophobic substrate in an air-flow cell were exposed to changing relative humidity (RH). Raman spectra of single particles were recorded. Changes in Raman spectral features as a function of RH were useful in determining the phase states and water content of the particles (Yeung *et al.*, 2009; Yeung and Chan, 2010)

The Results of phase characterization show that single-component particles usually undergo instant deliquescence and complete crystallization, while the multi-component systems may undergo gradual deliquescence and partial crystallization. Step-wise crystallization of AS-GA mixed particle is shown in Figure 1. Pure GlyA has an exceptional non-deliquescent behavior, which remained as supersaturated solution at dry condition as confirmed by the presence of water peak.

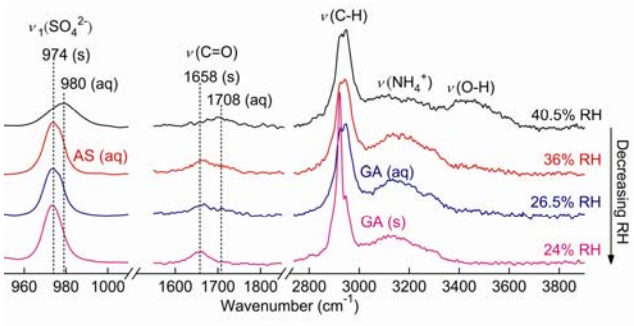

Figure 1. Raman spectra of AS-GA mixed particle to illustrate the occurrence of partial crystallization.

The hygroscopic properties of ammonium sulfate apparently altered after mixing with organic species (see Figure 2). When the water-soluble dicarboxylic acids (MA and GA) present, particle can retain water at low RH conditions (RHs below the crystallization point for ammonium sulfate). The less water-soluble AA exhibits insignificant effect on the particle water content during crystallization process. Early water-uptake behavior has been observed in all mixed systems.

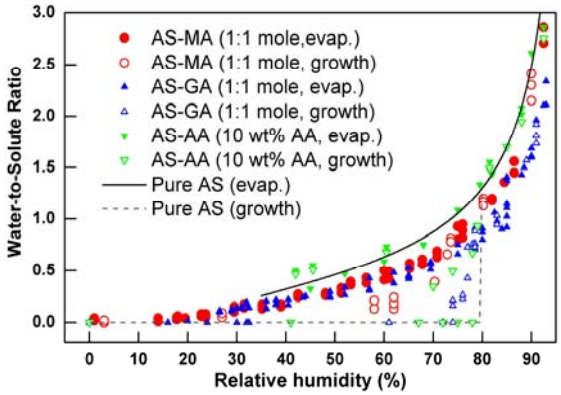

Figure 2. Hygroscopic properties (water-to-solute mass ratio) of pure AS and AS-organic mixed particles.

We also characterized two polymorphs of pure GA solid particles and investigated the effect of polymorphic transformation on deliquescence properties (Yeung *et al.*, 2010). The metastable α-form GA solids can either deliquesce or transform to the more stable β-form at 86% RH. Gradual water-uptake by β-form particles was observed until the RH further increased to ~90%. The water-uptake process was not completed in5 hours, indicating a mass-transfer effect for the β-form. Our observation can explain the discrepancies in the deliquescence of GA particle reported in literature, which was found to occur between 83% and 90% RH.

Raman spectroscopy has been demonstrated for investigating particle phase and hygroscopic properties. This laboratory technique will be further used for understanding the phase transition properties as well as the molecular interaction in other mixed particles.

This work was supported by Earmarked Grant (610909) from the Hong Kong Research Grants Council.

Cloud Condensation Nuclei Closure Study on Summer Arctic Aerosol

S. Sjogren[1], E. Fors[1], E. Swietlicki[1], M. Martin[2] and B. Sierau[2]
[1]Division of Nuclear Physics, Lund University, Lund, Sweden
[2]Institute for Atmospheric and Climate Science, ETH Zurich, Zurich, Switzerland
Keywords: Aerosol cloud interaction, Clouds, Arctic aerosols, AMS, HDTMA, CCN.
Presenting author email: staffan.sjogren@nuclear.lu.se

To better understand the warming of the arctic, the radiative balance of sunlight and infrared radiation needs to be described. Clouds play a major role in this balance. Each individual cloud droplet is formed on an atmospheric aerosol particle. Descriptions and measurements of relevant aerosol particle properties and the particle interactions with cloud droplets from the high Arctic are rare.

We present an aerosol-cloud condensation nuclei (CCN) closure study on summer high Arctic aerosol, based on measurements that were carried out in August 2008 during the Arctic Summer Cloud Ocean Study (www.ASCOS.se) on board the Swedish icebreaker *Oden*. The main data was collected during a three-week time period in the pack ice ($> 85^\circ$ N) when the icebreaker *Oden* was moored to an ice floe and drifted passively during a biological active period into autumn freeze up conditions.

Method and results

CCN number concentrations were obtained using two CCN counters from Droplet Measurement Technologies (DMT, USA), measuring at different supersaturations. The relevant dry particle size studied was approximately 0.03 to 1 μm. The directly measured CCN number concentration was firstly compared with a CCN number concentration predicted using bulk aerosol mass composition data from an aerosol mass spectrometer (AMS) and aerosol size distributions obtained from a differential mobility particle sizer, assuming κ-Koehler theory and an internally mixed aerosol. The AMS had a minimum dry particle cut-off diameter of about 70 nm, thus not capturing the chemistry of the smallest particles activated. Secondly, size-resolved measurements of the hygroscopicity (water uptake) of the aerosol particles were included in the closure, down to 30 nm. A hygroscopicity tandem differential mobility analyser (HTDMA) was used for this purpose.

For the first "AMS"-approach closure can be achieved (Martin *et al*, 2011), with different parameters for the hygroscopicity and density of the particles, at each of the 0.10, 0.15 and 0.20% supersaturations. For the best fits of the predicted CCN number concentration against the measured one, the organic fraction of the aerosol is found nearly insoluble ($\kappa_{org} = 0.02$). However, this is not ambigious and $\kappa_{org} = 0.2$ is found as an upper limit at 0.1% supersaturation. For the two highest supersaturations, 0.41 and 0.73%, closure could not be achieved with the investigated settings concerning hygroscopicity and density. The predicted CCN number concentration is always higher than the measured one, suggesting that the smaller particles that activate at these supersaturations have a relative larger insoluble and/or organic mass fraction than the larger particles. Current ongoing investigations use the measured hygroscopicity data in the subsaturated regime, with dry sizes measured down to 30 nm in the closure (see Fig. 1). As it is observed that the hygroscopicity decreases with decreasing size, this supports the assumption of more organics in the smallest particles. This will be more detailed during the conference.

Moreover, different periods will be investigated in more detail by case studies, i.e. taking different weather situations and the transport of air masses into consideration.

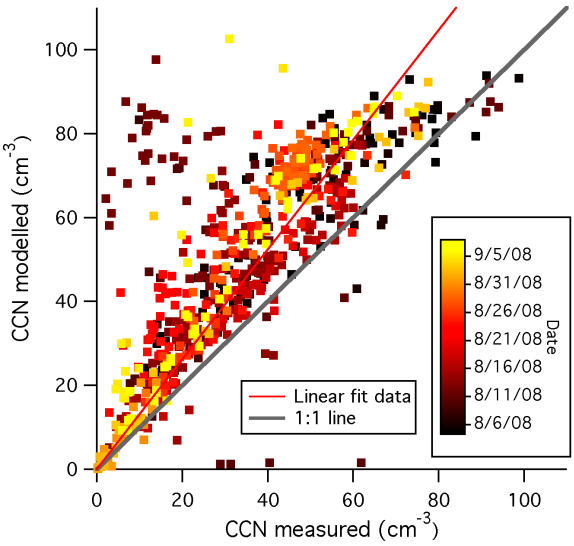

Figure 1: Preliminary closure from HTDMA data to 0.2%SS CCN measurements.

Importance of different surfactant representations for cloud droplet numbers predicted with the ECHAM5.5-HAM2 aerosol-climate model

Presenting author email: nonne.prisle@helsinki.fi

The indirect radiative effects of atmospheric aerosols via their influence on cloud drop formation and cloud properties constitute the single largest uncertainty in predictions of global climate and future climate changes (IPCC, 2007). Aerosol cloud condensation nucleus (CCN) activity is determined by both particle size and chemical composition, but CCN activity of the organic aerosol fraction in particular remains to be firmly constrained (Hallquist *et al.*, 2009). This in part owes to the surface activity (the tendency to preferentially accumulate in the surface region) in aqueous solutions of some organic components of atmospheric aerosol particles. Surface active molecules (surfactants) have been demonstrated in aerosol and cloud and fog water samples from a wide variety of atmospheric environments and can collectively comprise a significant fraction of the organic aerosol mass (Mochida *et al.*, 2003).

Both thermodynamic model calculations and laboratory experiments show that surface activity can significantly affect organic aerosol CCN potential (Prisle *et al.*, 2010a). The combined effects of partitioning of organic molecules to the droplet surface and of reduced droplet surface tension, for calculated cloud droplet activation, can be determined from numerical solutions to thermodynamic relations. Unfortunately, such calculations with several nested iterations are computationally too demanding for implementation into atmospheric models (Kokkola *et al.*, 2006). Therefore, Topping (2010), Raatikainen and Laaksonen (2010), and Prisle *et al.* (2010b) have proposed different parametrizations to account for the combined effects of surfactant properties in calculations of organic aerosol CCN activation.

In this work, we compare predictions of cloud droplet number concentrations using the aerosol-climate model ECHAM5.5-HAM2 with different representations of the aerosol organic carbon fraction in terms of the influence of surfactant properties on cloud microphysics. Specifically, we use the mentioned novel parametrizations, which account for the combined organic surfactant effects, in addition to the previously applied approaches using either reduced droplet surface tension without consideration of organic surface partitioning effects, or disregarding surfactant properties altogether (Prisle *et al.*, 2010a). The cloud droplet numbers are calculated using the cloud activation parametrization by Abdul-Razzak and Ghan (2000), which has here been extended to account for effects of organic surface activity according to each of the different approaches used.

We have made one year simulations with prescribed meteorology, assuming that all aerosol organics are surface active with properties corresponding to Suwannee River Fulvic acid. Our preliminary results show that including surfactant effects on cloud microphysics can significantly affect predicted cloud droplet numbers, compared to the conventional approach that disregards such effects altogether. This is especially the case in areas of high organic aerosol mass concentrations. Furthermore, how surfactant properties are accounted for, in terms of either including or disregarding effects of surface partitioning, also has a significant effect on droplet numbers in the cases studied. These results are the first to include such detailed effects of surfactant properties in global scale simulations, and somewhat contradict the anticipation that the non-linear responses predicted from thermodynamics to a combination of several surfactant effects on droplet activation would largely cancel out in large scale predictions.

The impact of mineral dust particles on cloud properties and the state of the atmosphere during an intense Saharan dust event over Western Europe

max.bangert@kit.edu

Dust, through their action as cloud condensation nuclei (CCN) and ice nuclei (IN), has long been hypothesized to impact clouds and the hydrological cycle. This effect is particularly strong during dust outbreaks. Europe, being adjacent to the Sahara, is susceptible to the effects of dust storms; a quantitative assessment remains elusive and is the subject of this study.

This talk focuses on one major dust event that occurred in May 2008. Its origin was the Sahara and from there mineral dust particles were transported over the western Mediterranean, covering large areas of Western Europe. During the episode, high aerosol concentrations were observed throughout Europe; ice nuclei concentrations significantly increased (compared to pre-event levels) at Kleiner Feldberg, Germany (Klein *et al.*, 2010). During this time, traditional weather forecast models (which currently neglect aerosol impacts on atmospheric processes) exhibited poor prediction skill.

The impacts of dust on atmospheric state is studied with the regional scale online coupled model system COSMO-ART (Vogel *et al.*, 2009) that accounts for feedbacks between chemistry, aerosols, radiation, and clouds. A two-moment cloud microphysics scheme (Seifert and Beheng, 2006) is coupled together with comprehensive parameterisations for aerosol activation (Barahona *et al.*, 2010) and ice nucleation (Barahona and Nenes, 2009) to simulate the impact of the various aerosol particles on the cloud microphysics and therefore on cloud properties and precipitation.

Two simulations were compared to investigate the impact of dust on clouds and the atmospheric state in detail. In simulation R the dust is neglected and just anthropogenic and sea salt particles are simulated. In simulation D the dust is considered during cloud formation and therefore has an impact on cloud droplet and ice crystal number concentrations.

Figure 1 shows that the dust strongly increases the ice crystal number concentration. The impact on the warm cloud phase is more complex due to the non-linearity of the involved processes. During the dust event we found a systematic cooling effect (~1 K) due to an increase in cloud optical depth.

The sensitivity of cloud properties and of the atmospheric state to the dust amount is thoroughly studied.

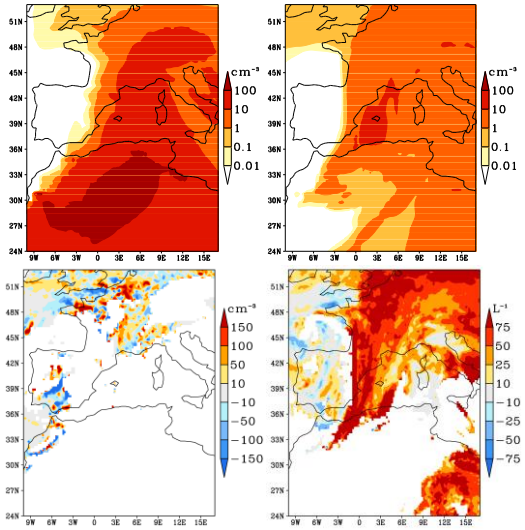

Figure 1. Distribution of dust number concentration in the lower (top left) and upper troposphere (top right) as well as the difference in the mean cloud droplet and ice crystal number concentration between simulation D and R at May 26th 2008.

Aerosols and clouds play an essential role in the Earth's radiation budget. Particularly aerosol-cloud interactions are a large source of uncertainty in climate sensitivity estimates. Although a variety of airborne measurements have been performed, most of them suffer from a low spatial resolution.

The helicopter-borne measurement platform ACTOS (Airborne Cloud Turbulence Observation System, Siebert *et al.*, 2006) is equipped with various instruments to investigate cloud and aerosol microphysical properties, meteorological and turbulence parameters at high temporal and spatial resolutions. Aerosol number size distributions were measured between 6 nm and 2.6 µm using an SMPS (6 to 260 nm, time resolution 2 min) and an OPC (250 nm to 2.6 µm, time resolution 1 s). In addition total particle number concentrations have been measured with a commercial CPC (TSI, D_p > 6 nm, time resolution 1s) and a fast mixing type CPC (Wehner *et al.* 2010, D_p > 7.5 nm, response time ~20 ms). Furthermore, cloud condensation nuclei (CCN) were measured with a miniaturized CCNC and droplet size distributions were measured by a Phase Doppler Interferometer for Cloud Turbulence (PICT) .

In November 2010, the Clouds, Aerosol, Radiation, and tuRbulence in the trade wInd regime over BArbados (CARRIBA) Experiment took place. Within the campaign 17 research flights (RF) inside and outside of trade wind cumuli, and additionally, ground-based aerosol and CCN measurements were performed.

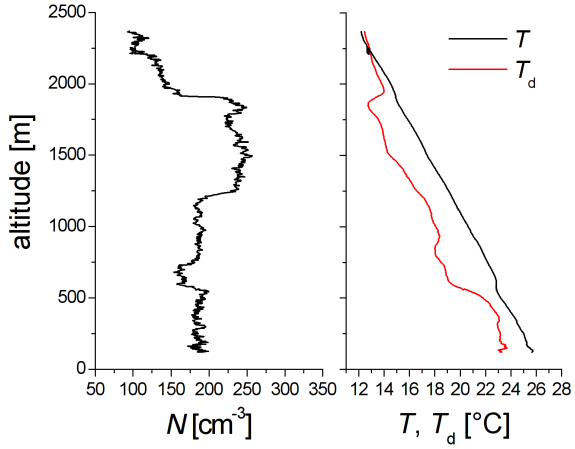

Figure 1. Vertical profiles of total particle number concentration (N), temperature (T) and dewpoint (T_d) during RF9.

Figure 1 presents vertical profiles of N, T and T_d recorded during RF9 on November 20th. The temperature profile illustrates weak inversions at 600 m and 2000 m above sea level (ASL), whereas the dewpoint indicates a humid layer up to 600 m and a cloud layer at 2200 m ASL. The total particle number concentration shows different aerosol layers. The lowermost 600 m represent the well mixed marine boundary layer and feature an average $N \sim 180$ cm^{-3}. At the altitude of the first temperature inversion, N exhibits a local minimum, which is followed by two layers of $N \sim 180$ cm^{-3} and $N \sim 220$ cm^{-3}. Finally, N decreases immediately at the second inversion reaching minimum values close to 100 cm^{-3}.

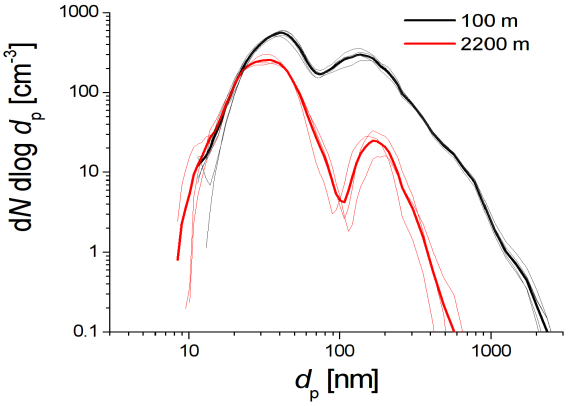

Figure 2. Aerosol number size distributions (NSDs) recorded during RF9 at different altitudes. Bold lines indicate average NSDs.

Figure 2 presents number size distributions (NSDs) of the aerosol measured at 100 m (black) and 2200 m ASL (red). All NSDs feature a bimodal shape typical for marine aerosol and a dominating Aitken mode. The NSDs at 2200 m were recorded inside a very thin stratiform cloud layer at the cloud top of surrounding cumuli.

With the help of simultaneous measurements of cloud micropysical and CCN properties as well as NSDs inside and outside of clouds this study aims at examining the complex interactions of atmospheric aerosols and small scale cloud dynamics in the vicinity of trade wind cumuli.

Session 7C: High Temperature Systems: Sampling and Quenching before Detection

Experimental study of aerosols and vapours at high temperatures: past and recent application of aerodynamic quenching.

S. Jiménez[1] and J. Ballester[2]

[1]LITEC-CSIC, Spanish Council for Scientific Research, María de Luna 10, 50018, Zaragoza, Spain

Keywords: high temperature aerosols, aerosol sampling, aerosol formation, low-pressure-impactor.
Presenting author email: yago@litec.csic.es

The study of aerosol formation in biomass combustion illustrates the relevance of relying on a suitable experimental technique to obtain samples representative of the sampled system, which may include inert gas and reactants, as well as coarse and fine aerosols and the most problematic component for this kind of studies: condensable vapours. The traditional solution for sampling in the presence of high concentrations of water or sulphuric acid vapour, i.e. keeping the sampled gas above the corresponding dew point, is hardly applicable to this study, since the inorganic compounds present in the fine aerosols generated after biomass combustion (mainly alkali chlorides and sulphates) have relatively high melting points (>750°C). Condensation or nucleation of these inorganic vapours in the sampling line is thus a (nearly) unavoidable problem, whose effects on the 'desired' sample must be minimised or at least controlled.

Among the sampling and analysis methods available, aerodynamic quenching appeared as a promising option for its known ability to generate extremely fast cooling and dilution rates (Bowman, 1977; Colkett *et al*, 1982). The application of a particle sampling probe based on this technique (AQPS probe) in combustion experiments in an entrained flow reactor allowed for establishing well differentiated steps in the aerosol formation route, namely alkali sulphate nucleation followed by alkali chloride condensation on these nuclei (Jiménez and Ballester, 2004), in good agreement with previous theoretical predictions (Christensen *et al*, 2000).

The main advantage of the use of this probe is to clearly separate aerosols that already existed in the sampled gas from freshly nucleated ones formed along the probe itself, most likely at its entrance. Figure 1 illustrates this feature: the 'coarse', opaque particles are sulphate aerosols sampled at 900°C, whereas the small, almost electron-transparent particles are composed of alkali chloride, which was in the vapour phase at the sampling point. In principle, this technique may thus provide information not only on the aerosols, but also on the inorganic vapours present at high temperatures.

A non-negligible drawback of the technique is that the gas at the exit of the probe is at low pressure (typically ~0.07 bar), which makes in-line analysis of the sampled gas and aerosols difficult. In the past, an impaction system was designed *ad hoc* in order to collect the aerosols on TEM grids for their analysis under the microscope. Recently, however, a commercial low pressure impactor has been used to characterise the aerosols exiting the probe, confirming and extending previous results from this group (Jiménez and Ballester, 2011). This required a prior study on the behaviour of the impactor at low inlet pressures.

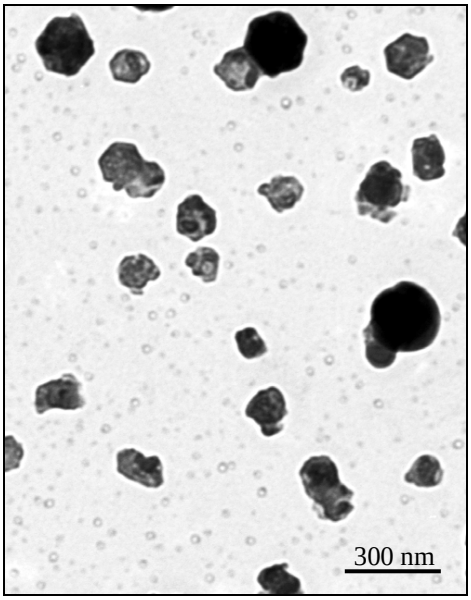

Figure 1. Sample obtained with the AQPS probe at 900°C in biomass post-combustion gases.

Automated sampling system for studying iodine chemistry at high temperature

J. Kalilainen[1], T. Kärkelä[1], P. Rantanen[1] J. Forsman[1], L. Kåll[1], A. Auvinen[1] and J. Jokiniemi[1,2]

Keywords: iodine, primary circuit, severe accident, automated sampling system.
Presenting author email: jarmo.kalilainen@vtt.fi

The aim of the work was to improve the instrumentation of the EXSI facility Kalilainen *et al* (2011), used at VTT for studying fission product behavior at high temperatures. As a result very accurate measurements on the transport of iodine in conditions typical to a hypothetical severe nuclear accident could be conducted.

Experimental facility

The experimental facility consists of a reaction furnace, in which various fission product species react on a surface at 400-650°C. Gaseous reaction products as well as vaporised compounds are transported from the furnace with a carrier gas flow. The concentration and number size distribution of particles as well as the gas composition are monitored online. In addition, filters and bubbling bottles are applied to carry out speciation of particle and gaseous samples off-line. The modifications made to the experimental facility included automated sampling system, extensive logging of pressure, temperature and flow rate data and improvements in the primary diluter, which reduced the retention on its walls.

The structure in the hot section of the two-stage primary diluter and the reaction furnace tube were modified in order to reduce the depositions caused by condensation and thermophoresis. The diameter of the furnace tube was decreased at the outlet from 24 mm tube to 10 mm. The outer diameter of the diluter was designed so that during the experiment, the hot dilution part is situated inside the reaction furnace all the way to the hot gas inlet tube. Hot and cold dilution stages are connected so that the walls of the sampling line remain at high temperature until the gas flows are mixed. In the new facility, both hot and cold dilution gas can be heated with Mayer-resistant 930 W flow heaters. Flow heaters are operated by using the controlling computer.

The sampling system for the filters and bubbling bottles has been entirely automated. The filter sampling is started by typing the desired sampling time to the controlling computer and choosing the desired sampling line. As the sampling switch has been activated on the program, the controlling computer automatically opens the valve of the sampling line, and again closes it after the sampling time has expired. Gas flow through the sampling line is controlled with a critical orifice and logged by the controlling computer.

Experimental work

Experiments on gaseous iodine production due reactions on the surface were carried out using CsI as a precursor. The gas atmosphere applied in the tests was a mixture of argon, steam and hydrogen. The concentration of gaseous iodine and iodine containing aerosol species was determined with ICP-MS analysis of the filter and bubbling bottle data. As evident in figure 1, the mass concentration of gaseous iodine decreased when the concentration of H_2 in atmosphere was increased. When either molybdenum oxide or boron oxide was added to the reaction furnace, the fraction of gaseous iodine was very significantly increased. The increase was due to formation of cesium borate and cesium molybdate species. Especially at 400°C essentially all iodine released was in gaseous form. The filter analysis was confirmed by online measurement devices such as TEOM and SMPS showing very low particle mass and number concentrations.

This result highlights the importance of controlled quench and dilution as losses even at a fairly moderate temperature would influence the experimental results very significantly.

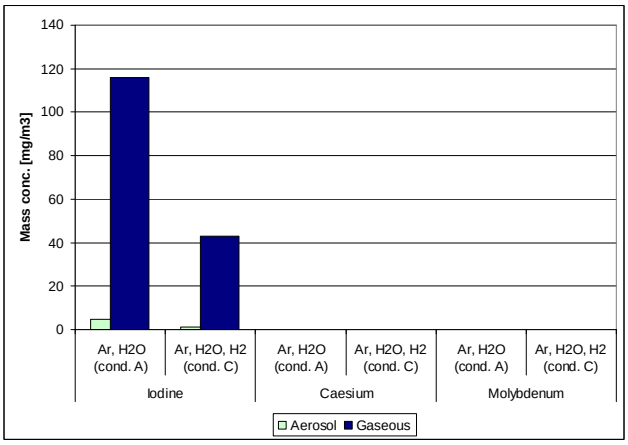

Figure 1. Iodine, caesium and molybdenum mass concentrations in the second experiment, calculated from aerosol filters and bubbling bottle ICP-MS data.

Combustion aerosols are the most important source for health relevant anthropogenic aerosols. As the physical-chemical properties of the emitted aerosols are determined on the processes in the high temperature region, the investigation of high temperature aerosol thus is of particular relevance. In order to understand the dynamic properties of freshly formed hot combustion aerosols, on-line measurements of the physical (size distribution) and chemical aerosol properties is required. An important aspect of studies addressing the chemical composition of high temperature aerosols is the temperature dependence of the particle-phase/gas-phase distribution. Many health-relevant semi-volatile organic compounds, such as the polycyclic aromatic hydrocarbons (PAH) which predominately are particle-bound under ambient conditions, are formed and are present in the gas-phase within the hot combustion flue gas. In order to analyse the organic gas-phase composition on-line mass spectrometric (MS) techniques using soft ionisation technologies can be applied. Unlike in aerosol mass spectrometers such as the AMS, ATOFMS or more sophisticated, experimental aerosol mass spectrometric devices which are addressing the particle-phase composition, the particles need to be precipitated before analysis in gas phase mass spectrometers. This usually is performed by hot-gas filtration at e.g. 250-300 °C (note that this has the advantage, that the collected filter samples can be off-line analysed for the PM composition [1], see also Figure 1). The transfer line to the mass spectrometer and the MS inlet then are heated at least to the same temperature as the filtering unit in order to avoid new particle formation during sampling due to condensation and nucleation effects. Two soft ionisation technologies for MS are particularly well suited to on-line analyse molecular combustion products. On the one hand, the laser based resonance-enhanced multiphoton ionisation (REMPI) method selectively ionises aromatic compounds [1], partially with extreme efficiency. On the other hand, single photon ionisation (SPI) with vacuum ultraviolet photons allows a universal ionisation of organic compounds (but at lower efficiency) [2]. In the case of REMPI-MS, PAH profiles can be detected if combustion aerosols form e.g. wood combustion [1,2] or car exhaust [3] are analysed. However, if pyrolysis gases or un-burnt fuel vapour are sampled, other compound profiles are getting dominant. In the case of wood combustion, e.g., phenolic compounds, stemming from the decomposition of lignin, are characteristic. Aliphatic molecules, however, are not addressed by the REMPI ionisation method. If SPI-MS is applied, the aliphatic compounds are visible too. In the case of un-burnt fuel (gasoline of diesel) the alkanes and naphtenes are detectable while the SPI-MS analysis of wood gasification gas shows celluloses decomposition products (carboxylic compounds, furane derivatives etc.) as well as the phenol from the lignin decomposition.

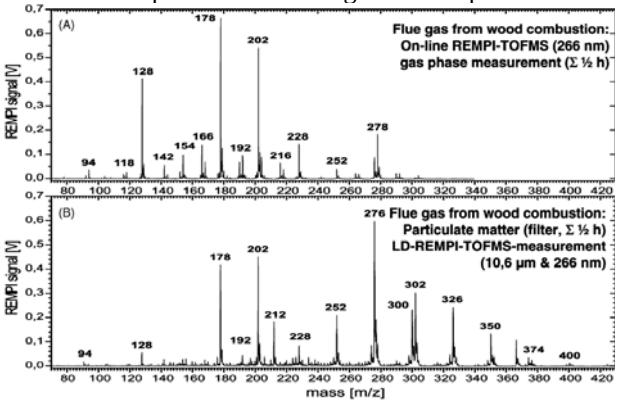

Figure 1: REMPI mass spectra from wood combustion gas-phase (on-line REMPI-MS measurement) and from the filter used for hot-gas particle precipitation (off-line, laser desorption-REMPI-MS) [1].

In addition to the gas phase compounds simultaneously the particle size distribution (e.g. by SMPS, ELPI etc.) as well as the particle chemistry (aerosol mass spectrometry, e.g. AMS, ATOFMS or LD/REMPI-ATOFMS[4] shall be on-line measured. Here totally different sampling approaches are required. This is in particular true as most particle measurement technologies are not capable to handle the hot aerosol directly. If the high-temperature properties shall be addressed the hot aerosol is diluted rapidly first with hot air then with ambient temperature air in order to "stabilize" the aerosol composition. Alternatively a dilution tunnel system is applied which, however, causes larger changes of the aerosol properties due to e.g. condensation effects but is reflecting the "chimney-near" properties of the emissions. In the contribution primarily REMPI/SPI-MS and size distribution results from wood combustion/pyrolysis and car exhaust (dynamometer) measurements are discussed.

High-Temperature extraction of aerosol particles from biomass combustion and gasification

M. Strand[1], E. Gustafsson[1], L. Lin[1], and J. Yang[1,2]

[1]School of Engineering, Linnaeus University, Växjö, 351 95, Sweden
[2]Technology and Management, Gjøvik University College, Norway
Keywords: Aerosol characterization, Combustion aerosols, High temperature aerosols.
Presenting author email: michael.strand@lnu.se

During biomass combustion and gasification, aerosol particles are formed from various mechanisms. In order to establish these mechanisms as well as to control and monitor the process operation, particles can be extracted from the hot reactor and then characterised. Most methods for analysing hot aerosols require cooling before feeding to the instruments. The hot gas contains both organic and inorganic species that will condense as the gas is cooled, and these species must be separated from the gas in order to avoid distortion of the PM sample. At gas temperatures above 600ºC vapours from alkali and heavy metals may be present in the gas from both combustion and gasification. Biomass gasification also produces heavy tar components that condense below 400 ºC

In order to enable characterisation of PM in the hot gas from combustors and gasifiers, a sampling system has been developed (Figure 1.). The system includes a two-stage separation unit. In the first stage the gaseous alkali and heavy metals are separated during cooling by guiding the condensation towards the internal surface of the probe. In order to improve the operation of the separation unit the vapour pressure is reduce before cooling by dilution with hot air/nitrogen at the probe tip. In the second stage the tar is removed through sequential cooling and adsorption by activated carbon. Downstream the sampling system the PM characterised using a battery of aerosol instruments. The system is described in detail by Gustafsson *et al* (2007).

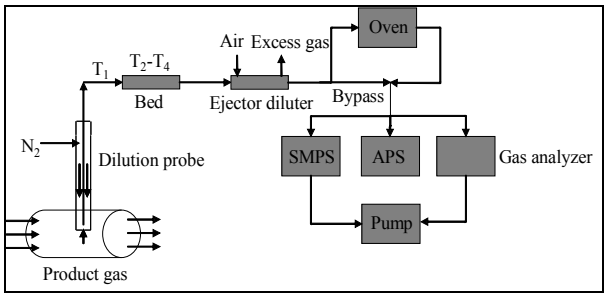

Figure 1. Schematic view of the sampling system and the battery of aerosol instruments.

The sampling system was used in order to characterise aerosol particles in the producer gas from three different types of pilot scale biomass gasifiers at a gas temperature of 500-850 °C. The aerosol was characterised using an electric mobility analyser (SMPS model 3080, TSI Inc.), a time of flight instrument (APS model 3321, TSI Inc.), a low pressure cascade impactor (DLPI, Dekati inc.) and an electric low pressure impactor (ELPI, Dekati Inc.). Figure 2 shows the coarse mode particle mass size distribution obtained from the APS/ELPI data, assuming spherical particles with a density of 1000 kg/m^3. The results have been corrected for losses in the two-stage separation unit but not for the remaining probe and dilution system. The elementary and morphology analyses of the DLPI samples showed that the particles from the three gasifiers had different origin. PM from the BFB gasifier was dominated by char, the PM from the CFB gasifier was dominated by bed material, and the PM from the indirect gasifier was dominated by fly ash.

The tar adsorption capacity of the second stage of the separation unit was evaluated by re-heating the aerosol stream at 400°C in an electric oven. The aerosol size distribution obtained from the CFB gasifier did not change substantially when passed through the oven, which indicates that the PM was tars had been successfully removed. When reheating the aerosol stream from the indirect BFB the PM in the sub-micrometer size range changed, indicating that the tar separation unit was not operating satisfactory in this case.

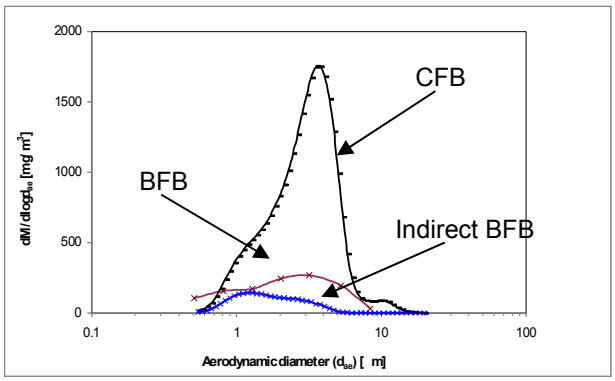

Figure 2. Estimated mass size distribution

The tar adsorption capacity of the separation unit was evaluated in the laboratory using a gas containing a model tar compound (Gustafsson and Strand, 2010). The removal efficiency of the first stage of the separation has been evaluated (Strand et al, 2005). The unit is presently being investigated in detail and the new results will be presented.

Presenting author email: Olli.Sippula@uef.fi

In order to get experimental data on the aerosol formation and transformation inside the high temperature systems a quench-diluting sampling system has been developed. In this system, the sample is quenched, by rapidly decreasing temperature and concentrations, to freeze the chemical reactions, particle agglomeration and, at the same time, to prepare the sample suitable for different analyzers. However, in many cases, for example due to the large amount of condensable vapours in the samples, considerable changes in the samples cannot be avoided. Thus, a reliable sampling from the hot process gas is usually challenging.

The aim of this work was to study the porous tube diluting probe for high temperature sampling of aerosol. For testing the probe two different high temperature aerosols were generated. First, the high temperature probe was used on conditions typical in biomass-fired boilers. Secondly, the probe was used for sampling inside the high temperature nanoreactor. The sampling system in this study is similar to the porous tube diluting probe used previously in combustion studies (Sippula et al., 2008).

The experiments were carried out with laboratory reactors where synthetic aerosols were generated by chemical vapour synthesis. The first aerosol consisted of principal components present in biomass combustion aerosol (KCl and K_2SO_4). KCl vapour was supplied into the reactor, using a saturator. K_2SO_4 particles were produced inside the reactor by supplying controlled amounts of SO_2 and H_2O gases into the reactor. The amount of K_2SO_4 formed was tracked by measuring SO_2 and HCl concentrations using an FTIR analyzer (Gasmet). In the second experiments, iron oxide nanoparticles were produced using iron pentacarbonyl as a precursor material.

In both reactors the aerosol sample was drawn into the porous tube diluting probe at temperatures varying from 300 to 750 °C. The sampling point was varied. After the porous tube diluting probe the secondary dilution was conducted in an ejector diluter. The diluted samples were analyzed for particle size distributions using Nano-SMPS (TSI) and FMPS (TSI). To get information on the conditions inside the diluter, axial profiles of sample temperature and mixing with the dilution air were measured. The mixing was measured by moving a thin probe at the centreline of the diluter and measuring the marker-gas (CO_2) concentrations. The experimental results were interpreted using a 1D sectional model (Backman et al., 2002) which solves numerically the particle size distribution and particulate chemical composition, given by nucleation, condensation, coagulation and surface reactions.

The measurements showed a relatively fast mixing and cooling in the porous tube (Fig 1). The particle size distributions were sensitive to sampling conditions, as expected. The experimental results and simulations agreed well showing that the condensing vapours tend to nucleate in the probe at high cooling rates despite of high concentrations of seed particles.

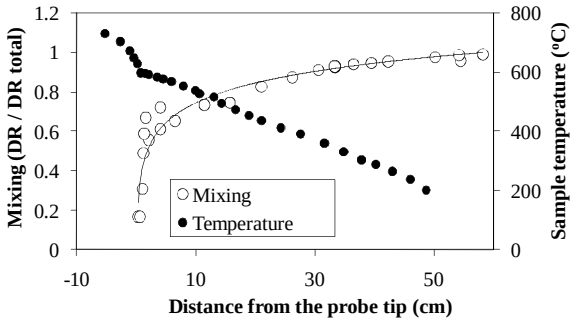

Figure 1. Measured mixing and temperature profiles in the diluting probe.

The separation of condensing vapours and particulates during high temperature sampling would be important for the interpretation of the results. The used sampling probe was found to favour the formation of nucleation mode with high cooling rates. The used 1D aerosol dynamics model was found to be useful for pre-evaluating different sampling probe constructions and to select optimal sampling conditions.

Research has been supported by the strategic funding of the University of Eastern Finland and the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 211464.

For different toxic potentials (Antonini *et al*, 2004) have been postulated for coarse and submicron to nanoparticle size range, a crucial aspect of welding fumes is the variability of the morphological and chemical characteristics within a rather small area from the electrode tip. SEM/TEM analyses together with real-time size distributions as well as elemental analysis of bulk samples have been chosen as core experimental method. This methodological approach is consistent with that of (Moroni *et al*, 2009) although special consideration of the differences depending on the aerosol history has been made. Therefore, it focuses on the spatial differences of chemical, structural and size distribution parameters of welding fumes.

Experiments consist of 8-hour periods of welding operation. For emission dynamics is variable, real-time size analysis of size distribution was accomplished by means of an APS3321 (TSI), an ELPI (Dekati) and a WPS (MSP). Samples for SEM/TEM analysis were taken using a MOUDI (MSP) and a NAS (TSI). Sampling positions were chosen as representative of the inhaled aerosol, of the primary emission (thus close to the arc and exhaust flow) and finally of the working place environment. Temperature and gas composition (FTIR) data allow dilution and cooling estimates.

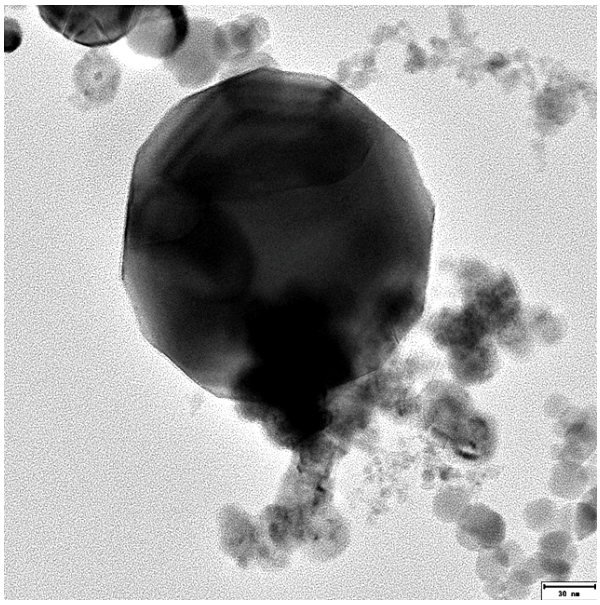

Figure 1 Freshly nucleated AISI 308 stainless steel aerosol. Primary particle size of magnetite and Ni-rich dendrites.

Primary particles of SS fume are almost spherical, whereas larger crystals rich in magnetite evolve to euhedral shapes, showing a increased contribution of Cr, Mn and Ni as particle size increases. SAED spots of high intensity and sharpness indicate high crystallinity of primary particles. The final result of cooling and dilution depends on the reaction mechanisms, the O2 availability and, on the non-measurable interfacial conditions (as a result of combined heat and mass transfer). The map of observed complex structures will be defined on the basis of aerodynamic diameters, thus, classifying di spinel-like oxides formed during cooling, core-shell structures and agglomerates of magnetite-like particles. Twinning of magnetite-rich structures is shown as dependent of the dilution and cooling history.

In contrast, although expected due to Al high stacking fault energy, neither twins nor dislocations were observed, although core-shell structures account for up to 20% of 40nm particles.

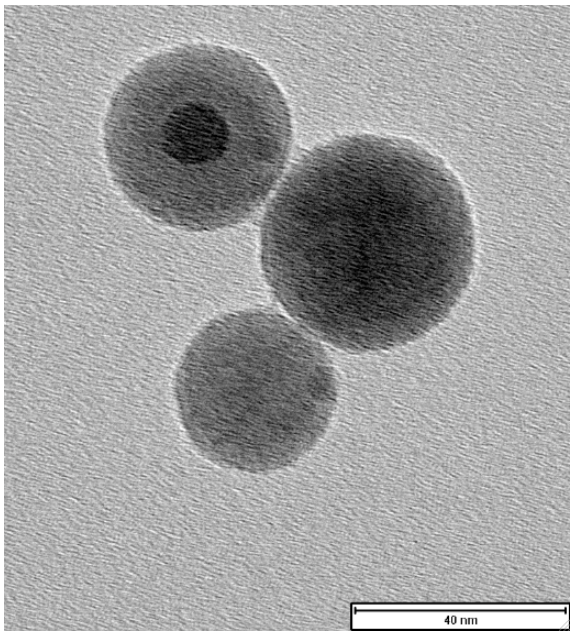

Figure 2. Freshly- to medium-aged Al aerosol. The Al nanoparticles appear as spheres from 20 to 40 nm.

Session 7D: Particle-Lung deposition and Pharmacological Aerosol

Producing Drug particles for Inhalation via Electrospray

C.U. Yurteri and J.C.M. Marijnissen

Delft University of Technology, Delft, 2628 BL, The Netherlands

Keywords: Electrospray, Inhalation, Micro Droplets, Nanoparticles

Presenting author email: c.u.yurteri@tudelft.nl

Drug delivery by the inhalation route is a non invasive and historically one of the oldest methods to administer drugs and fight several lung diseases such as asthma, emphysema, bronchitis, and chronic obstructive pulmonary diseases. As new types of drugs based on proteins, peptides, and DNA are developed, inhalation routes are considered to be used for insulin delivery, cancer treatment, pain control, and nanotherapeutics (Yurteri et al. 2010). What makes pulmonary administration in general an advantageous route to deliver therapeutics is the ease of administration, rapid onset because of the area available for permeation to cells and the blood stream, smaller doses administered compared to the oral administration route, and better efficacy to safety ratio compared to systematic delivery. Use of nanoparticles, in addition, could improve release properties in the lung (Sung et al. 2007). However, the success of administration depends greatly on the performance of the delivery device, the size distribution of the delivered particles, the lung state of the patient, and the coordination between device and patient. These aforesaid merits and needs in the pharmaceutical industry has lead into many developments in inhalation devices such as nebulizers, metered dose inhalers, and dry powder inhalers, and quest for novel delivery devices. Advantages and disadvantages of these devices are discussed in books and reviews such as by Hickey (1996), Gradon and Marijnissen (2003), and Geller (2008). The electrospray technique has the ability of producing monodisperse aerosols with a controlled and predetermined droplet size and therefore it resolves particles size distribution related issues in conventional inhalers and is a perfect technique to produce aerosols for drug inhalation (Geerse and Marijnissen 2003). We will present a state of art review of use of electrosprays for inhalation.

Development of an anatomically correct segmented model of the human mouth for deposition studies of the particle and vapour phase of tobacco smoke during inhalation

R.A. Cabot, C.M. McGrath, P.J. Biggs and C.J. Dickens

British American Tobacco, Group R&D, Southampton SO15 8TL, UK
Keywords: Aerosol measurement, Deposition, Inhalation, Respirable aerosols
Presenting author email: ross_cabot@bat.com

British American Tobacco is researching the deposition of smoke particles and vapours in the human respiratory system. An integral part of this research is understanding how smoke ages and deposits in the mouth after puffing. An anatomically correct model of the human mouth has been created to conduct smoke aging and deposition experiments in conjunction with a system that can simulate human puff and inhalation profiles.

The mouth cast geometry was created from a CT (computerised tomography) scan of the mouth of a healthy adult male. Bio-modelling software was used to manipulate the data, increasing the volume of the mouth cavity to better represent the mouth while puffing on a cigarette. A circular aperture was added to the lips with an internal diameter of 8mm to match the diameter of a standard cigarette. The model was divided into three sections representing the mouth, the throat and the trachea down to the first bronchial split. The interface between each section was kept planar for ease of assembly and sealing of the physical model. Matching flanges were added for each interface at each section split, with a groove for an o-ring and integral holes for bolts to secure the sections together.

A physical version of the model was created in Nylon-12 using selective laser sintering, a rapid prototyping technique. Nylon-12 was chosen after spiking and subsequent recovery tests of both solanesol and nicotine were performed on small test disks of the material. Solanesol is a high boiling point alcohol which is regularly used as a marker for the particle phase of tobacco smoke.

The physical model was connected to the in-house developed Puff Inhale Exhale (PIE) simulator, which replicates recorded human smoking profiles. This allows smoke to be puffed, aged, diluted during inhalation and deposited in the mouth cast.

A range of measurements can be taken during an experiment, including real-time particle size and concentration, smoke opacity (estimation of smoke mass concentration) and chemical analysis of solanesol and nicotine deposition in the three sections of the cast.

The mouth cast was used in a study of the aging of smoke in the human mouth. An example of a mouth hold only smoking event was selected from a database of measurements recorded during a volunteer smoking study. The measurements included puffing profile, puffed smoke aerosol size and concentration, mouth hold time and exhaled smoke aerosol size and concentration. Cigarettes were smoked in the mouth cast using the selected puffing profiles and associated mouth hold period. After the mouth hold, smoke was flushed from the mouth cast into a differential mobility spectrometer (Cambustion, UK) to measure particle size and concentration of the aged smoke. The size and concentration of the puffed smoke aerosol were measured by re-smoking cigarettes to the same puffing profiles using a smoking cycle simulator (McAughey, 2007) and a differential mobility spectrometer. The experiments were repeated but with mouth hold times set to 1, 2 4 and 8s. All measurements were performed in triplicate.

Coagulation was expressed in terms of growth factor, the increase in the mean particle diameter. A trend of increasing growth factor with increasing mouth hold time and with increasing puffed total particle number was observed (figure 1). The average growth factor for the human measurements was 0.72 compared to 0.38 for the comparable mouth cast measurements. The difference is probably due to geometry of the mouth cast being different to the geometry of the mouth of the human volunteer. The total deposited fraction by particle mass was 65.6% and 58.9% for the human measurements and the mouth cast measurements respectively.

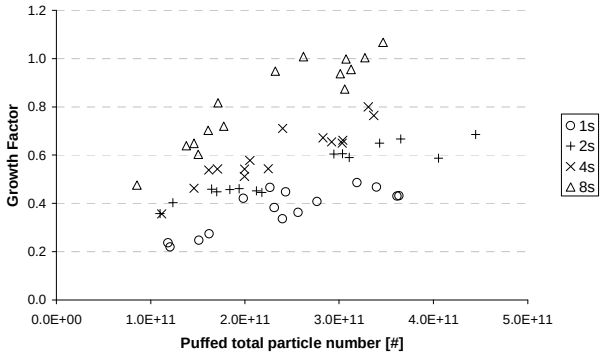

Figure 1. Particle growth factor against puffed total particle number by mouth hold time

The limited data show that the mouth cast can be a useful tool for studying the deposition and aging of cigarette smoke in the human mouth, however differences between the geometry of the mouth cast and the geometry of individual smoker's mouths will produce differences between in vitro and in vivo data.

Keywords: chronic rhinosinusitis (CRS), topical aerosol therapy, pulsating aerosols
Presenting author email: moeller@helmholtz-muenchen.de

Chronic rhinosinusitis (CRS) is one of the most commonly diagnosed chronic illnesses, and approximately 10-15 % of the European and US population suffer from CRS (Dykewicz *et al.*, 2010). Inflammation of the nasal mucosa due to bacterial, fungal or viral infections, or allergies can lead to CRS. The current approach to treat CRS is a combination of topical and systemic steroids and antibiotics, and in case of failure, functional endonasal sinus surgery (FESS) has been the primary approach for treating CRS. An efficient topical therapy may allow treating upper respiratory diseases more effectively prior or post surgery.

The paranasal sinuses are involved in CRS, they are poorly-ventilated hollow organs; therefore cannot be reached by conventional nebulizers or nasal pump sprays. Gas and aerosol transport into non-actively ventilated spaces can be achieved by diffusion and flow induction by pressure differences, and pulsating airflows can generate such pressure gradients, enabling the possibility of aerosolized drug delivery to the sinuses (Kauf, 1968).

A pulsating aerosol is an aerosol stream superimposed by a pulsation (sound wave). The PARI Vibrent (Pari Pharma, GmbH, Germany), a prototype pulsating aerosol device, was used in all studies. Gamma camera imaging during ^{81m}Kr-gas inhalation was applied to assess the ventilation during pulsating airflow. A pulsating aerosol was generated using ^{99m}Tc-DTPA. The mass median diameter (MMD) was 3.0 µm with a geometric standard deviation of 1.6. For comparison to standard therapies a nasal pump spray aerosol (100µl) was generated (MMD ≈ 60 µm). Nasal deposition, retention and clearance (24 h) were measured using planar gamma camera imaging.

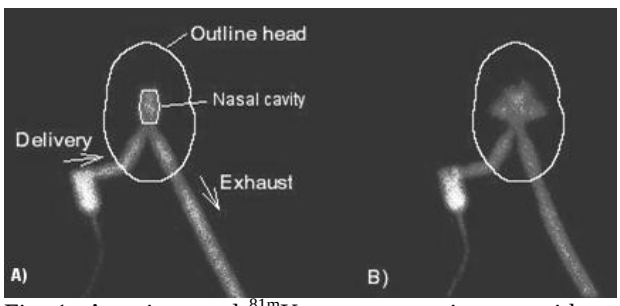

Fig. 1: Anterior nasal ^{81m}Kr-gas gamma images without (w/o, A) and with (w, B) pulsating airflow.

Anterior ^{81m}Kr-gas ventilation images obtained with and without pulsation are shown in Fig. 1. Without pulsation only the central nasal cavity appeared on the image. In addition the delivery system is shows the nebulizer coupled to the right nostril, as well as the exhaust tubing coupled to the left nostril. With pulsation, the maxillary and frontal sinuses appeared on the gamma camera image, showing efficient ventilation (Fig. 1B).

The dominant fraction of ^{99m}Tc-DTPA aerosol is deposited in the central nasal cavity (Fig. 2). With the pulsating aerosol total deposition in the nasal cavity was 69+/-10% of the nebulized dose (Tab. 1) and 7.0+/-2.4% of the deposited activity penetrated to the sinuses (Möller *et al.*, 2010). Delivery of the activity by the nasal pump spray resulted in 100% nasal deposition but less than 1% of the dose penetrated into the sinuses.

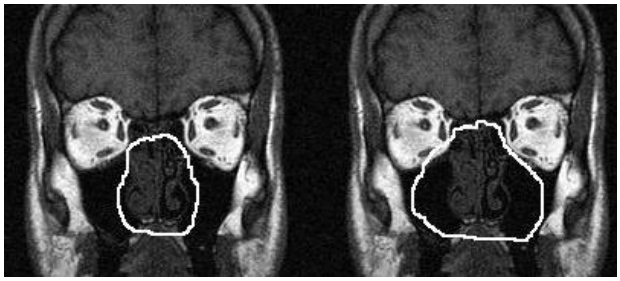

Fig. 2: Illustration of the nasal activity distribution (line at 5% max. activity level) within the MRT-image after pump spray (left) or vibrating aerosol (right) delivery.

Table 1: ^{99m}Tc-DTPA aerosol deposition and retention.

	Pump spray	Pulsat. aerosol
Total aerosol depos.	100%	69+/-10 %$^{++}$
Sinus aerosol depos.	< 1 %	7.0+/-2.4 %**
50 % nasal retention	15+/-6 min	55+/-24 min^{++}
25 % nasal retention	1.4+/-1.6 h	4.4+/-2.7 h^{++}

Aerosol delivered by pulsating aerosol was associated with a retarded clearance rate from the nose (Tab. 1), showing longer drug residence time in the nose. Significant amounts of drug can be deposited in the paranasal sinuses during pulsating airflow allowing topical treatment protocols.

The study was supported by Pari GmbH, Starnberg, Germany and by the BMBF (03FPE00028).

The administration of drugs directly into the respiratory tract has been used in a number of therapeutic area, including treatment of both lung and systemic diseases. The respiration of nano-sized particles gives some advantages with respect to the inhalation of micron-sized ones. First of all, the particles 10 to 20 nm in size deposit to the alveolar region about 4 times more efficiently than those of several microns in diameter. Moreover, the nanoparticles are easily transported across the membranes. In this paper we study the anti-inflammatory and analgesic effects from inhalation of nanopaticulate of non-steroid anti-imflammatory drugs (sodium diclofenac, indomethacin and ibuprofen) synthesized via the evaporation-condensation route. The nose-only exposure chambers were used to determine the lung deposited dose and the particle deposition efficiency as a function of the mean particle diameter (Fig. 2).

The inhalation scheme includes a flow aerosol generator, plastic boxes for mice, filters, diluters, flow control equipment and aerosol spectrometer (Fig. 1). The evaporation - condensation aerosol generator consisted of a horizontal cylindrical quartz tube with an outer heater. Argon flow was supplied to the inlet and the aerosol was formed at the outlet. The particle mean diameter and number concentration were varied in the ranges 3 to 200 nm and 10^3 to 10^7 cm^{-3}, respectively, as measured by an Automatic Diffusion Battery. The Liquid Chromatography and X-Ray Diffraction methods were used to control the particle composition. The nose-only exposure chambers (Fig. 2) were used to determine the lung deposited dose and the particle deposition efficiency (Fig. 3) as a function of the mean particle diameter.

The analgesic effect was estimated in the "acetic acid writhing" test. When studying the anti-inflammatory action, one hour after the aerosol exposure, 0.05 ml of 0.1% histamine solution in water was injected into the subplanar surface of the mouse hind paw. Six hours later the mice were killed by cervical dislocation. Then the mouse's paws were cut off at the ankle joint and weighed. The ratio of the difference in weight between the treated and untreated hind paws to the weight of the untreated hind paw was used as an edema index (Fig. 4).

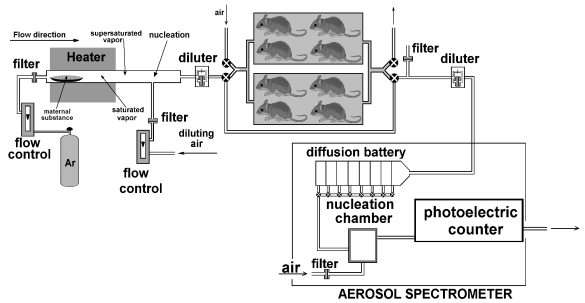

Fig. 1. Experimental set-up for inhalation experiments.

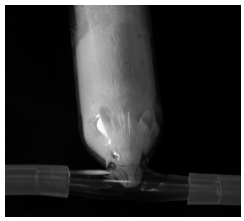

Fig. 2. Nose-only exposure chamber

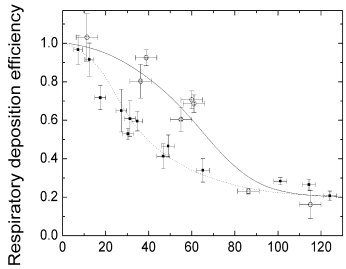

Fig. 3. Mouse respiratory efficiency *vs.* mean particle diameter; circles - ibuprofen, squares - indomethacin nanoparticle inhalation experiments.

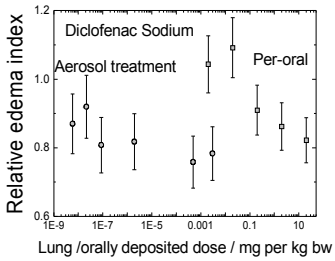

Fig. 4. Relative edema index vs. the lung (circles) or orally (squares) deposited dose.

It was found that the aerosol administration is more effective than the peroral treatment i.e. results in the same analgesic or anti-inflammatory effect even at the lung deposited dose six orders of magnitude less than the per-oral dose.

Carbon Nanotubes – too "big" AND too "small" to deposit efficiently in the lungs?

A. Buckley[1], R. Smith[1], R. Maynard[1]

[1]Health Protection Agency, Centre for Radiation, Chemical, and Environmental Hazards, Chilton, Didcot, Oxfordshire, OX11 0RQ, UK

Keywords: nanotubes, nanoparticle aggregates, exposure, lung deposition

Presenting author email: alison.buckley@hpa.org.uk

Alongside the potential benefits we are likely to gain from the fast-developing field of nanotechnology, there are concerns regarding the possible health and environmental impacts of nanomaterials. High aspect ratio nanoparticles such as carbon nanotubes (CNT) have caused particular concern following the finding of a preliminary study that long (>15μm), relatively straight CNT (Fig 1a) introduced into the abdominal cavity of mice displayed asbestos-like pathogenic behaviour (Poland *et al*, 2008). The effect was, however, not seen with shorter and tangled CNT (Fig 1b).

As part of any assessment of the potential risk posed by inhalation, the behaviour of CNT aerosol particles in the lung needs to be understood, in particular, whether they are likely to deposit in the pulmonary region. This will clearly depend upon the characteristics of the CNT aerosol particles. CNT aerosol particles sampled in research and industrial facilities, while low in concentration, show a wide range of shapes and structures (e.g. Maynard *et al*, 2004; Han *et al*, 2008). These fall into two general categories: dispersed, or lightly agglomerated, 'fibre-like' CNT aerosol particles, which can consist of either individual, or ropes of tubes, with lengths typically < 10 μm; and CNT 'agglomerate' aerosol particles consisting of bent and tangled CNT with physical diameters from a few hundred nanometres up to tens of micrometres.

This paper poses the following questions: "what is the aerodynamic and diffusive behaviour of these 'real' CNT aerosol particles in the lung?" and "what is their expected pulmonary deposition? ". In an attempt to answer these questions, a simplified, theoretical approach to the deposition of CNT in the lungs covering a range of realistic CNT forms, based on those observed in real exposure settings, is presented. To assess the validity of the approach, results have been compared with available experimental data.

Particles are deposited in the lung as a result of leaving the air streams within the airways and coming into contact with the walls of those airways. There are five mechanisms which control this: inertial impaction and sedimentation, which are governed by the particle's aerodynamic diameter; Brownian motion, characterized by the particle's translational diffusion coefficient; electrostatic forces, which are dependent on the particle's charge state; and interception, which is governed by the physical shape and size of the particle in relation to that of the airway.

Aerodynamic and diffusion equivalent diameters have been estimated for a range of 'realistic' CNT aerosol particles. For CNT 'agglomerates', assumed here to be low density spheres, calculations were based on the standard spherical model using Stoke's drag. For 'fibre-like' particles, modelled as straight cylinders, aerodynamic and diffusion equivalent diameters were derived using the drag force on a cylinder given by Asgharian *et al* (1988) and slip correction factor based on Dahneke's (1973) adjusted sphere approach. The impact of cylinder orientation was addressed using the Rotational Péclet Number.

Comparison with experimental measurements of CNT aerodynamic and diffusion diameters has confirmed the validity of this approach.

In the pulmonary region of the human respiratory tract diffusional deposition peaks for particles with diffusion equivalent diameters of around 20 nm and aerodynamic deposition for particles with aerodynamic diameters of approximately 2 μm. While some CNT 'agglomerate' particles, which can be aerosolised in a wide range of sizes, are likely to fall into one of these categories, 'fibre-like' CNT particles, particularly those considered to be 'long', are not expected to be deposited efficiently by either mechanism – being aerodynamically too small to deposit efficiently by impaction or sedimentation but thermodynamically too large to deposit efficiently by diffusion.

Modelling coagulation of liquid particles within the human respiratory system

L. Pichelstorfer and W. Hofmann

Department of Materials Research and Physics, University of Salzburg, 5020 Salzburg, Austria
Keywords: Coagulation, size distribution, aerosol concentration, human lung
Presenting author email: Lukas.Pichelstorfer2@sbg.ac.at

To assess health risks due to airborne particle exposure, it is necessary to obtain information on regional and local deposition. Since particle diameter is a key parameter of physical deposition mechanisms, the size distribution of an aerosol within the human respiratory tract is an important determinant of particle deposition.

For an aged aerosol with typical low concentrations, the particle diameter may safely be assumed to remain constant (except for phase transition or hygroscopic growth) during the breathing cycle. This, however, is not a reasonable assumption when dealing with fresh aerosols, e.g. cigarette smoke, vehicle exhaust, etc.). Indeed, these systems are highly dynamic and concentrations, diameter and even composition of the particles may vary significantly within fractions of a second. Thus the objective of this work is to develop a numerical model for coagulation of liquid aerosols within the human respiratory tract.

In the present model different types of coagulation have been considered: thermal coagulation drive by thermal motion, kinematic coagulation, including coagulation due to laminar shear flow, turbulent shear flow and settling of the particles. Initially inhaled and newly formed particles are assumed to be spherical.

Table 1. Changes of the primary size distribution due to coagulation during inhalation.

Coagulation type	Change of concentration	Change of average diameter
Thermal	- 83%	1.99 $d_{(t=0)}$
Kin. shear	- 42%	1.03 $d_{(t=0)}$
Kin. turbulent	- 0.5%	1.0001 $d_{(t=0)}$
Kin. settling	-0.7%	1.002 $d_{(t=0)}$
Total	- 89%	2.04 $d_{(t=0)}$

Table 1 presents the relative changes of the primary inhaled aerosol due to coagulation during inhalation, using the cigarette smoke size distribution measured by Keith (1982) with an average diameter of 250 nm, classified into size bins with a width of 5%. The breathing pattern is that of a male under sitting breathing conditions (ICRP, 1994) with an additional 1s residence time of the puff in the mouth and the lung geometry refers to the stochastic lung morphology of Hofmann and Koblinger (1990). For this simulation static aging in the oral cavity, no mixing of the puff with residual air, and no deposition were assumed.

Clearly, thermal coagulation dominates the process at the beginning of the breath. As a result, the number concentration of the smallest particles is reduced to almost zero within fractions of a second. Kinetic shear coagulation starts to contribute from airway generation 9 on, if the puff is not diluted. Relatively large particles trigger this type of coagulation. Turbulent and settling coagulation turn out to have almost no effect on the size distribution for this initial particle diameter and breathing related Reynolds numbers.

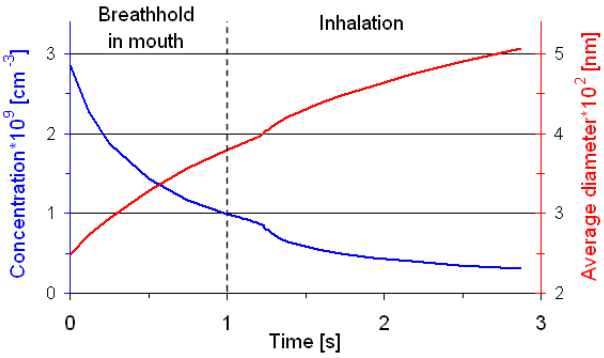

Figure 1. Particle concentration and diameter as functions of inspiratory time.

The time dependent behavior of the number concentration and the average diameter of the size distribution are plotted in Figure 1. Within half a second the concentration declines by a factor 2 marked by a steep slope of the concentration curve. After 1.5 s, the reduction of particle number gets distinctively slower and becomes almost linear. As expected, the average particle diameter increases with the elapsed time. The reason is less the growth of individual particles but the fact that particles adhere to big ones. Subsequently the diameter of the big particles stays almost constant. Since the small size fraction of the distribution is practically removed, the average diameter increases.

This coagulation model will subsequently be implemented into the stochastic deposition model IDEAL (Hofmann and Koblinger, 1990), considering dilution and deposition mechanisms (see companion abstract by Winkler-Heil and Hofmann).

Regional lung deposition of tobacco smoke constituents

J.McAughey[1] and C. Dickens[1]

[1]British American Tobacco, Group R&D Centre, Southampton, SO15 8TL, UK

Keywords: tobacco smoke, deposition, dosimetry.
Presenting author email: john_mcaughey@bat.com

Tobacco smoke is a complex dynamic aerosol suspended in an equally complex vapour cloud, and is a significant elective source of inhaled particles in the population, despite it being a recognized cause of disease. However, little is known of the regional deposition of smoke and local micro-dosimetry from both its vapour and particle phase constituents. Such data offer context to better understand biologically effective dose and potential modes of action of disease initiation, both in model disease systems and populations.

Measured mass deposition efficiencies of the order of 60-80% for particle species are significantly greater than modelled deposition estimates of 30-40% (Baker & Dixon, 2006). Many authors have suggested that the smoke particles must grow significantly to super-micron diameters, to explain observed patterns of disease in the conducting airways, by a combination of coagulation, hygroscopicity, condensation, and colligative 'cloud-like' behaviour (e.g. Robinson, 2001, Broday, 2003). Others have suggested evaporative losses with increased pulmonary deposition of the smaller residual particles by diffusion (Ingebrethsen, 2006, Kane, 2010).

In this work, a series of measurement tools have been developed to assess deposition by direct measurement of exhaled particles and vapour by electrical mobility spectrometry and selective photo-ionisation time-of-flight mass spectrometry respectively. Measured smoking patterns are then replicated to produce intake estimates with deposition calculated by difference.

In addition, hybrid Computational Fluid Dynamic – Pharmacologically Based Pharmacokinetic models (CFD-PBPK) have been developed to assess local deposition in the upper airways and subsequent systemic uptake; initially for volatile aldehyde species.

Soluble vapour species such as acetaldehyde and acrolein show near 100% retention from modelling and measurement data but particle deposition is significantly lower and related principally to inhalation depth and inhalation cycle time. Particle diameter may also have a role but this may be better reflected by a modified diameter reflecting ageing in the mouth, principally via coagulation, rather than the diameter of fresh smoke. However, consideration of all ageing and growth / evaporation processes of the smoke predict it will remain sub-micron and this is confirmed by size measurements of volume- weighted median diameters of approximately 250 – 350 nm for exhaled smoke.

Thus, a majority of particle mass deposition is calculated to occur in the deep lung via diffusion. However, higher local airway particle and vapour doses occur in the upper airways driven by the smaller surface areas available for deposition. Calculated regional values for particle (tar) deposition as ng.cm^2 of lung surface (per mg tar delivered by the cigarette) are 409 (ET – extra-thoracic), 45 (BB – bronchial), 4.8 (bb – bronchiolar) and 0.1 (AI – alveolar). Transformations of size and concentration data allow equivalent number and surface-area weighted regional deposition to be calculated.

In conclusion, new insight has been gained into local dosimetry of tobacco smoke constituents in the lung through measurement and modelling. Both soluble vapour and particle deposition are driven principally by diffusion processes. Local dose remains highest in the upper airways through the relatively smaller airway surface available for deposition.

Further refinement of deposition and CFD-PBPK models will offer an improved approach to quantitative risk assessment. This will derive from the provision of improved relative dose assessment for *in vitro* models of disease applied to smoke exposure and the a combined dosimetric and mechanistic approach to assessing the impact of technologies designed to reduce selective toxicant dose from smoke.

Keywords: personal nanoparticle sampler; respirable cyclone; nanoparticle impactor.
Presenting author email: cjtsai@mail.nctu.edu.tw

At present, there are no active personal sampling devices to assess the exposure levels of workers to engineered nanoparticles (NPs). To meet the demand, a novel IOSH-NCTU personal nanoparticle sampler (IOSH-NCTU PNS) was designed and tested. The PNS operates at 2 L/min with a pressure drop of 125 cm H_2O by a SKC XR 5000 pump. The present PNS was calibrated for the collection efficiency curve by both liquid and solid particles. The effect of heavy particle mass loading on performance of the PNS was also evaluated. For assessing its sampling accuracy, the measured RPM and NPs concentrations by the PNS were compared with those of a collocated MOUDI.

As shown in figure 1, the PNS consists of a respirable cyclone and a micro-orifice impactor (137 55 μm nozzles) in series for classifying respirable particulate matter (RPM) and NPs, respectively. The impaction plate is rotated by a stepper motor to deposit particles uniformly on the substrate, and the substrate is coated with silica oil to prevent solid particle bounce. After the micro-orifice impactor, a 37 mm teflon filter is used to collect NPs. The sampler is light weighted (250 g) and compact (H-10.5 cm, D- 6.3 cm), which is suitable for personal wearing.

Calibration results show that the cutoff aerodynamic diameter (dpa_{50}) of the respirable cyclone and the micro-orifice impactor is 3.98±0.1 μm and 101.4±0.1 nm, respectively. The ratio of jet to plate distance and nozzle diameter (S/W) with the S/W of 13.8. A decreasing S/W from 16.2 to 3.13 in the micro-orifice impactor results in a decreased dpa_{50} from 111 to 72.5 nm. The particle loading tests reveals that the PNS has a maximum loading of 0.65 mg with a less than 5 % shift of dpa_{50} and a negligible solid particle bounce. It was found that the change of the pressure drop was less than 5 cm H_2O after heavy particle loading and the RPM and NPs concentrations agreed well with those of the MOUDI. Therefore, the IOSH-NCTU PNS sampler is capable of assessing personal exposure levels of RPM and NPs in workplace.

Portable real-time detection of airborne asbestos fibres for tradespersons

C. J. Stopford, P. H. Kaye, E. Hirst, R.S. Greenaway, and W.R. Stanley.

Centre for Atmospheric & Instrumentation Research, University of Hertfordshire, Hatfield, U.K.
Keywords: asbestos, spatial light scattering, magnetic alignment
Presenting author email: c.stopford@herts.ac.uk

Asbestos has been widely used as a building material due to its many desirable physical properties – thermal resistance, tensile strength, etc. However, asbestos fibre inhalation, especially of the amphibole varieties such as crocidolite and amosite, causes serious health problems. Tradespersons working in environments where asbestos is present are at particular risk of disturbing and inhaling fibres, and asbestos inhalation remains the leading cause of occupational deaths in Europe.

Identification of airborne asbestos is usually performed *ex situ* by collecting a sample of filtered aerosol and subsequently performing extensive manual fibre counting from microscopic examination or EDAX (Energy Dispersive Spectroscopy). Whilst instruments do exist for the real-time detection of airborne *fibre* particles (eg: MIE Fibre Monitor Model FM-7400, Mie Inc., Billerica, Mass.), these are generally incapable of differentiating between asbestos fibres and other airborne fibres that may be present, such as gypsum, glass, etc. Currently, there is no reliable real-time *in situ* technique specifically for the detection of airborne asbestos fibres. The authors' present work seeks to develop a relatively low-cost real-time detector for airborne asbestos fibres that may be routinely used by tradespersons to reduce inadvertent exposure to asbestos dust.

Previous research at the University of Hertfordshire has established that airborne particles may be detected and classified according to their morphology by analysis of their spatial light scattering patterns (eg: Kaye *et al*, 1996). Fibres are particularly well suited to this type of classification (Kaye *et al*, 1997) due to their distinctive scattering patterns (Figure 1), and indeed, information relating to the fibre size and aspect ratio, required for accurate assessment of the inhalation risk, may also be extracted from the patterns.

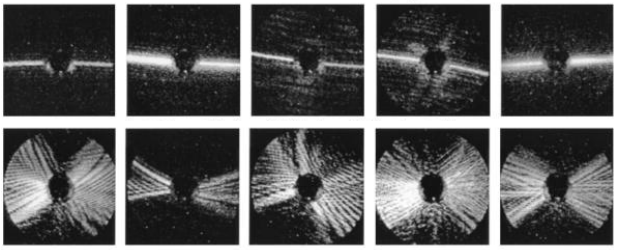

Figure 1. Spatial light scattering patterns from individual crocilodite (top) and chrysotile (bottom) asbestos fibres.

In order to differentiate asbestos fibres from non-asbestos fibres of similar morphology, the authors' present work seeks to combine the spatial scattering analysis technique with a process that exploits the magnetic anisotropy of asbestos fibres (Ulanowski and Kaye, 1999). By preferentially aligning all fibres in a sample flow and subsequently applying a magnetic field to the flow, discrimination of asbestos fibres from all other fibres maybe achieved by detecting the re-orientation suffered by the asbestos fibres alone.

A prototype laboratory system will be described in which a test aerosol is drawn by a sample pump through a specially designed optical scattering chamber. The sample aerosol enters the chamber at a rate of approximately 500 ml. min^{-1} via a laminar flow inlet tube that preferentially aligns fibre particles towards the axis of the flow. In trials with gypsum fibres (used as a non-hazardous analogue for asbestos) this configuration aligns more than 80% of fibres to within 10 degrees of the flow axis.

Rare earth magnets aligned at 45° to the flow axis (thus producing maximum torque on any asbestos fibres present) are positioned below the exit of the aerosol inlet tube. In principle, asbestos fibres carried in the airflow are re-oriented toward the field lines and well beyond the distribution of orientations exhibited by non-asbestos fibres. A laser beam orthogonal to the flow axis illuminates particles as they pass through the region of maximum magnetic field strength and the light scattered by individual particles is detected by two linear 512 pixel CMOS arrays. A small amount of scattered light is also reflected via a beam-splitter to a photodiode responsible for triggering data capture from the arrays.

High speed algorithms have been developed to analyse the CMOS array data and enable rapid identification of fibres from a high concentration of other dust particles. Further computation is performed to determine the angular orientation of each fibre, together with metrics relating to fibre size and aspect ratio based on comparison with theoretical data using the RTDF model (Hesse, 2008). Preliminary experimental results and analysis will be presented on the performance of this novel approach to real-time airborne asbestos fibre detection.

The Transfer Function and the Resolution of a DMA with Multiple Monodisperse Outlets: Sensitivity Analysis for the Case with the Two Monodisperse Particle Outlets

M.Giamarelou[1] and G. Biskos[1,2]

[1]*Department of Environment, University of the Aegean, Mytilene 81100, Greece*

Keywords: MMO-DMA, Dual-DMA, transfer function, resolution.
Presenting author email: giamarel@env.aegean.gr

DMAs are widely used in aerosol research as a tool for sizing and for producing monodisperse airborne particles having diameters in the submicron and nanometer ranges (Flagan, 1998; McMurry, 2000). Since the 1970's when the DMA was realized to be ideal for aerosol particle size classification in the submicron range (Liu and Pui, 1974; Knutson and Whitby, 1975), many single-outlet designs have been proposed and built for improving its performance. DMAs with multiple monodisperse outlets can significantly reduce the scanning time when employed in aerosol spectrometers because particles of different mobility can be classified and detected simultaneously. In addition, depending on the relative location of the first and the last outlet from the inlet, one can increase the dynamic mobility range of the selected particles in a single measurement.

In this regard, Takenchi *et al*. (2005) designed a dual-type DMA in order to measure particles having diameters within a wide size range. Chen *et al*. (2007) designed and built a DMA having three monodisperse exits for fast measurements of particle size distributions. Despite these experimental attempts, to the best of our knowledge, there is no theoretical study providing the transfer function or the resolution of DMAs with more than one monodisperse outlets.

In this paper, following Stolzenburg (1988) approach, we derive the expression of the non-diffusional transfer function of Mulitple Monodisperse Outlet (MMO) DMAs, and extend it to take into account particle diffusivity. When including particle diffusivity, the derived transfer function of the i^{th} sample exit of the MMO-DMO is shown to be:

$$\Omega_{d_i} = \frac{\sigma_i}{\sqrt{2}\beta_i(1-\delta_i)}\left\{-\mathcal{E}\left(\frac{\bar{Z}_{p_i}-(1-\beta_i\delta_i)}{\sqrt{2}\sigma_i}\right)+\mathcal{E}\left(\frac{\bar{Z}_{p_i}-(1-\beta_i)}{\sqrt{2}\sigma_i}\right)\right.$$
$$\left.+\mathcal{E}\left(\frac{\bar{Z}_{p_i}-(1+\beta_i)}{\sqrt{2}\sigma_i}\right)-\mathcal{E}\left(\frac{\bar{Z}_{p_i}-(1+\beta_i\delta_i)}{\sqrt{2}\sigma_i}\right)\right\}, \quad (1)$$

where σ_i is the standard deviation of Ω_{d_i}, $\bar{Z}_{p_i}$ is the dimensionless particle mobility, and β_i, δ_i are dimensionless flow parameters. We further derive a general form for the resolution of the MMO-DMA, using the method proposed by Flagan (1999), and show that this can be described by:

$$\mathcal{R}_{diff_i} = \frac{1}{2\sqrt{2\ln 2}\,\tilde{\sigma}_i} = \frac{1}{2\sqrt{2\ln 2}}\left[\frac{Pe^*_{mig_i}}{G_i}\right]^{1/2}, \quad (2)$$

where $\tilde{\sigma}_i$ is the dimensionless standard deviation, G_i is a geometry parameter, and $Pe^*_{mig_i}$ is the particle migration Peclét number. Finally, we employ our models to optimize the design of a DMA with two monodisperse outlets, namely the Double Monodisperse Outlet (DMO) DMA. Selected plots of the transfer function for the optimum DMO-DMA design are shown in Figure 1.

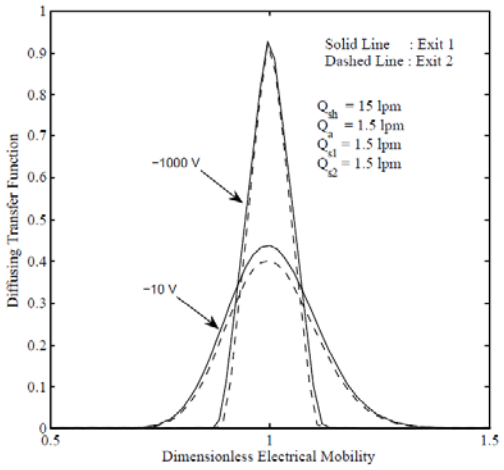

Figure 1. Transfer Function of the DMO-DMA for which the first sample exit is located at distance 44.369 cm downstream the inlet, while the second at distance 4.987 cm. The outer radius of the apparatus is 1.961 cm and the inner radius is 0.937 cm.

Development and Characterization of a Novel Approach for Water-Based Condensation Growth of Aerosols

Aaron M. Collins[1], William D. Dick[1], Benjamin Y. H. Liu[1] and Francisco J. Romay[1]

[1]MSP Corporation, Shoreview, Minnesota, 55126, United States of America
Keywords: Instrumentation, CPC, CFD

Condensational growth is commonly used in Condensation Particle Counters (CPC) to provide the necessary particle enlargement to detect particles smaller than 1 µm using conventional light scattering techniques. Traditionally, laminar thermally diffusive methods of condensation particle growth have relied on butyl alcohol and other fluids with similar thermodynamic properties.

In traditional laminar diffusive methods a hot, vapor-laden aerosol is introduced into a cold wall condenser where, due to a Lewis number greater than unity, a central core of high-supersaturation ratios provides the necessary activation for condensational growth of nanometer-sized particles (Stolzenburg et al. 1991).

Because water vapor in air has a Lewis number less than unity, the regions of high supersaturation form near the walls in a traditional laminar diffusive approach. This results in reduced particle growth and activation when water is used as the working fluid (Hering et al 2005).

We have developed a new growth method to generate sufficient supersaturation conditions with a traditional hot to cold thermal approach. The Single Flow Mixing (SFM) method (patent pending) results in the turbulent mixing of a hot, water-vapor-saturated aerosol stream in a cool mixing chamber to produce supersaturation values sufficient for nanoparticle growth. The geometry consists of an inlet placed perpendicular to a tapered cylinder. The inlet flow impinges on the cylinder wall resulting in turbulent mixing within the device as shown in Figure 1.

Using a commercially available Computational Fluid Dynamics (CFD) software package, a 3D fluid model was developed for the flow geometry. Parameters investigated were the flow, temperature and vapor profiles generated by the SFM method. Further computations were performed to determine Kelvin diameter and expected particle growth rates.

Measurements of particle activation were performed using DMA-classified aerosol in the 5 to 40nm size range. A Faraday Cup Electrometer (FCE) was used as the reference concentration measurement, whereby combined with the CPC count data, provide a measurement of counting efficiency. Material effects were also investigated using both hydrophobic and hydrophilic particle materials to ascertain the influence of hydrophobicity in the SFM method of condensation growth.

Figure 2 shows the counting efficiency for both Ag (hydrophobic) and NaCl (hydrophilic) particles as function of electrical mobility diameter. As expected, the counting efficiency decreases with deceasing particle diameter with a measured cutpoint (dp_{50}) of 4.6nm for the NaCl test data. The measured cutpoint for the Ag test data is 9.8nm. The observed effect of particle hydrophobicity on the measured counting efficiency is consistent with the work of Hering et al.(2005), Stratmann et al.(2009) and Mordas et al.(2008).

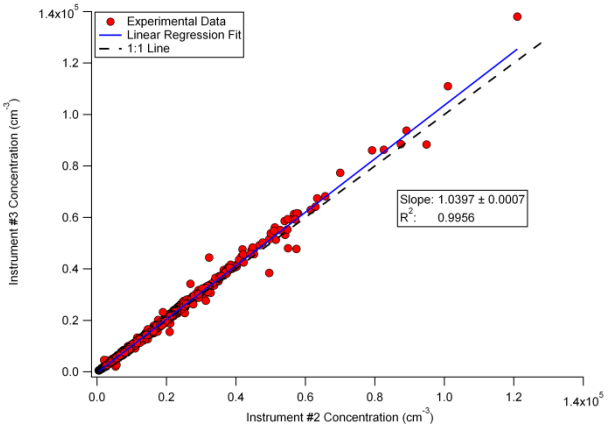
Newly developed instruments need to be thoroughly tested before they can be made commercially available. As part of the development of a second generation of water-based CPCs, the TSI Model 3783 Environmental Particle Counter (EPC) was designed for long-term environmental monitoring of particle number concentration. Comparison testing of these instruments provided the unique opportunity to run up to 12 EPCs alongside other new and existing water-based CPCs (Models 3781, 3787, 3788) for more than 40 days. This provided the opportunity for multiple studies, including: 1) long-term correlation between instruments; 2) challenging the instruments with different water sources and different wick materials; and 3) testing the probability of random failures and determining a statistical confidence level.

The EPC counts single particles in the range from 7 nm (D_{50}) to above 3 µm, with a concentration range of up to 10^6 particles cm^{-3}, using exclusively single-particle counting. A sample flow rate of either 0.6 or 3.0 l min^{-1} can be chosen. Data can be collected with a sampling rate of up to 1 s^{-1} in a number of ways:

- TSI's Aerosol Instrument Manager (AIM) software
- Ethernet
- USB storage device
- USB or RS232 output to an independent data collection system (e.g. LabView)
- Analog output

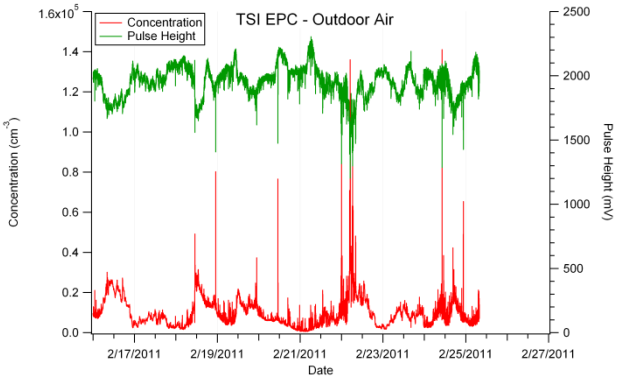
During the test period, all available instrument information was collected once per minute. This included particle concentration, counts, instrument parameters such as temperature measurements and pressure readings, as well as a number of diagnostic readings.

For the long-term instrument comparison, the instruments ran for more than 40 days uninterrupted, first sampling room air, then ambient air through a PM_{10} inlet. A custom-built sampling manifold was attached to the inlet through ~8 meters of 1" stainless steel pipe. All instruments were drawing air from the manifold through conductive tubing. The tested instruments ran without any serious issues, and compared very well between each other. Instrument comparability was tested by linear regression analysis of the concentration measurements of the different instruments. Both the slope and regression coefficient R^2 give an indication of the quality of the comparison. Instruments were typically well within the ±10% specified. A typical correlation plot between two EPC instruments is shown below.



Instruments were tested with a number of different wick materials and with water of different qualities (e.g. distilled water, tap water, etc.). The instruments were challenged with both indoor and outdoor air, and were subjected to a number of real-world conditions, such as water deprivation to test the ability to recover from these incidents.

Particle concentrations and pulse heights were monitored continuously, with the pulse height providing an indication of the condition of the instrument. The figure below shows a typical graph from one instrument. The relatively flat value of the pulse height measurement indicates that the system is operating well and. The momentary drops in pulse height are due to increased particle concentrations, which lower the supersaturation in the growth tube. Although there are momentary drops in pulse height, values are still well above the threshold warning level, indicating that the instrument is counting normal.



These tests illustrate the capabilities of the Model 3783 EPC for long-term monitoring. The instruments have been shown to run autonomously for at least a month, providing accurate particle concentration measurements with high time resolution.

A Novel Optical Real Time Sensor for Radioactive Aerosol

Soohyun Ha[1], Chirag K. Vyas[2], Atul Kulkarni[3], Vijay K. Manchanda[2] and Taesung Kim[1, 3]

[1]SKKU Advanced Institute of Nano Technology, Sungkyunkwan University, Suwon, 440-746, Korea

Presenting author email: sean0125@skku.edu

Release of radioactive aerosols is an important health and environment issue associated with the nuclear power industry, and the manufacture and use of nuclear weapons. High levels of naturally-occurring radioactive aerosols, particularly from decay products of radon gas, can pose a pollution problem at indoor locations such as mines and houses (Stephen D. Schery, 2001). Therefore, radioactive aerosol measurement sensors have been developed for reducing the damage of environment and workers exposed to radioactive aerosol and detecting unexpected air pollution.

Common method of measuring the activity concentration of atmospheric radioactive aerosol particles is to collect them on a filter by drawing a known volume of air through the filter. The activity deposited on the filter is then measured, often in a second step following completion of sampling. A filter may be manually removed from the collection instrument and taken to a detector for counting (Otto G. Raabe, 2007). Another method is Solid State Nuclear Track Detectors. When a heavily ionizing charged particle passes through detectors, it leaves a narrow trail called 'Latent Track' as it cannot be seen with the naked eye. It is possible to view this latent track with an electron microscope (D. Nikezic, K. N. Yu, 2004). However, these methods for measuring radioactive aerosol are not satisfied in real-time radiation detector because these need a sampling process and counting equipment. In consequence, a newly designed radiation measurement sensor is required for real-time detection of radioactive aerosol.

An optic fiber which consists of a scintillator have been developed for real-time detection of radioactive aerosol but this method needs photomultiplier tube (PMT) (K.W. Jang *et al* (2010)), hence it is complicated and not cost effective. To simplify the available methods, we developed a novel real-time radiation measurement sensor by utilizing solid state nuclear track detectors and optic fiber for the first time.

Figure 1 shows the schematic of experiment set-up. Using atomizer, we generated radioactive aerosol from aqueous radioactive. The radioactive aerosol passes through the chamber where optical fiber probe with solid state nuclear tracks detector (SSNTD) film is installed. Due to interaction of the nuclear aerosols, the SSNTD films changes its optical properties casing change in the reflected signal back in to the fiber. Similar type of fiber optic sensors is reported earlier in our group for aerosol sensing (Atul Kulkarni *et al* (2010)). The change in the reflected light is proportional to the radiation. The preliminary results were encourging. Also, theoretically we can estimate the radiation intensity by knowing radioactive aerosol numbers. Further, we can establish the relationship between number of radioactive particle and radiation by using condensation particle counter (CPC). Hence, the proposed method is simple, safe (remote measurement is possible) and can detect the radioactive aerosols in real time.

Direct integration of a GPS/GPRS unit into a miniature diffusion size classifer

M.Fierz, P.Steigmeier, M.Glettig, B.Wyrsch and H.Burtscher

University of Applied Sciences Northwestern Switzerland, 5210 Windisch, Switzerland
Keywords: instrumentation, air quality network, personal sampling.
Presenting author email: martin.fierz@fhnw.ch

We have recently developed a miniaturized version of the diffusion size classifier (miniDiSC, Fierz et al. 2011). It can measure particle number concentration, average particle diameter and lung-deposited surface area with a one-second time resolution. It operates on a purely electrical basis, with a unipolar charger followed by two electrometer stages, i.e. there are no working fluids or radioactive sources. The instrument is about the size of a multimeter, and thus one of the smallest aerosol instruments available today, which makes it ideal for personal monitoring.

For personal monitoring, it is useful to record location information with a GPS. While a separate GPS receiver can be used with any instrument, it is a bit cumbersome to operate because the data of instrument and GPS have to be combined manually. We have therefore integrated a GPS receiver directly in the miniDiSC. Furthermore, we also added a GPRS chip to transmit data from the instrument to a server in the internet in real time. The transmitter board measures 60x80mm and can easily be accommodated in a slightly larger housing than the standard miniDiSC housing (45mm thickness instead of 40mm).

Data is transmitted by the miniDiSC to a TCP server located in the internet, which stores the data in an SQL database. A standard 3-tier-architecture (Database, web-application, browser) is used to view the data in near-realtime (about 5 seconds delay) in any internet browser. Figure 1 shows an overview of the measurement network structure. The instruments also transmit status information besides the measurement data. This allows for a quick overview of the status of all deployed minidiscs (see Figure 2), which is useful when running a measurement campaign - problems with the instruments can be detected and resolved easily during the campaign.

Data can be displayed as real-time chart or as table or downloaded as delimited text file or as a Google Earth file. The Google Earth download is perhaps the prettiest way of visualizing the data (see Figure 3).

In conclusion, we have developed an enabling technology to easily collect and view data of the miniDiSC online. We anticipate that this will be useful for measurement campaigns, both for personal monitoring and for stationary measurements.

Nuclear aerosols in primary circuit and containment: a review of the Phebus experiments

A.V. Jones[1] and R. Zeyen[2]

[1]4A Dukes Lane, London, W8 4JL, UK
[2]Institute for Energy, European Commission Joint Research Centre, PO Box 2, NL-1755 ZG Petten, Netherlands
Keywords: nuclear aerosols, aerosol modelling, high temperature aerosols, particle deposition.
Presenting author email: alanxispra_alt@yahoo.co.uk

The Phebus FP severe accident experiments FPT0 and FPT1 were performed at IRSN Cadarache (France) in 1993 and 1996 respectively. In each test, Fig. 1, a 1 m long bundle of fuel rods encircling a silver indium cadmium control rod was heated to an advanced state of degradation in the Phebus reactor, and the materials released were swept by an injected steam flow through a model circuit and into a miniature PWR containment vessel. Test FPT0 used fresh fuel, while in FPT1 the fuel had a typical mid-life burnup of 23 GWd/tonne. Conditions were non-reducing throughout. The circuit included a hot section and a cooler inverted U-tube (wall temperatures 700 C and 150 C) with diameter typical of a steam generator tube. The containment vessel, which had a volumetric scaling factor of 5000, was designed primarily for the study of chemistry but included facilities for condensing the incoming steam and collecting deposits so that the main containment aerosol phenomena could be investigated.

In an international effort coordinated by the European Commission Joint Research Centre and IRSN intensive analysis of the circuit and containment has been performed using a variety of models and codes, seeking to reconcile and comprehend the wide variety and copious quantity of online and post-test data available. Both integral (multi-volume) codes widely employed in reactor safety analysis and more detailed codes have been applied with alternative models of aerosol processes to help evaluate uncertainties. This paper makes a critical survey of the degree of success achieved and draws conclusions as to where understanding can be considered good and where it appears necessary to perform further experimental and analytical work, factoring in both findings from other tests of the Phebus FP series and from other experimental programmes.

Some conclusions for the FPT0/FPT1 circuit include the fact that deposited caesium is in dynamic equilibrium with the carrier stream and may constitute a late radiological source in the event of an accident, that at the temperature of the “hot” section of the circuit most elements are transported as an aggregated aerosol, which may be adequately treated as single-component, and that predicted aerosol deposition in the steam generator tube, mostly by thermophoresis, is roughly double the experimental value, Fig.2. The explanation may be resuspension, which experimentally was found to occur under Phebus conditions, although it was not predicted by code models. The circuit chemistry of iodine and of caesium is complex and interlinked, and cannot be predicted by codes with fixed chemistry. Codes with dynamic chemistry have had some success but require further verification. A radiologically significant fraction of transported iodine is in gaseous form at the circuit outlet. This fraction is sensitive to the source from the degrading bundle as a function of time, and at present cannot be reliably calculated.

Concerning the containment, a single-component treatment of the aerosol behaviour appears adequate in Phebus conditions, which were dry. Single-volume codes predicted aerosol removal quite well. Experimental data were inadequate to distinguish between removal by diffusiophoresis and that by settling. CFD calculations have helped explain details of the aerosol deposition not predicted by the containment codes.

Uncertainty Analysis of Aerosol Retention in the Break Stage of a Vertical Steam Generator under SGTR Accident Conditions

López del Prá C., Herranz L. E.
Unit of Nuclear Safety Research, CIEMAT, Avda. Complutense 22, 28220 Madrid, Spain
Keywords: retention efficiency, severe accident, nuclear power plant, SGTR.
Presenting author email: claudia.lopez@ciemat.es

During reactor operation, a variety of phenomena may degrade the primary-to-secondary barrier of a pressurized water reactor up to the point of causing tube ruptures. In the highly unlikely event of a core meltdown, such a tube ruptures would result in a radioactivity ingress in the secondary side. These scenarios are generally termed Steam Generator Tube Ruptures (SGTRs). The radioactive discharge into the secondary side is assumed not to be retained to any extent, so that all the material escapes to the environment. However, even in the most severe case of total absence of water in the secondary side, a fraction of the particles released may get trapped onto the tube surfaces of the secondary side of the steam generator.

A sound and comprehensive database on the aerosol behaviour in the secondary side of a steam generator has been generated within the international EU-SGTR (Auvinen et al., 2005), ARTIST (Güntay et al., 2004) and the current ARTIST-II projects. Concurrently, a theoretical work has been undertaken at CIEMAT to develop theoretical tools for estimating the aerosol retention in the secondary side. In particular, it has been developed a model ARI3SG, focused on the break stage of the SG that estimates the collection efficiency (η_{TB}) under the most severe conditions of absence of water:

$$\eta_{TB} = \frac{m_{dp}}{m_{in}} \qquad (1)$$

ARI3SG is based on a filter approach and takes into account through empirical correlations the most important underlying aerosol phenomena that are present in the scenario: inertial impaction, turbulent deposition and resuspension (Herranz et al., 2007).

The comparison of its predictions with the experimental data SGTR and CAAT have shown a good quantitative and qualitative consistency (López del Prá et al, 2010). Following the data trends, the model indicates collection efficiencies within the lower range (≤20%). However, given the ARI3SG approach, the empirical nature of the equations embedded and the requested input parameters, the ARI3SG estimates are forcefully affected by uncertainties of different kinds. Here two categories are distinguished: epistemic and stochastic uncertainties. The former comes from an incomplete knowledge of the system, not from its nature but from the limitation of our ability to model it (i.e. wrong modeling, measurement errors, etc), therefore they can be reduced. The later arise from the natural random variability inherent to the system itself, they can be more accurately characterize but not reduced. Different methodologies can be applied for their analysis: stochastic, deterministic, UMAE, CSAU, response surface among others. In the present work, the experimental ISO norm (1995) has been followed and the performance of ARI3SG given the random dispersion of the governing model equations has been assessed. According to the law of propagation, each phenomena uncertainty has been analytically propagated through the model.

Fig 1 shows that consideration of these uncertainties brings most of predictions and data within the resulting uncertainty band. The bands that vary estimates around 38% and 62% of the SGTR and CAAT cases respectively, overlap half of the experimental uncertainty range. The different lengths in both sets of uncertainty bands might be due to the different weight that each phenomenon involved has on each scenario, which might arise from the slight differences of the modeling of the initial and boundary conditions.

In the near term it is foreseen to extend the current model uncertainty assessment of ARI3SG to consider the effect of input variables uncertainties as well. To do so, the stochastic methodology will be applied to the ARI3SG input variables (i.e., density, velocity and particle size).

Keywords: Carbonaceous particles, deposition, High Temperature Reactor, periodic steps, resuspension
Presenting author email: martin.lustfeld@tu-dresden.de

Radioactive carbonaceous aerosol particles deposit within the primary circuit of a high temperature reactor (HTR). These particles can pose a considerable threat if resuspended by a shock wave in the case of an unlikely loss-of-coolant accident and partially released into the environment (Kissane, 2009).
Stempniewicz et al. (2010) carried out simulations of the spatial and temporal development of carbonaceous dust deposits in the primary circuit of a HTR. Maximum dust layer thickness after full operation time of 60 years was well above *10 mm*. However, the underlying multilayer models require additional experimental verification.
Therefore, particle deposition and resuspension experiments of multilayer graphite deposits have been conducted in a small-scale test facility. The results for particle layer thickness have been correlated to corresponding flow data as measured by means of a 2C2D Particle Image Velocimetry (PIV) system.
The experimental facility consists of a ventilated square duct (*d = 100 mm*), which is operated with air at ambient conditions. The average air velocity can be regulated over the range $\langle u \rangle$ = *1..7 m/s*, corresponding to Reynolds numbers between Re_d = *8.9k..42k*. As flow obstacles, periodic steps have been chosen (Fig. 1) allowing the comparison of results with previous studies on monolayer deposition (e.g. Lai et al., 1999).

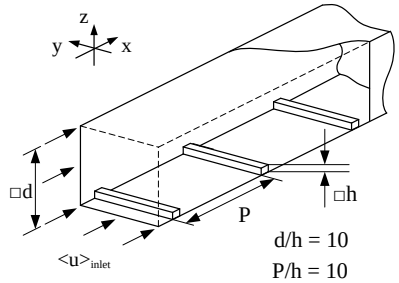

Figure 1. Experimental setup of periodic steps

Graphite aerosol particles (Thielmann Graphite, 23061) have been injected into the duct 15 diameters upstream of the test section by means of a dust disperser TOPAS - SAG 410. Setting the mass flux to *80 g/h* an average mass concentration of airborne particles of up to *2 g/m³* is established. The aerodynamic particle size distribution of the graphite particles was determined by means of a TSI – APS 3321confirming that the particles cover well the range of interest for HTR conditions (quantiles: $d_{P,10}$ = *1.83 µm*, $d_{P,50}$ = *4.40 µm* and $d_{P,90}$ = *10.64 µm)*.
The deposition experiments have been conducted under different flow conditions and the development of graphite particle deposits in the vicinity of the steps has been observed by hourly laser triangulation measurements. Subsequently, the generated multilayer has been resuspended at a higher flow velocity and the thickness of the remaining structure has been measured using the same techniques.

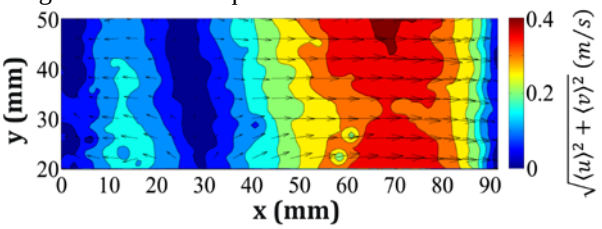

Figure 2. Flow field at Re_d = *8.9k (z=5 mm)*

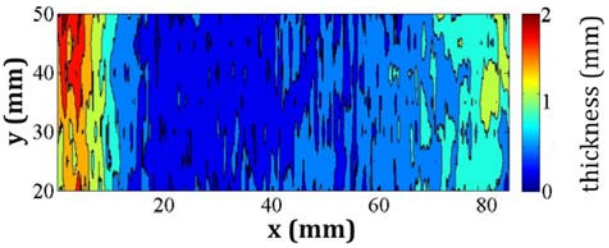

Figure 3. Layer thickness after resuspension at Re_d = *27.2k*

Results show that for a relatively low Reynolds number of Re_d = *8.9k* (Fig.2), deposition is mainly governed by gravitational settling and the deposition rate is almost independent of position and time. On the other hand, subsequent resuspension at higher flow velocities (Re_d *=27.2k*) reveals a strong relation between flow field and remaining layer (Fig.3), which is further being investigated.

Classification of Dust Days over Israel by Integration of Satellite Remote Sensing Products

Sorek-Hamer M.[1], Broday D.M.[1], Levy R.C [2], Cohen A.[3]

[1]Department of Civil and Environmental Engineering, Technion, Haifa, 32000, Israel

[3]Department of Industrial Engineering, Statistics Laboratory, Technion, Haifa, 32000, Israel
Keywords: remote sensing, dust, aerosols.
Presenting author email: dbroday@tx.technion.ac.il

Satellite observations have been suggested as a useful and powerful tool for event detection (e.g. volcanic activity, large biomass fires, dust storms, thick haze, etc). In particular, the last decade has shown a considerable progress in satellite remote sensing of dust aerosols. From an environmental health perspective, such an event detection, after linking it to ground PM observations, can proxy acute exposure to respirable particles of certain properties (i.e. size , composition, toxicity). In order to assess such exposures based only on remotely sensed data with sufficient spatiotemporal coverage, one should be able to differentiate between different common types of aerosols, e.g. dust, long range transport (i.e. mainly sulfates in the East Mediterranean), sea spray, local anthropogenic PM emissions, etc.

Being affected considerably by atmospheric dust, previous studies in the Eastern Mediterranean and in Israel in particular, focused on mechanistic and synoptic prediction, classification, and characterization of dust events, partially based on satellite observations. These studies were complemented by mineralogical and chemical characterization of dust particles and of long range PM transported to the East Mediterranean. These studies revealed that days heavily affected by dust, termed here as dust days (DD), are associated with certain synoptic patterns and meteorological conditions (Ganor *et al*, 2010). Hence, these conditions carry with them information on the origin of the dust and therefore its related attributes.

In particular, Ganor *et al* (2009) suggested a scheme for identifying DD in Israel based on ground PM_{10} measurements, validated by compositional analysis. The basic criterion to assess retrospectively a DD is whether at least 3 consecutive hours (6 half hourly readings) of PM_{10} concentrations were above 100 $\mu m/m^3$, with a maximum value of at least 180$\mu m/m^3$.

However, this scheme requires information about ground PM_{10} levels, which is clearly not available in places with limited ground monitoring coverage. In such cases satellite remote sensing (SRS) products may be an efficient and cost-effective alternative to ground measurements, and be used for classification of DD and non-DD (NDD) in environmental health related studies.

This work demonstrates the possibility to identify DD and NDD over southern Israel from merely satellite observations, and suggests a tool for estimating the contribution of dust to ground PM concentrations. Initially, an extension to the scheme suggested by Ganor *et al* (2009) for DD identification has been used. Namely, since dust events are expected to have a considerable spatial scale, the scheme was modified by requiring these criteria to occur simultaneously in at least 3 PM monitoring stations in the study region. Using this modified scheme, we obtained a list of DD and NDD based on ground PM_{10} records in the years 2007-8. These two populations (DD and NDD) have distinct properties, and could be distinguished using other ground measured parameters (i.e. $PM_{2.5}$, RH, etc.) (Fig.1). Next, we analyzed various SRS parameters (AOD, SSA, AE, AAI) from several satellite platforms (MODIS, OMI) for these two populations, to assess the possibility to use them as predictor variables of DD.

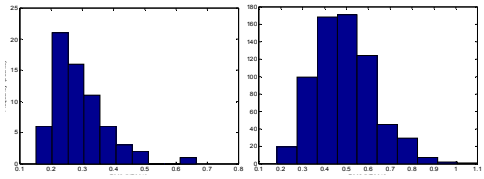

Figure 1. Ratio of ground $PM_{2.5}$ to PM_{10} concentrations in DD (left) and NDD (right).

A classification and regression tree (CART) analysis was used to evaluate interactions between the explanatory variables for predicting DD, followed by a logistic regression to develop a model that will be able to classify DD based on the integration of only SRS data.

The annual average number of model predicted DD is in good agreement with actual observations (Table 1).

Table 1. Comparison of annual average number of DD by ground PM_{10} data and by the logistic model.

Year	1958-2006 Observ.	2007-8 Observ.	Model Predict.
Annual average number of DD (DD/365days %)	20 (6%)	33 (9%)	29 (8%)

We expect this model to enable environmental epidemiologists, as well as ecologists, to distinguish among health/ecological/environmental effects that result from exposure to dust and to non-dust particles on a temporal scale that fits such studies.

Aerosol exposure in combination with aerosol impacts on climate: What is the total health outcome?

Jakob Löndahl[1], Erik Swietlicki[1], Elisabet Lindgren[2] and Steffen Loft[3]

Presenting author email: Jakob.londahl@gmail.com

Emission of aerosol particles is one of the largest environmental problems concerning human health. Traditionally only the health effects related to aerosol exposure are considered. However, for outdoor air pollution the climate change mediated health effects also need to be taken into account.

It has been estimated that climate change caused a loss of 160 000 lives from malaria, malnutrition, diarrhoeal disease, heat waves and floods in year 2000 because of the 0.4°C heating compared to the 1961-90 average climate (World Health Organization 2002). Aerosol cooling of climate, as in the below described case of ship emissions, may thus reduce death rates. Conversely, aerosol heating of atmosphere, as for black carbon, may lead to increase in mortality both due to exposure and due to adverse effects from global warming.

The objective of this work was to investigate the "total health effects" aerosol emissions which include both exposures to particles and consequences from climate change. Based on recent studies it has become possible to approximate, as a first source, the "total health impacts" of shipping emissions (Löndahl et al. 2010).

Emissions from shipping are relatively well-known from both a health and climate perspective. Exposure to air pollution from shipping were responsible for 63 000 (43 000 – 83 000) deaths globally year 2000 (Corbett et al. 2007). Skeie et al. (2009) estimated that the global temperature change this year was −0.05 °C ($\Delta T_{surface}$) because of emissions from shipping.

There is no linear relationship between climate change and human health, but in a small temperature interval a first approximation of the number deaths may be

$$N_{deaths,cooling} = \Delta T_{surface} \cdot \theta_{\Delta T}$$

where $\theta_{\Delta T}$ is a constant representing the number of deaths caused by one degree warming. With 160 000 deaths due to 0.4 °C, the constant becomes 400 000 deaths/°C. In reality $\theta_{\Delta T}$ is thus not a fixed number, but rather a function of global temperature (i.e. $\theta_{\Delta T}(T)$) with higher values for increasing temperatures. Using the equation above, ship emissions are estimated to cause a climate related life loss of -20 000 (-40 000 to -4000). The "total health effect" considering both the number of lives saved by the atmospheric cooling effect and the deaths from exposure to air pollutants, then is 43 000 (14 000 to 69 000) deaths for year 2000.

The outcome may vary depending on choice of scenario. For instance it may be of interest to omit CO_2 from the calculations since the gas is not affected by suggested regulations (which focuses on SO_x, NO_x and PM). In this case the "total health effect" in deaths year 2000 becomes 29 000 (−500 to 58 000). Some publications also provide substantially higher values of the aerosol indirect effect (see Eyring et al. 2010). Using these larger aerosol coolings result in a "total health effect" of −42 000 (−139 000 to 68 000) deaths (i.e. ship emissions would save lives on a global scale). However, ship emissions are an extreme example. With similar estimations for other sources with emissions closer to populations the negative health effects from exposure are likely to dominate.

At current state of scientific knowledge calculations of "total health effects" are highly uncertain (Löndahl et al. 2010). Especially the relationships between climate change and health is poorly understood. The value of $\theta_{\Delta T}$ used in this work is probably an underestimate since several effects were omitted such as impacts on infectious diseases other than malaria, extreme weather events other than heat waves, and climate change related impacts on allergen levels, population displacement, water shortage, and conflicts over natural resources.

To maintain one environmental problem (particulate air pollution) in order to reduce the burden of another (climate change), is close to geoengineering and is certainly dubious. Nevertheless, because of the risk that anthropogenic emission will move the climate system beyond an irreversible tipping point, there is an urgent need to develop strategies and metrics for regulation of short-lived cooling components in the atmosphere. For instance more attention might be given to lower the levels of black carbon. Reductions of pollutants to improve air quality, should ideally consider impacts on global warming.

Modeling and Measurement of ENP Dynamics in a Ventilated Two-Zone Chamber

Mingzhou Yu[1], Martin Seipenbusch[1] , Kun Gao[1]

Institut für Mechanische Verfahrenstechnik und Mechanik, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany
Presenting author email: mingzhou.yu@mvm.uni-karlsruhe.de

Engineered Nanoparticles (ENP) have been found to pose greater potential risks on human health and environment than macro- and micro-scale particles due to their unusual physicochemical properties including their small size, chemical composition, surface, solubility, shape and state of aggregation (SCENIHR 2009). Development of realistic exposure scenarios should play an essential role in the protection of workers' health and improvement of workplace safety in nanotechnology research activities. In order to meet this requirement, it is necessary to develop an accurate and simplified analytical model to simultaneously trace the temporal and spatial evolution of polydisperse aerosols.

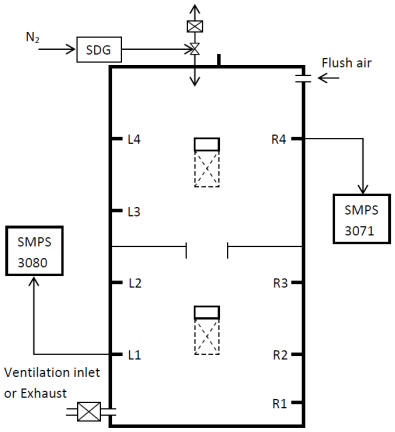

Fig.1 Experimental Setup

The aim of the present work is to get an analytical aerosol dynamic model with respect to Brownian coagulation among ENPs, as well as between ENP and background aerosols through experimental studies (Fig.1) and numerical simulations. This model is extended from one-zone studies conducted by Seipenbusch et al. (2008) to two-zone studies, and it is expected to be more useful to test the hypothesized modifiers in their influence on ENP number concentration because the study on nanoparticle dynamics in both time and space scales can be performed. The so called two zone model can then be formulated with two coupled differential equations, each describing the aerosol dynamics in one of the zones, and especially the information on convectional transport between chambers is included. The analytical solution is prior to numerical solutions in that it has more simplified mathematical construction and needs less computational time.

In the experiments, we used a spark discharge generator to produce NPs and background Gold particles. Two fans were used to mix the aerosol at each chamber. The particle size spectrum was measured by two instruments, scanning mobility particle sizer (SMPS, TSI model 3080), and scanning mobility particle sizer (SMPS, TSI model 3071). Two experiments were carried out for estimating friction velocity and particle loss rate due to deposition inside the chamber when the fan is on and off. Five main experiments were carried out for investigating the evolution of particle size distributions in both two chambers with the injected nanoparticles (continuous and pulse injection), shown in Table 1. Fig.2 shows the measured data from SMPS with continuous injection for 156 min.

Table 1

Experiment	Fan	Injection time	Background Particles	Injection status	Measurement status
B1	ON	156	NO	continuous	continuous
B2	ON	60	YES	continuous	continuous
B3	OFF	60	NO	continuous	interval (once per 30)
B4	ON	Once per 11.25	NO	interval	continuous
B5	ON	120	NO	continuous	Interval (once per 50)

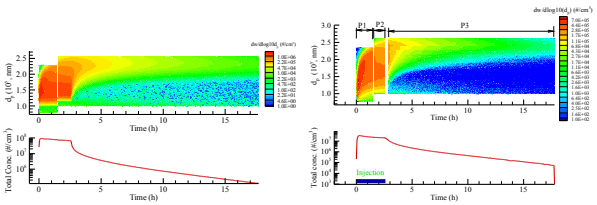

Fig.2 The measured particle size distribution as well as its total particle number concentration with time for top- and low-chamber.

In the numerical simulations, the particle general dynamic equations for both chambers were constructed following Muller's study (1928). In order to distinguish the background particles from the newly injected particles, two separated control equations for them were proposed. In order to accurately trace the evolution of particle size distribution at each chamber, the sectional method with fixed scale factors was used. In the numerical calculation, the fourth-order Runge-Kutta method with fixed time step was used to solve the set of ordinary differential equations. Both experimental and numerically simulated results were used as reference to validate the newly proposed analytical model.

With the help of experiments and numerical simulations, the simplified analytical model is expected to be proposed by simultaneously considering particle ventilation between two chambers, particle loss due to deposition, and coagulation. The model has an ability to trace evolution of particle number concentration for polydisperese system which will lead to be more reasonable risk assessment.

The response of PM concentrations in the UK to changes in industrial and agricultural emissions: implications for the exceedance of Air Quality Standards

E. Nemitz[1], M. Vieno[1, 2], U. Dragosits[1], C.F. Di Marco[1], M. Twigg[1,2] and M.A. Sutton[1]

Keywords: Abatement strategies, air quality, PM (general), ammonium nitrate, ammonium sulphate, precursors, inorganics, chemical transport model

Presenting author email: en@ceh.ac.uk

In the UK, secondary organic ammonium (NH_4^+) salts, formed from the reaction of ammonia (NH_3) with the oxidation products of sulphur dioxide (SO_2) and nitrogen oxides (NO_x), typically account for 20-40% of the $PM_{2.5}$ and 10-30% of the PM_{10}. With increasingly more reliable chemically speciated aerosol data becoming available, it is becoming clear that nitrate (NO_3^-) is a larger contributor than sulphate (SO_4^{2-}) and that it is particularly associated with pollution episodes during which the Air Quality Standards for PM are exceeded (Charron et al., 2006; Harrison et al., 1997). Nitrate formation is favoured by the relatively high emissions of NH_3 from agricultural activity, coupled with a cool humid climate. By contrast, SO_2 emissions have decreased by >80% over the past 15 years.

In this study we are using a high resolution version of the EMEP chemical transport model (EMEP4UK) (Vieno et al., 2010) to predict annual time-series of NH_4^+, NO_3^- and SO_4^{2-} for a number of urban locations, which are analysed in the context of measured PM concentrations.

The skill of the model in predicting NH_4NO_3 concentrations and their response to precursor gas concentrations has been carefully assessed by comparison of long-term trends and hourly variability against data from a number of sources, including: (a) a UK network that measures monthly gas and aerosol concentrations at 33 sites with a denuder / filter-pack sampler (UKEAP), (b) long-term measurements of aerosol composition at the UK EMEP Supersites 'Auchencorth' and 'Harwell' using a MARGA wet-chemistry analyser and (c) campaign-based measurements by Aerosol Mass Spectrometry (AMS) (Nemitz et al., 2011), including measurements in London (Allan et al., 2010).

Model simulations were then performed for several emissions scenarios: experiments were emissions were perturbed within and outside the UK, future emissions predictions, and scenarios in which different levels of agricultural NH_3 abatement (BAT) have been implemented.

Figure 1 compares the model predictions of monthly fine and total nitrate against a Scottish UKEAP measurement site, based on runs of full emissions and only non-UK emissions, showing that a long-term high nitrate event in spring 2003 represented mainly fine nitrate which was formed partly from UK and partly from non-UK precursor gases.

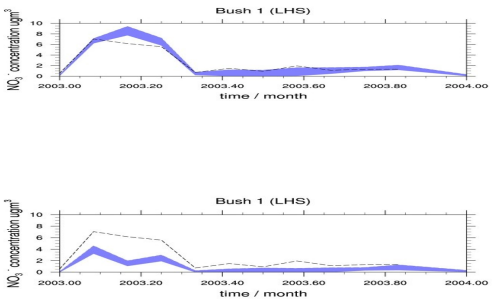

Figure 1. Nitrate monthly surface concentration at the Bush UKEAP site. The dashed line represents the observed nitrate concentration the blue shaded region represents the EMEP4UK model predicted range of fine nitrate (lower boundary) and total nitrate (upper boundary), with the thickness of the shaded area showing the predicted concentration of coarse nitrate. Top graph shows the base run, whereas the bottom graph represents a model run where UK emissions of precursor gases have been removed.

Plenary 4

The scientific challenges involved in using aerosols as a strategy for geoengineering climate.

By Phil Rasch:

The scientific challenges involved in using aerosols as a strategy for geoengineering climate

Philip Rasch

Pacific Northwest National Laboratory, 902 Battelle Boulevard,
P. O. Box 999, MSIN K9-34,Richland, WA, 99352, USA

Presenting author email: Philip.Rasch@pnnl.gov

Geoengineering is a term referring to the deliberate modification of the Earth's climate to counter some of the negative consequences of increasing greenhouse gas concentrations to the planet. Some suggested geoengineering strategies use aerosols to increase the planetary albedo, or to make the atmosphere less opaque to the emission of outgoing longwave energy. I will review a few of these strategies, discussing modeling studies (by myself and colleagues) used to explore some of the consequences to the planet that might arise from their use, and to identify some of the scientific and engineering challenges that exist in employing these technologies and approaches.

Session 8P: Poster session B

Combustion Aerosols

Determination of loss factors of aerosol particles in the sampling systems of nuclear power plants

Rainer Jonas, TÜV Nord SysTec GmbH & Co. KG, Große Bahnstr. 31, D-22525 Hamburg , Germany,
Gerfried Lindenthal, Ingenieurbüro für Partikeltechnologie und Umweltmesstechnik, Steinweg 8, D-34314 Espenau Germany

As with all measured quantities the stack emission of radioactive material of a nuclear power plant with exhaust air includes an uncertainty. This is caused by the statistical error and additionally by the non-representative sampling and the deposition of aerosols in the sampling systems. The non-representative sampling results from the insufficient mixing of the air (inhomogenous concentration) and from the non-isokinetic flow in reaching the inlet of the screen of the sampling system. The deposition depends on the particle diameter and is caused by molecular diffusion, impaction and sedimentation. The ratio of the mass concentrations in front of the screen and at the end of the sampling system is called the pipe retention factor. According to the German nuclear technical rule KTA 1503.1 the sampling system must be able to collect aerosols with aerodynamic diameters between 0.1 μm and 20 μm with pipe retention factors below 3.

Pipe retention factors and loss factors (without consideration of non representative sampling) have been investigated for sampling systems of different nuclear power plants in Germany using three methods of determination:

1) Dispersion of test aerosols directly into probes at the screen of the sampling system and comparing the aerosol concentrations with those at the end of the sampling system

2) Generation of a defined quantity of aerosol particles at the bottom of the chimney and measuring the particle concentrations by using aerosol collectors or aerosol monitors at the end of the sampling system

3) Measuring the size distribution by number of the ambient aerosol in the chimney in front of the screen and at the end of the sampling system with optical particle counters.

The poster gives a survey of the results of the measured loss factors and pipe retention factors.

The results are in compliance with theoretical estimations. The measured loss factors and pipe retention factors lie below 3, if the time interval for cleaning is adequately short. The transfer properties of the sampling systems for larger particles (aerodynamic diameters up to 3 mm), have also been investigated. The results show that the sampling systems are suitable even in these cases.

Investigating the sampling system in a time interval of 5 years according to the German nuclear technical rule KTA 1503.1 is not sufficient in every case, because the pipe retention factor may increase rapidly in case of pollution. Cleaning of the system is necessary. A realistic determination of the pipe retention factor may be expected if the time interval for cleaning is once a year especially after maintenance periods. The time interval for cleaning may be appointed depending on the sampling system.

Development of high-performance Cu-La nanomaterials as efficient catalyst for ammonia removal

Keywords: selective catalytic oxidation, ammonia, Cu-La nanomaterials.
Presenting author email: hungcm1031@gmail.com

Extensively adopted in industrial processes, ammonia (NH_3) can be eliminated in numerous ways. Apparently, NH_3 is used in the ammonium nitrate and nitric acid production industry, livestock feedlots, urea manufacturing plants, the nitrogen fertilizer application industry, fossil fuel combustion and petroleum refineries as well as the refrigeration industry. NH_3 is a toxic inorganic gas with a pungent odor under ambient conditions, and is potentially harmful to public health reported in the literature (Hung, 2008; Hung, 2009; Hung, 2010; Hung, 2011).

Nowadays, catalytic oxidation has been established to increase the effectiveness of AOP (Advanced Oxidation Processes) technology using dedicated catalysts, which potentially shorten the reaction times of oxidation, and allow it to proceed under milder operating conditions. The selective catalytic oxidation (SCO) of NH_3 in a stream to molecular nitrogen and water is one method for solving problems of NH_3 pollution. This work considers the oxidation of NH_3 by selective catalytic oxidation (SCO) over Cu-La nanomaterials at temperatures between 150 and 400℃. Figure 1 shows the effects of composite catalysts with various Cu-La molar ratios on the extents of conversion of NH_3, in terms of the extent of removal during the SCO process. The extent of catalytic oxidation of NH_3 over Cu-La nanomaterials is determined by the Cu-La molar ratio of the catalyst. The extents of conversion of NH_3 were 95 and 79% when catalytic oxidation proceeded under particular operating conditions over Cu-La nanomaterials with molar ratios of 8:2 and 7:3, respectively. To gain further information on the state of Cu-La species in these catalysts, the UV-Vis spectroscopic studies are carried out and the spectra are shown in Fig. 2. Generally, the bands were observed for Cu-La nanomaterials in the ranges of 300-350 nm and 700-900 nm. This band at 300-350 nm is attributed to the $Cu^{2+}-O^{2-}$ electronic transition species. The band at 700–900 nm is associated with the d-d transitions of Cu^{2+} in an octahedral environment with O_h symmetry. Conclusively, this work shows that the SCO process has the potential to treat highly concentrated streams of NH_3, helping industrial plants to meet discharge regulations.

Burning woodchips is recognized as one of the major renewable energy (Turner, 1999). Utilizing wood as fuel can replace fossil fuels, reduce carbon dioxide emission and thus help in fighting global warming. Consequently, wood could be a more important source of energy in the future.

Polybrominated diphenyl ethers (PBDEs) are the most used brominated flame retardants (BFRs). BFRs have widely applications such as comsumer products and electronic materials to prevent the spread of the flame. Due to the properties of persistence, bioaccumulation and ubiquity of PBDEs, two main PBDE commercial mixtures, penta-BDE and octa-BDE, are banned by the European Union in 2004. Therefore, with the increasing usage of PBDEs, which was concerned by the public.

The boiler investigated in this study utilizes woodchips as fuel. The woodchips in this study are collected from chipping or shredding wood for the productions of furniture with bromine content smaller than 15.9 mg/kg, water content of 6.1 %, ash content of 5.7 %, combustible content of 88.3 % and low heat content of 4559 kcal/kg.

The boiler being investigated in this study is a grate furnace boiler for the production of steam without power generator. The woodchip feeding rate of the intermittently operating boiler was 730 kg/hr, and the mean steam generation rate is 2.51 metric ton/hr. Its air pollution control devices include cyclone and bag filter with a flue gas oxygen content of 15.7 %. The output rates of the bottom residues, cyclone ashes and bag filter ashes are 0.38, 3.2 and 3.4 kg/hr, respectively.

In this study, the characteristics of PBDEs in the stack flue gases and the fly ashes of the cyclone and bag filter were investigated. Total PBDE concentrations (summation of 30 congeners) were listed in Table 1.The concentration in the stack flue gases of the wood-fuelled industrial boiler is much lower than municipal solid waste incinerations (26.1-109 ng/Nm^3) (Wang *et al.*, 2010). As it shown in Figure 1., the BDE-209 is the most abundant PBDE congener (73.4%) in the flue gas of the wood- fuelled industrial boiler.

By using the wood-fuelled industrial boiler, PBDEs is still existing in the stack flue gas, in the fly ashes and in the bottom ashes. How to arrange an appropriate air control system and how to have a good management process for the combustion ashes are also an important issues for using wood chip as a kind of sustainable and renewable green energy.

Table 1 PBDEs contents (concentrations) in the feeding woodchips, cyclone ashes, bag filter ashes and stack flue gases of the wood-fueled industrial boiler

	feeding woodchips (n=2) (pg/g)	cyclone ashes (n=2) (pg/g)	bag filter ashes (n=2) (pg/g)	stack flue gases (n=3) (pg/Nm^3)
Total PBDEs	5,221	142	1,470	2,735

Presenting author email: lincc@mail.npust.edu.tw

The adverse effects of ambient particles on human health have been an environmental concern for decades. Epidemiological studies have successfully related ambient particulate matter (PM) exposures with adverse respiratory effects, including chronic obstructive pulmonary disease (COPD) and asthma, and PM may cause increases in pneumonia and cardiopulmonary diseases (Pope et al., 1995; Tao and Kobzik, 2002). This study was conducted from November, 2009 to July, 2010 at a semiconductor plant in a science park in southern Taiwan to understand the characteristics of ambient atmospheric aerosol using a micro-orifice uniform deposition impactor (MOUDI) and a nano-MOUDI equipped with Teflon filters (with diameters of 37 and 47 mm, respectively) in the vicinity of semiconductor plants. The sampling periods covered trhee types of days: episode days (PM concentration > 100 μg m^{-3}), sunny days, and sunny days after rain.

The mean concentrations (with standard deviations) of the $PM_{0.1}$, PM_1, $PM_{2.5}$, $PM_{2.5-10}$, and PM_{10} particles were 4.31 ± 1.35, 38.8 ± 9.24, 66.3 ± 17.1, 50.0 ± 9.23, and 116 ± 25.9 μg m^{-3} on the episode days, respectively (Fig. 1). On the sunny days, the mean concentrations (with standard deviations) of the $PM_{0.1}$, PM_1, $PM_{2.5}$, $PM_{2.5-10}$, and PM_{10} particles were 7.14 ± 4.64, 33.8 ± 17.2, 48.4 ± 22.6, 27.8 ± 4.39, and 76.1 ± 24.8 μg m^{-3}, respectively; however, on the sunny days after rain, these PM data were 7.71 ± 5.71, 22.8 ± 6.38, 28.7 ± 7.49, 13.1 ± 1.69, and 41.8 ±7.23 μg m^{-3}, respectively. The particle mean concentrations of PM_1, $PM_{2.5}$, $PM_{2.5-10}$, and PM_{10} followed the order episode days > sunny days > sunny days after rain; however, the mean concentration of $PM_{0.1}$ was in order sunny days after rain > sunny days > episode days.

Episode day and sunny day samples exhibited a similar bi-modal particle size distribution within the size range 0.01–100 μm, with a major and a secondary peak in the coarse and fine size ranges, respectively (Fig. 2). The particles collected on sunny days after rain displayed a tri-modal distribution, with a major, a secondary, and a minor peak in the coarse (3.2–5.6 μm), fine (0.56–1.0 μm), and nano (0.01–0.032 μm) size ranges, respectively. With an additional minor peak in the nano size range (0.018–0.032 μm), the particles collected following rain had a tri-modal size distribution. The former result follows from the fact that the washout coefficients for PM sizes of 3–10 μm may increase significantly during heavy rain events (Chate and Pranesha, 2004). The latter result may be associated with the fact that the sampling site was close to the emission sources (semiconductor plants) and most of the collected ultrafine particles were freshly emitted in the stack flue gases from the sources. Therefore, the effect of rain on the ultrafine particle size distribution was not significant.

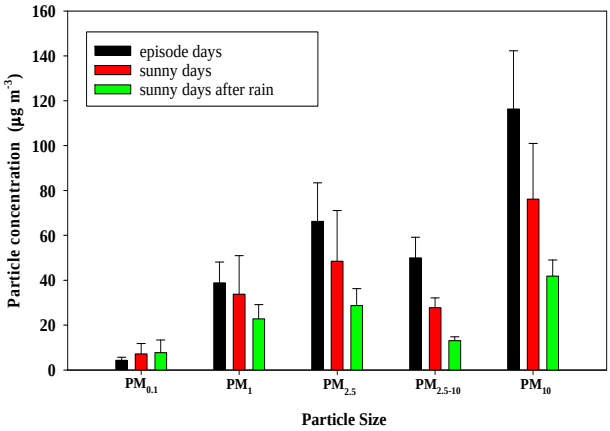

Figure 1. Mean concentrations of the $PM_{0.1}$, PM_1, $PM_{2.5}$, $PM_{2.5-10}$, and PM_{10} collected on episode days, sunny days, and sunny days after rain.

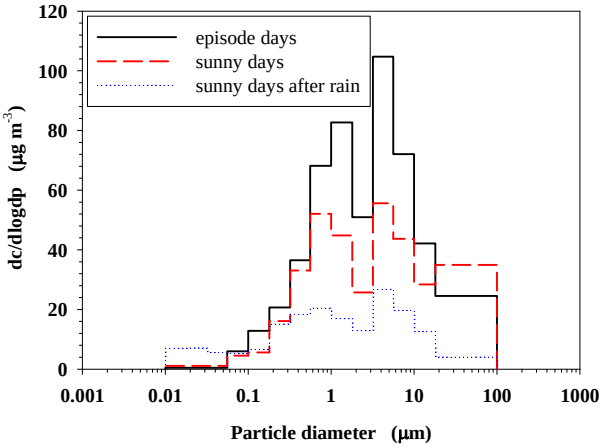

Figure 2. Size distributions of the mean PM collected on episode days, sunny days, and sunny days after rain.

The effects on health and environment that can cause the fine and ultrafine particles emitted from the industry are well known. Particle size distribution and that of heavy metal traces that accompany them are two key parameters to be evaluated. In the non ferrous metals industry, the emission of the particulate matter (PM) is mainly related to the processes of treatment and smelting. Therefore, the generated by-products will fundamentally depend on raw material characteristics, and on the conditions of operation.

For the present study, a total of 19 installations have been tested including plants of three non ferrous metallurgic sectors: primary zinc and secondary copper and aluminium In all cases, the sampling point was selected at the exit stacks from the melting furnace. The PM10, PM2.5 and PM1.0 fractions were sampled using a cascade impactor technique. Sampling and measurement was carried out in accordance with US EPA 201A and VDI 2066/5 procedures, using three types of cascade impactors: Mark III (eight stages) and DEKATI PM10 and KS207 Kalman System GMBH (three stages). Additionally, impactor substrates were chemically analyzed (method EPA IO-3.1) by ICP-OES and/or ICP-MS and FAAS to determine the concentration of: Al, As, Be, Cd, Cr, Cu, Mn, Mo, Ni, Pb, Sb, Ti, V y Zn.

The measurement data have been analyzed according to four particle size intervals: >PM10, 10>PM>2.5, 2.5>PM>1 and 1>PM. The results showed that in the copper and aluminium smelters, the emitted particles mass was practically distributed by equal in the studied intervals. In contrast, it was observed a maximum in the range 2.5<PM<1 in the case of zinc smelters.

Table 1 Percentage of the metals by particle size range for the three type of smelter: Zn, Cu and Al.

Range (µm)	Smelter.	As	Cd	Cr	Cu	Ni	Pb	Zn
>PM10	Zinc	27	24	63	2	71	34	5
	Copper	30	14	26	13	22	12	12
	Aluminium	35	26	37	29	34	26	30
10>PM>2.5	Zinc	27	30	13	2	17	10	14
	Copper	21	29	19	28	32	28	24
	Aluminium	24	23	21	19	19	22	21
2.5>PM>1	Zinc	13	15	2	1	1	18	23
	Copper	27	40	17	27	18	27	28
	Aluminium	28	25	28	30	33	31	28
1>PM	Zinc	33	31	22	95	11	38	58
	Copper	22	17	38	32	28	33	36
	Aluminium	13	26	14	22	14	21	21

The table1 shows the measurement results corresponding to metals to which apply a minimum threshold for releases to the atmosphere according to European Pollutant Release and Transfer Register (E-PRTR). In zinc smelters, the emitted submicron particles contain a high percentage of Cu y Zn (95 y 58 % respectively of the total mass of each element is in the interval 1>PM) and other although less significant as As, Cd and Pb are present in more than 30 %. Whereas the particles bigger than ten micron have more Cr (63 % of total chromium) and Ni (71 % of total nickel). In copper smelters, Zn, Cr, Cu and Pb (more than 32 %) are predominant in smaller particles, and only Cd (40 %) stands out in the interval 2.5>PM>1. Finally, in smelters of aluminium, As, Ni, Cr and Al have a presence higher than 30 % in the in bigger particles.

The distribution of trace metals by size of particle is primarily produced in the melting stage and transport of gases towards emission control system (ECS). Different metals contained in the raw materials are evaporated in the furnace and cooled into the duct forming new particles or being incorporated to the existing ones. Long residence time in the duct or ECS contributes to agglomerate particles and consequently to the process of distributing trace metals.

Knowledge of the distribution of heavy metals would allow realizing modifications in the process, so it would be possible to minimize its presence in the particle size range more difficult to separate by means of the conventional ECS. Effective separation of particles could be directed to metallic elements of particular interest, either for its high toxicity or for being catalysts in the formation of other pollutants such as PCDD/Fs.

This work was supported by the Ministry of the Environment and Rural and Marine Environs. Special thanks to Associations of Metallurgical Sector of Aluminium, Copper and Zinc and to each one of the staffs of facilities.

Workplace exposure to fine particles from welding fumes

E. Jankowska

Department of Chemical and Aerosol Hazards, Central Institute for Labour Protection – National Research Institute, Czerniakowska 16, 00-701 Warsaw, Poland
Keywords: welding fume, fine particles, concentration, exposure.
Presenting author email: eljan@ciop.pl

This abstract presents results of research on concentrations and size distribution of particles emitted as welding fumes. Investigations were conducted in a typical welding shop. Sampling points were located in the breathings zone of welder. Before welding process started, background levels out of the welding shop and in the welding shop were determined. The welding process was conducted in fifth stages (Table 1).

Table 1. Stages of welding process

Stage	Time	Number of electrodes (OK 61.30/308L-17) used
1	09:59	1
2	10:37	2
3	11:12	2
4	12:15	2
5	12:50	1

Measurements were done with:

- GRIMM Dust Monitor model 1.108 - number concentration and size distribution for size fractions 0,4-0,5µm, 0,5-1µm, 1-3µm and 3-10µm (Figure 1),
- AERO-TRAK 9000 (TSI) – surface concentration of particles in the 100-10000nm range, alveolar fraction - A (Figure 2).

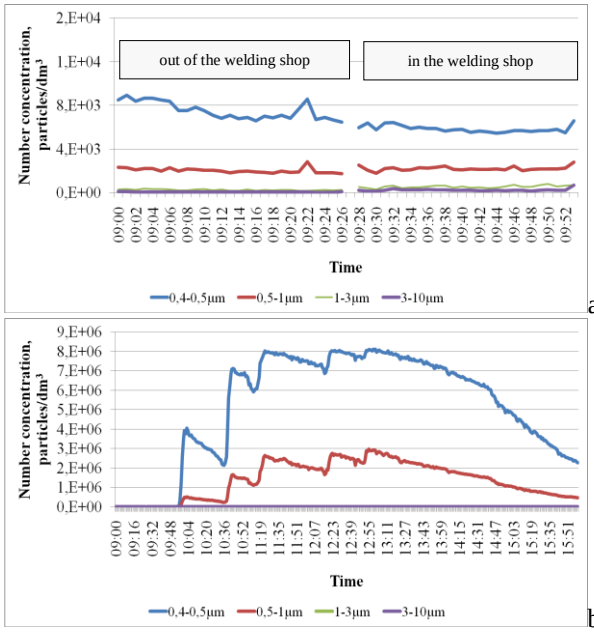

Figure 1. Number concentrations of particles (GRIMM): a) background levels out of the welding shop and in the shop, b) before, during and after welding process.

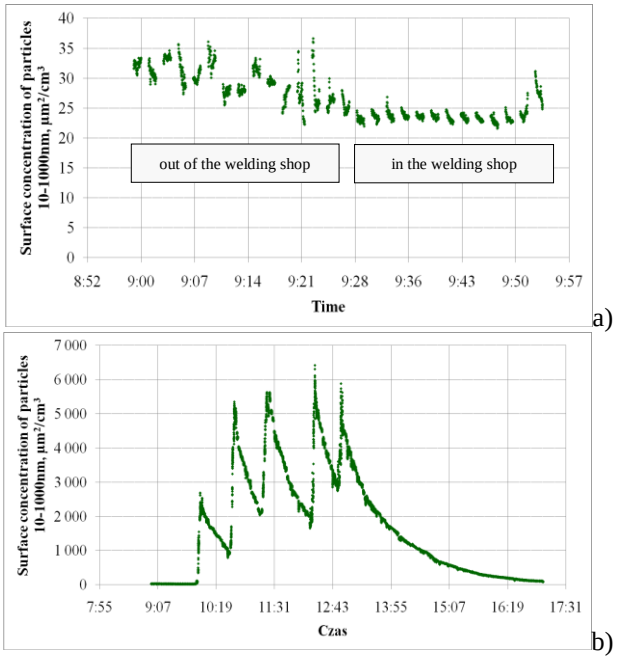

Figure 2. Surface concentration of particles 10-1000nm: a) background levels out of the welding shop and in the shop, b) before, during and after welding process AERO-TRAK results (A fraction).

Measurements date shown that:

- Number concentrations of fractions 0,4-0,5µm and 0,5-1µm (GRIMM results) and surface concentration (AERO-TRAK results) determined as background levels out of the welding shop were higher than that for background levels in the welding shop. For fractions 1-3µm and 3-10µm it was vice versa.
- Number concentrations of 0,4-0,5µm fractions after 3rd stage of welding remained almost in the same level (about 8^{e+6}partices/dm^3) between and during next stages of welding. Similar tendency was observed for number concentrations of 0,5-1µm fractions while number concentrations of fractions 1-3µm and 3-10µm were significant lower.
- Surface concentrations of particles 10-1000nm were in similar level after 3rd stage of welding (about 5700-6500 µm^2/cm^3, but between and during next stages surface concentrations dropped to about 1700-2900µm^2/cm^3.

This study was prepared on the basis of the results of research project 2.R.03 carried out within the scope of the National Programme "Improvement of Occupational Safety and Working Conditions" supported by the Polish Ministry of Science. Main co-ordinator CIOP-PIB.

Study of particle chemical composition and size distribution in the pyrolysis gas flow

A. Bologa[1], H.-R. Paur[1], H. Seifert[1], F. Weirich[2] and K. Woletz[1]

Karlsruhe Institute of Technology,
[1]Institute for Technical Chemistry, [2]Institute of Catalysis Research and Technology,
Eggenstein - Leopodshafen, 76344, Germany
Keywords: pyrolysis, particle size distribution, chemical analysis, chemical composition
Presenting author email: andrei.bologa@kit.edu

The Bioliq® process is developed by Karlsruhe Institute of Technology, by which the fully synthetic fuels, also called BtL fuels (Biomass to Liquid), can be produced from straw and other agricultural and forestal residues. KIT applies the four-stage Bioliq® produce a fuel, the quality of which will by far exceed that of conventional biofuels and even mineral oil products (Dahmen, 2007).

In the current work are presented the results of the study carried out at the first step of the Bioliq® process. At this step the biomass is converted into a transportable liquid intermediate product of high energy by a so-called flash pyrolysis. The pyrolysis product is gasified and the resulting syngas is used for production of biofuel. The tests were carried at the pyrolysis pilot plant in which dry biomass (straw) is mixed with hot sand at ambient pressure in the absence of air in a twin-screw mixing reactor. Pyrolytic conversion of the biomass particles at approximately 500 °C, and condensation of the pyrolysis vapors take a few seconds only.

The 1st objective of the current work was the measurement of particle mass concentration and particle size distribution in the pyrolysis gas flow. Two series of measurements were carried out. The probes were taken out by the Anderson Mark 3 Impactor downstream the 1st gas condenser. The raw material (straw) flow rate was up to 350 kg/h varying from plant operation conditions. During the 1st measurements the raw gas temperature was T=115°C and during the 2nd measurements the T=75°C. The impactors and the sampling system were heated up to 150°C.

The 2nd objective of the work was the chemical analysis of the straw, coke and collected pyrolysis product. The following methods were used: Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES); Total Inorganic Carbon Analysis (TIC-Analysis); Carbon, Hydrogen and Nitrogen Analysis (CHN-Analysis); Ion Chromatography (IC-Analysis) and Atomic Absorption Spectroscopy (AAS Analysis) of Hg. The analysis was performed for straw, coke and pyrolysis product collected on the impactor filters 1, 3, 7 and back-up filter (filter 1 is for particles >13,3 µm; filter 3 is for particles 5,6 µm; filter 7 is for particles 0,76 µm and back-up filter is for particles <0,52 µm).

The analysis of the impactor - probes shows that the mean particle size diameter is 1-3 µm (Figure 1). The aerosol mass concentration depends on the straw feed rates and varies from 15 g/Nm³ to 50 g/Nm³.

Carbon forms the main mass % of the tested matters. For the impactor filters, the carbon mass concentration in the collected pyrolysis product is highest for the smallest particle sizes. The mass % concentration of the hydrogen remains practically constant.

Coke particles are precipitated in the gas cleaning units installed up-stream the measurement point.

Calcium has the maximum mass concentration both in the straw and pyrolysis product and coke. In the coke the Ca concentration is up to 10 g/kg.

In comparison with other elements, relatively high concentrations are observed for Cu, Fe, K, Na and S. The absolute values for these elements strongly differ for analysed material. For example, K has high concentrations in the coke and low concentration in the pyrolysis product.

The chemical composition of the particles is similar and does not depend on the particles size. Similar is the concentration of the Si in the straw, coke and pyrolysis product.

The concentration of As, Cd, Hg and Pb in the straw and pyrolysis product is lower than 5 mg/kg.

Evaluation of the efficiency of the fume cupboards in the laboratory

T. Jankowski
Department of Chemical and Aerosol Hazards, Central Institute for Labour Protection – National Research Institute, 00-701 Warsaw, Poland
Keywords: tracer method, fume cupboard, ventilation, en 14175 test

According to data from the Central Statistical Office, in 2009 the threat of chemicals in the workplace in Poland related to 24.6 thousand. people. Specific hazard exists when working in the laboratory with new chemicals, whose physical, chemical, biological, have not been sufficiently investigated. These substances can be explosive, flammable, highly toxic, carcinogenic or dangerous to the skin, eyes or respiratory tract. In laboratory areas where there are factors harmful to health (mainly dust and chemical agents) should be applied to technical solutions that prevent the proper penetration of these factors to other facilities, and installed and an efficient mechanical ventilation intake-exhaust, guaranteeing the exchange of air needed to eliminate or reduce exposure to these factors.

The performance of the fume cupboard can be expressed in terms of quality as the ability to capture and remove one or more pollutants released from a source inside the workspace and the ability to extract to minimize any disruption caused by drafts, or traversing movements operating room personnel.

Hence it is important to study the safety and effectiveness of the fume cupboard as specified in the standards series EN 14175.

Testing methods described in the above standards may be used to evaluate the performance:

- fume cupboard at the specified by the manufacturer of the test conditions (tests in laboratory conditions),
- fume cupboard installed in a room equipped with a ventilation system of general and local ventilation devices. other fume cupboards such as laboratory (test conditions of use.)

Particularly important are the fume cupboards tests in conditions of their use, because the working parameters are closely dependent on the effectiveness of general ventilation systems and equipment of local ventilation systems installed in the room.

Currently, many research centers are conducted investigation on the use of tracer gas to study the performance of laboratory fume cupboards. The main centers are: HSL, INRS, FIOH, and NIOSH.

The CIOP-PIB studies are carried out air velocity, air flow rate, pressure drop, the degree of containment and air exchange of the laboratory fume cupboards. As part of these works are carried out the study:

- the impact of changes in flow characteristics inside the fume cupboard and its surroundings on the parameters related to emissions - a method of visualization and anemometric,
- parameters related to emissions in selected types of laboratory fume cupboard - a method of tracer gas, ie:
  - a given pollutant emissions from sources with the capture system switched on and off,
  - the efficiency of the laboratory fume cupboard, by measuring the mass concentration of sulfur hexafluoride in the vicinity of the object.

  Tests were carried on using two methods:
- Vivo Draught 20T35 Transducers for measuring air flow velocity,
- MIRAN SapphIRe 100E Portable Gas Analyzer for measuring sulfur hexafluoride (SF_6) concentration.

Figure 1 and 2 illustrates the example results of smoke visualization, distribution of air flow velocity and tracer gas concentration.

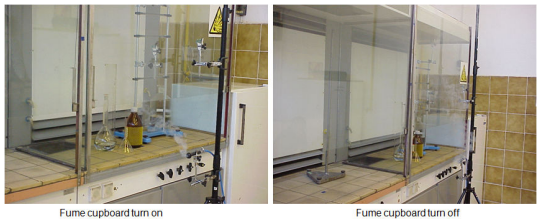

Figure 1. Smoke visualisation at the front of the fume cupboard at the laboratory.

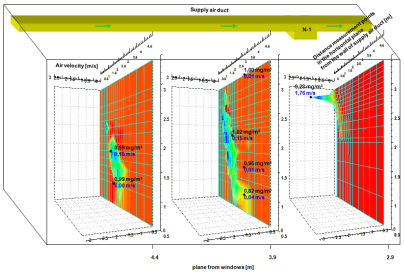

Figure 2. Distribution of air velocity at the laboratory.

Analysis of test results can assist the design and testing of laboratory performance fume cupboards to ensure effective protection of workers from the harmful effects of air pollutants from sources inside the laboratories.

This paper has been prepared on the basis of the results of task carried out within the National Programme “Improvement of safety and working conditions” partly supported in 2011-2013 within the scope of state services by the Ministry of Labour and Social Policy. The CIOP-PIB is the Programme's main co-ordinator.

Standard No. EN 14175. Fume cupboards.

Removal of Polychlorinated Dibenzo-*p*-dioxins and Dibenzofurans for physico-chemical pre-treatment and thermal treatment of Electric Arc Furnace fly ashes

S.I. Shih[1], W.J. Lee[2], Y.C. Hsu[1], Z.S. Wu[2], L.C. Wang[3] and G.P. Chang-Chien[3]

[2]Department of Environmental Engineering, National Cheng Kung University, Tainan City, 701, Taiwan
[3]Department of Chemical and Materials Engineering, Cheng Shiu University, Kaohsiung City, 833, Taiwan
Keywords: PCDD/Fs, Chloride, Coagulation, Filtration, Ash.
Presenting author email: ssi10@mail.ksu.edu.tw

Electric Arc Furnace (EAF) fly ashes were produced annually of 160,000 tons in Taiwan and 700,000 in European Union (Barna et al., 2000). They were rich in polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDD/Fs) and needs to be properly treated to conform to the regulated soil standard (1000 ng I-TEQ/kg in Taiwan) before landfill.

Pre-treatment (water-wash, including coagulation, sedimentation and filtration), that is usually used in water treatment, was firstly employed to treat EAF fly ashes. The contents or concentrations of PCDD/Fs and chlorides in three phases (sediment, suspension, and filtrate) were examined. Thermal treatment equipment was then used to treat EAF fly ashes to evaluate the removal efficiencies of PCDD/Fs at 900-1450 ^{o}C.

The experimental procedures of water-wash were very similar to jar test that is usually used in water treatment, and the sampling for PCDD/F analyses in three phases referred to the descriptions of Lee *et al* (2008). A graphite crucible, with inside diameter 70 mm and height 95 mm, containing 40 g of EAF fly ashes was placed in the primary furnace. Thermal treatment was then performed by raising the primary furnace temperature at 5 ^{o}Cmin^{-1} from room temperature and maintaining at 900-1450 ^{o}C for 1 h. Gaseous samples were withdrawn after the secondary furnace at 12 Lmin^{-1}. The batch experiment was repeated twice for consistency.

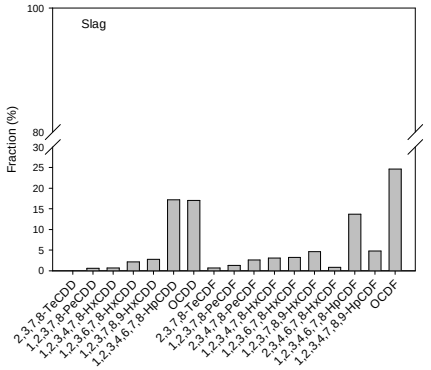
Table 1. PCDD/F contents of EAF fly ashes and treated ashes (slag) and their removal efficiencies after thermal treatment at 1450 ^{o}C

	EAF fly ashes (ng/kg)	Slag (ng/kg)	Removal (%)
Total PCDD/Fs	168952.0	1.103	99.999
Total PCDD/F I-TEQ	6639.9	0.0822	99.999

Analyses of PCDD/Fs were performed in a laboratory certified in Taiwan. Each sample was spiked with a known standard and extracted for 24 h. Then the extract was concentrated and treated with sulfuric acid; followed by a series of cleanup and fractionation procedures. A high resolution gas chromatography with mass spectrometer (HRGC/MS) was used to determine the concentrations of 17 individual PCDD/Fs. Helium was used as the carrier gas. The analyzer mode was selected ion monitoring with resolving power at 10,000.

Experimental results showed that, there was not a significant variation of PCDD/Fs after three rounds of water-wash of EAF fly ashes, owing to lipophilic character of PCDD/Fs. Nevertheless, concentrations of chlorides in three phases decreased substantially. Particularly in sediments, there was an approximately 95% reduction of chloride. Thus, it is expected that there would be a significant reduction of PCDD/F formation in the following thermal treatment.

As shown in Table 1, more than 99% of DRE (Destruction Removal Efficiency) of PCDD/Fs was achieved and the PCDD/F content of treated ash could be reduced to 0.0822 ng I-TEQ/kg. It is far below the soil standard regulated by Taiwan EPA (1000 ng I-TEQ/kg) and thus could be disposed with landfill undoubtedly. Mass distribution of PCDD/Fs in each air pollution control devices (cooling unit, filter and PUF cartridge) at 1450 ^{o}C thermal treatment temperature were 10.5, 16.7 and 72.8%, respectively. OCDD、OCDF、1,2,3,4,6,7.8-HpCDD and 1,2,3,4,6,7.8-HpCDF were the top four predominant species for the slag (Figure 1). Due to the high reduction of chloride after water-wash, less energy (low temperature) is needed to obtain the same PCDD/F removal efficiencies.



PCDD/F congeners

Figure 1. Congener profiles of PCDD/Fs in the slag after thermal treatment of EAF ash at 1450 ^{o}C.

The role of diffusiophoresis in fouling of exhaust gas recirculation heat exchangers

G. Hörnig and R. Niessner

Technische Universität München, Institute of Hydrochemistry, Chair for Analytical Chemistry,
Marchioninistr. 17, D – 81377 Munich, Germany
Keywords: Condensation, Diesel exhaust, Diffusiophoresis, EGR
Presenting author email: gabriele.hoernig@ch.tum.de

The combustion process in diesel engines is a source for hazardous environmental pollutants such as nitrogen oxides (NO_x) or particulate matter (soot). Future emission standards require increased application of exhaust gas recirculation (EGR), which is a very effective way to reduce NO_x emissions in diesel exhaust gases. However, due to incomplete combustion, diesel exhaust gas contains not only soot particles, but also other components like unburnt hydrocarbons (HC) and sulfuric acid (H_2SO_4). These constituents are responsible for EGR heat exchangers being very prone to fouling. Reduced heat transfer efficiencies and increased pressure losses are the consequence of various acting deposition mechanisms (Abd-Alla, 2002).

Some of the mechanisms involved in the particle deposition have already been investigated in great detail such as e.g. diffusion (Gormley and Kennedy (1949)) or thermophoresis (e.g. Romay *et al.* (1998), Messerer et al. (2003)). The latter is often described as being the most important acting mechanisms in heat exchanger fouling (e.g. Abarham *et al*. (2010)).

Yet in our experiments aerosol containing HC or H_2SO_4 vapor showed a higher potential for deposit build-up. Nuclei present in the exhaust gas condense on the cooled wall and build up a sticky layer where soot particles are firmly attached. Additionally, condensation creates a concentration gradient which leads to an enhanced particle transport to the wall, the process being known as diffusiophoresis (Hirschfelder (1954)).

Experiments were performed using model EGR heat exchanger and aerosol.

Size-dependent particle deposition was regarded for different aerosol temperatures and compositions. Coolant temperatures and thus the temperature differences within the heat exchanger were also varied. Soot was produced using a spark discharge generator (GfG) and monodisperse aerosols with particle sizes between 10 nm and 200 nm were generated by using a Differential Mobility Analyzer (DMA). Sulfuric acid vapor was added to the soot aerosol in concentrations comparable to those present in real diesel engine exhaust gas. A summary of the relevant parameters is given in Table 1.

Table 1. Summary of experimental conditions

Parameter	Regarded settings
$T_{gas,\ in}$ [°C]	150; 300
$T_{coolant}$ [°C]	20; 40; 60; 80
c_{H2SO4} [ppm]	0; 0.3; 0.45; 0.9
$\dot{m}_{Air}$ [kg/h]	5; 10; 15

The particle concentrations of the model aerosol were measured at different positions within the heat exchanger using a specially designed sampling probe. Particle Numbers were counted using a Faraday-Cup Electrometer.

For the dry soot aerosol deposition efficiencies increased due to thermal forces with increasing temperature gradients established inside the cooler. Yet for gas and coolant temperatures of 150°C and 20°C respectively, the aerosol containing H_2SO_4 vapor showed even higher deposition efficiencies (Table 2). The acid condenses on the cooler wall and diffusiophoresis acts in addition to thermophoresis.

We found that diffusiophoresis has a major contribution to EGR heat exchanger fouling and needs to be considered besides thermophoresis and turbulent deposition.

Table 2. Deposition efficiencies ε for varied aerosol composition at $T_{gas,\ in}$ = 150°C, T_C = 20°C, $\dot{m}_{Air}$ = 5 kg/h

Particle size [nm]	ε (dry aerosol)	ε (0.9 ppm H_2SO_4)
16	3%	16%
26	2%	6%
36	2%	10%
52	3%	1%
70	4%	2%
95	4%	17%
129	7%	20%
159	13%	17%
186	17%	33%

PCDD/F release inventory has been extensively investigated due to their acute toxicity and potential health effects. Many significant PCDD/F emission sources are related to combustion processes (US EPA, 2000). Numerous studies have focused on the PCDD/F emissions from various stationary sources, such as municipal solid waste incinerators (MSWIs), and metallurgical activities (Wang and Chang-Chien, 2007; Wang et al., 2010). Only a few studies reported data of PCDD/Fs emission from mobile sources; moreover, remarkable research differences, depending on tested types of vehicles, exist in literature (Dyke et al., 2007; Weilenmann et al., 2005). However, the contribution of PCDD/F from mobile sources is a matter of concern.

This study investigates engine tailpipe exhausts of 12 sport utility vehicles (SUVs), (light duty) diesel passenger vehicles (DPVs), and heavy-duty diesel vehicles (HDDVs) to elucidate the PCDD/F emissions and congener characteristics of tested vehicles using dynamometer tests. For simulation of real on-road operation status and the vehicle exhaust gas emission measurements, FTP-75, NEDC, and FTP transient cycle test procedures were applied for SUVs, DPVs, and HDDVs, respectively. The PCDD/F exhaust samplings (conducted isokinetically) and PCDD/F analyses both followed the US EPA modified method 23. Prior to sampling, XAD-2 resin was spiked with PCDD/F surrogate standards pre-labelled with isotopes. A higher solution gas chromatograph/high-resolution mass spectrometer (HRGC/HRMS) was used for PCDD/Fs analyses.

As shown in Fig. 1, the mean PCDD/F emission concentrations were 1.03, 0.599, and 2.65 ng/Nm^3, with the corresponding mean PCDD/F I-TEQ concentrations were 0.0591, 0.0344, and 0.121 ng I-TEQ/Nm^3 for SUVs, DPVs, and HDDVs, respectively. Moreover, the mean ratio of the PCDDs to the PCDFs concentration (PCDDs/PCDFs) and that of corresponding (PCDDs/PCDFs) I-TEQ in exhaust gases of the SUVs were 0.79 and 0.34, respectively; in the meanwhile, the data were 0.87 and 0.31, respectively, for the DPVs, and were 0.87 and 0.36, respectively, for the HDDVs. The results indicate that the equivalent toxicity from PCDFs dominated the total PCDD/Fs toxicity in the exhaust gases of vehicles.

The calculated mean PCDD/F emission factors were 2.28, 1.48, and 38.8 ng/km, with the corresponding mean emission factors (in terms of total PCDD/F I-TEQ) of 0.123, 0.0802, and 1.69 ng I-TEQ/km for SUVs, DPVs and HDDVs, respectively (Fig. 2). The PCDD/F emission factors followed the order HDDVs > SUVs > DPVs with significant differences (t-test, $p < 0.05$). The emissions from HDDVs were the most dominant PCDD/Fs contributor among the three types of vehicles. Compared with those of previous studies (Dyke et al., 2007; Weilenmann et al., 2005), the relatively high PCDD/F emission factors of SUVs, DPVs, and HDDVs found in this study may be attributed to the operations of cold start tests.

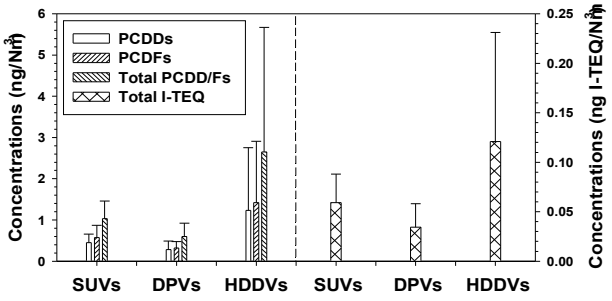

Figure 1. Mean PCDD/F concentrations of SUVs, DPVs, and HDDVs.

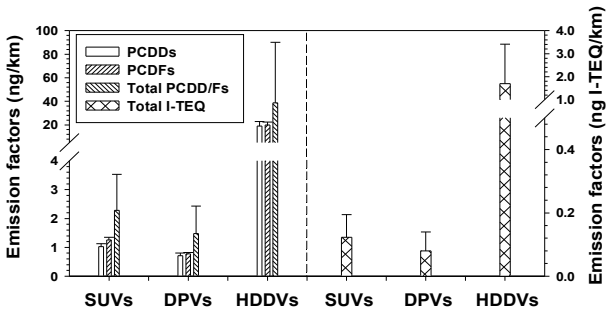

Figure 2. Mean PCDD/F emission factors of SUVs, DPVs, and HDDVs.

Performance of a new condensation particle counter for engine exhaust gas (PMP-CPC)

L. Keck[1], M. Pesch[1], M. Richter[1], and G.P. Reischl[1]

[1]Grimm Aerosol Technik GmbH&Co. KG, 83404 Ainring, Germany
Keywords: Instrument development, CPC, Diesel exhaust.
Presenting author email: lk@grimm-aerosol.com

EU emission standards Euro 5b/6 specify a maximum particle number of 6.0×10^{11} Particles/km in engine exhaust gas of diesel passenger cars and of light commercial vehicles. This limit value refers to the concentration of nonvolatile particles larger than 23 nm, for which the EU particle measurement program (PMP) specifies a measurement procedure that involves a two stage diluter (Giechaskiel *et al.* 2010) and a special concensation particle counter, the PMP-CPC as detection system.

Grimm has developed a PMP-CPC, which has several advantages that benefit also to the standard CPC line, which employs the same detector head. The PMP-CPC is a butanol based full flow counter with 0.6 lpm sample air, designed to measure also low concentration in diluted exhaust gas downstream of diesel particle filters. The instrument features a novel electronic circuit to separate even strongly overlaping electric peaks generated from the optical detection cell. To investigate the performance of the peak detection technique, we have measured the linearity of the counter, following the PMP protocol (Giechaskiel *et al.* 2009), with soot particles and an faraday cup electrometer (FCE) as a reference (Figure 1).

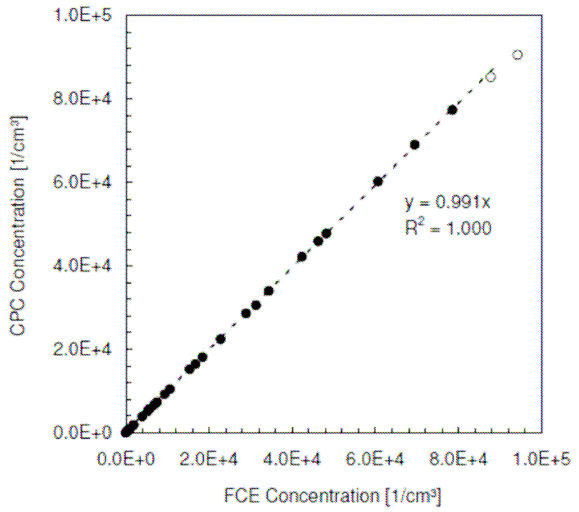

Figure 1. Linearity of the PMP-CPC. Open symbols are not included in the linear regression.

The maximum coincidence correction specified by the PMP regulations, 10%, was reached at 23,000 particles/ccm, which is almost two times the requested minimum value of 12,000 particles/ccm. The CPC can be operated in single count mode for concentrations up to 100,000 particles/ccm, where the coincidence correction amounts to 43% only.

The peak detection circuit employs also two different thresholds where peaks above the higher threshold refer to fully grown butanol droplets, and peak heights between the lower and higher threshold to incompletely grown droplets. The ratio of both count rates is monitored and, as a unique feature, also included in the data protocol. Ratios below unity are a sensitive indicator to any distortion of the condensation process and ensure a maximum reliability of the results for Euro 5b/6 compliance. The data protocol of the instrument includes also the final number concentrations with and without coincidence correction, and, for the CPC standard models, also the concentrations with and without photometric mode.

Condenser temperature is adjusted online to ambient pressure in order to maintain the detection efficiency for 23 nm particles in the target range of 50 ± 12 %. The saturator of the PMP-CPC can not only be heated, but also be cooled. Thus the instrument can be operated also during potential heat accumulation when using several apparatuses at an engine test stand.

Characterization of soot structure and reactivity based on Raman microspectroscopy

J. Schmid, B. Grob, R. Niessner and N.P. Ivleva

Chair for Analytical Chemistry, Institute for Hydrochemistry, Technische Universität München, Munich, Bavaria, 81377, Germany

Keywords: Oxidation reactivity, multiwavelength Raman microspectroscopy, soot structure, reactivity index.

Presenting author email: Johannes-Schmid@mytum.de

The reduction of anthropogenic aerosol sources is essential for the overall improvement of air quality. Soot emitted by diesel engines account for a major fraction of air pollutants in urban areas. To meet the present and future emission limits, soot particles must be removed from the engine exhaust. Diesel particulate filters, which have been applied for this purpose, need to be regenerated by gasification of the deposited soot. The efficiency of this regeneration step is strongly affected by the oxidation reactivity of the deposited soot particles. In particular, the formation of highly reactive soot would make it possible to reduce energy consumption at the regeneration step due to shorter combustion times and lower temperatures (Knauer, 2009). Therefore it is highly desirable to establish a rapid and robust analytical tool for determining the soot reactivity by its structure.

A link between Raman spectroscopic parameters and the structure of carbonaceous and soot has already been discussed in literature. Soot spectra show peaks at 1580 cm^{-1} ("graphite", or G) and 1350 cm^{-1} ("defect", or D), but the G and D peaks exhibit strongly varying relative intensities and widths that can be used for structural characterization. Moreover, for different carbonaceous materials and soot the D mode is dispersive (i.e. a higher intensity and a red shift with higher excitation wavelengths, λ_0), while the position of the G peak is invariant. Reich and Thomsen (2000) have attributed the dispersive character of the D mode to the double-resonant Raman process, which selectively enhances a particular phonon wave vector and phonon frequency. Sood *et al.* (2001) have proposed double resonance and disorder-induced two-phonon scattering combining an optic photon at the K point and acoustic phonon to explain this phenomenon.

By utilizing the dispersive character of the D mode we developed multiwavelength Raman microspectroscopy (MWRM) analysis of soot. The efficiency of MWRM was demonstrated by investigating carbonaceous materials with different structural order at three λ_0 (532 nm, 633 nm and 785 nm, see Figure. 1). In order to compare the behavior of the D mode for various samples and to derive a single parameter characterizing the soot structure, the difference of integrals for pairs of spectra collected at different λ_0 was calculated.

The relation between structure and reactivity of soot was investigated by combining temperature-programmed oxidation (TPO) with MWRM analysis. TPO allowed us to characterize the oxidation behavior of soot by utilizing the maximum emission ($CO + CO_2$) temperature. In order to interpret the TPO data more easily, a reactivity index RI_{soot} can be introduced. Spark discharge soot represents the high reactivity limit and therefore RI_{soot} is set to 100%. In contrast, graphite powder consists of stacks of graphene layers with predominant well-defined long-range ordering and therefore represents the lower reactivity limit (0%), with T being the maximum emission ($CO_2 + CO$) temperature.

$$RI_{soot} = 100\left(\frac{T_{Soot} - T_{Graphite}}{T_{GfG} - T_{Graphite}}\right)$$

This index can be used to compare results from different thermoanalytical methods e.g. TGA vs. TPO more easily and enables for correlation of structure and reactivity.

The comparison of the TPO data by RI_{soot} and the MWRM difference integrals revealed a linear correlation between oxidation reactivity and soot structure. Thus we demonstrated for the first time the potential of MWRM for a robust and rapid prediction of diesel soot reactivity based on the structure-reactivity correlation. (Schmid, 2011)

Presenting author email: wylin@ntut.edu.tw

Although interests in PCDD/F emissions have considerably increased in recent years, the PCDD/F emissions from on-road vehicles are still largely unexplored. Intensive studies have focused on the PCDD/F emissions from various sources, such as municipal waste incinerators, metallurgical activities, and temples, due to their vast majority of the total PCDD/F contribution (Hu et al., 2009; Wang et al., 2010). Only limited studies paid attention to traffic PCDD/F emissions (Kim et al., 2003), and no information on PCDD/F emission from motorcycles is available in literature. Because of exclusive proportion in transportation, motorcycle fleets (dominated by four-stroke engines) are considered more important in traffic and air pollution control than on-road vehicles in many countries.

In this study, emission tests for 12 motorcycles (including six 2-stroke engines and six 4-stroke engines) were performed using the regulated driving cycles to obtain the emission concentrations, emission factors, and I-TEQ data of PCDD/Fs according to their toxic equivalency factors (TEFs). The class A urban driving pattern, used for the motorcycles with the maximum velocity over 50 km/h to simulate the on-road emission status, adopts the standard test procedures similar to those of Economic Commission for Europe (ECE) cycle (Taiwan EPA, 1996). A complete test cycle (195 s) composed of the stages of idle (60 s), acceleration (42 s), cruising (57 s), and deceleration (36 s) operations. The maximum, minimum, and mean velocities were 50, 0, and 16.1 km/h, respectively. The PCDD/F exhaust samplings, which were conducted isokinetically, and PCDD/F analyses both followed the US EPA modified method 23. Prior to sampling, XAD-2 resin was spiked with PCDD/F surrogate standards pre-labelled with isotopes. A higher solution gas chromatograph/high-resolution mass spectrometer (HRGC/HRMS) was used for PCDD/Fs analyses.

Fig. 1 shows the congener profiles of the seventeen 2,3,7,8-substituted PCDD/Fs illustrated as the signatures of motorcycle tailpipe emissions. The fraction (%) of a congener is its concentration percentage normalized by a corresponding total PCDD/F emission concentration. The 2-stroke and 4-stroke motorcycles exhibited similar 2,3,7,8-substituted PCDD/F congener profiles. The dominant PCDD/F congeners of motorcycles in emission priority were OCDD, OCDF, 1,2,3,4,6,7,8-HpCDD, and 1,2,3,4,6,7,8-HpCDF, accounting for 37, 15, 10, and 9%, respectively. A similar PCDD/F congener profile was also observed for those of unleaded gas-fueled vehicles and diesel-fueled vehicles (US EPA, 2001).

Two 4-stroke motorcycles (A and B) were also tested to explore effects of lubricant renewal on PCDD/F emissions of motorcycles. After lubricant renewal, the PCDD/F emissions dropped. As expected, the reductions of total PCDD/F and I-TEQ emissions from the lubricant renewal were 26–45 and 41–63%, respectively (Figure 2). Therefore, regularly replacing lubricant oil is helpful for reducing PCDD/F emission from motorcycles.

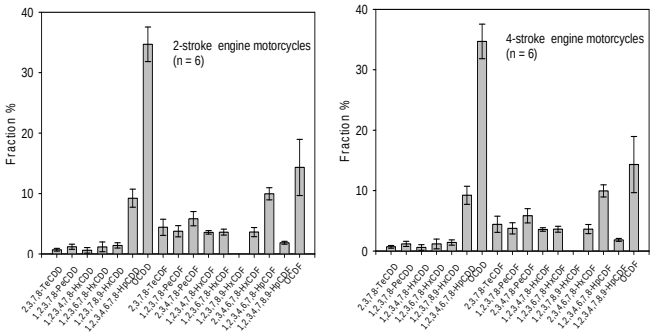

Figure 1. Congener profiles of seventeen 2,3,7,8-PCDD/Fs in the exhausts of motorcycles.

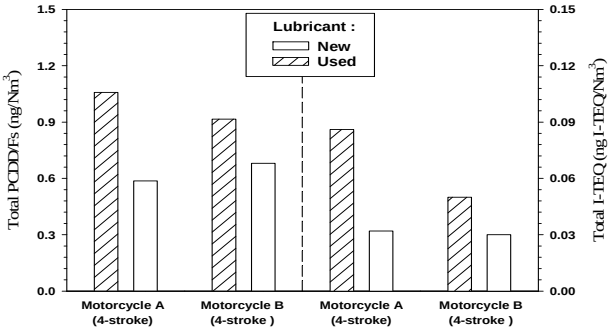

Figure 2. Reductions of PCDD/F emissions from motorcycles after lubricant renewal.

Reactive oxygen species (ROS) emissions from diesel engines running on various biofuels

S.D. Stevanovic[1, 3], B. Miljevic[1], N.C .Surawski[1, 2], S.E. Bottle[3], R. J. Brown[2] and Z.D. Ristovski[1]
[1]International Laboratory for Air Quality and Health, Queensland University of Technology, 4001, Brisbane, Australia
[2]School of Engineering Systems, Queensland University of Technology, 4001, Brisbane, Australia

Keywords: biofuels, reactive oxygen species, profluorescent nitroxide.
Presenting author email: s.stevanovic@qut.edu.au

Due to rising worldwide demand for energy and the prospect of climate change as a result of greenhouse gas emissions, there is a need to develop alternative energy sources. Therefore it is important to verify the potential of biofuels, as a renewable energy source, and to estimate the health and environmental impacts of their implementation (Gomes and Muylaert de Araújo 2009)

The mechanisms of particulate matter related adverse health effects are still incompletely understood, but a hypothesis under investigation is that many of these effects may derive from oxidative stress, initiated by the formation of reactive oxygen species (ROS) at the surface of and within target cells. Cumulative epidemiological and experimental data support the association of adverse health effects with cellular oxidative stress, including the ability of PM to induce pro-inflammatory effects in the nose, lung and cardiovascular system .High levels of ROS cause a change in the redox status of the cell and its surrounding environment, thereby triggering a cascade of events associated with inflammation and, at higher concentration, apoptosis.

The main aim of this study was to examine the relationship between different alternative fuel substitutions and the oxidative potential of particles emitted from an ethanol fumigated common rail diesel engine that was also equipped to run with biodiesel. To estimate the oxidative potential of ethanol and biodiesel at two different load settings, a pro-fluorescent probe BPEA nitroxide was used. This probe is poorly fluorescent; however the presence of ROS triggers a fluorescence response which makes it a powerful optical sensor for radicals and redox compounds. Samples were collected by bubbling aerosol for 20-30 minutes through an impinger containing 20 ml of 4 μM BPEA nitroxide solution after which fluorescence was measured. The amount of ROS was calculated based on the difference in fluorescence intensity for the test and the filtered control sample and was further normalised to the PM mass. Tests were designed to present emission differences due to changes in fuel and load settings.

The collection of other data was performed to support ROS measurements which involved volatility measurement using a Volatility- Tandem Differential Mobility Analyser (V-TDMA) system and particle composition using a Time of Flight Aerosol Mass Spectrometer (ToF-AMS).
The results depicting volatility properties as well as size-resolved aerosol chemical composition will be discussed.

Figure 1 shows ROS concentrations for diesel (E0), 3 ethanol substitutions of 10, 20 and 30 % (E10, E20, E30 respectively) and neat soy biodiesel (B100). It can be noticed that with an increased ethanol substitution (and also for biodiesel) an increased amount of ROS can be observed, with respect to E0.

It is proposed that ethanol combustion involves more available OH radicals that oxidise the particle surface. This might be a reason for the observed increase in the ROS on the surface of the soot particles (Surawski, Miljevic et al. 2009).
Furthermore at full load setting, concentration of ROS is significantly lower for all fuels, except for biodiesel. In addition, emissions with 100% biodiesel contained the highest concentration of ROS per mg of PM.

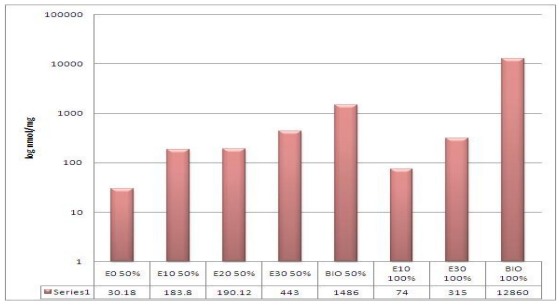

Figure 1: Average ROS concentrations for different fuel and load settings. Note that concentrations of ROS per mg of particulate matter are presented on a logarithmic scale.

Electrical conductivity as sensor principle for a sensor to measure soot aerosols

B. Grob[1], J. Schmid[1], N. Ivleva[1] and R. Niessner[1]
[1]Department of Analytical Chemistry, Technical University of Munich, Munich, Bavaria, 81377, Germany
Keywords: soot, electrical conductivity, raman, sensor
Presenting author email: benedikt.grob@mytum.de

It is well known that aerosol particles may have a great influence on the climate and public health. Especially in urban areas soot particles emitted by diesel engines are very harmful for human health. Future emission limits require that these particles have to be removed from the diesel engine exhaust. This is accomplished by diesel particle filters (DPF), which have to be regenerated periodically by oxidation. Since the DPFs can be damaged by thermal and mechanical forces, an on-board diagnostic system is required (OBD) to realize malfunction of the DPF system premature. For this purpose several approaches are currently under investigation to develop such a OBD particle sensor (Ochs, 2010, Spetz, 2010).

A promising attempt is the detection of particles with a resistive sensor. The sensor can detect particles by measuring the electrical resistance of deposited particles between two electrodes. To understand the sensors a basic knowledge of electrical conductivity of soot is necessary. In this study influences on conductivity of different factors like the morphology of soot, density and temperature should be taken into account. Also the effect of composites of soot with conductive and insulating admixtures should be investigated. The effect of urea, injected by the selective catalytic reduction system (SCR) into the exhaust pipe, has to be considered also.

Different soot samples (Printex 30, Printex XE2, Flammruss 101, Spezialschwarz 4, spark discharge soot and graphite powder) are pressed into pellets and the electrical conductivity is measured by a van der Pauw arrangement (van der Pauw, 1958). This method allows us to determine the conductivity in dependence of the density. Additionally, graphite powder is mixed with SiO_2, TiO_2 and Fe_2O_3 nanoparticles (d_p = 12 - 50 nm) . This allows us to interpret the influence of less conductive particles being mixed with soot depending on the concentration of the admixture. The composites show a percolation behavior (Figure 1). For structural analysis Raman microspectroscopy is applied. Therefore we use our newly developed multi-wavelength Raman microspectroscopy method (Schmid, 2011) to characterize the structure and to correlate the structural with conductivity data. Additionally, a five-band fitting procedure (Sadezky, 2005) is applied to gain parameters concerning the graphitic and amorphous content of soot and related carbonaceous samples.

Moreover, a thermophoretic precipitator has been developed to deposit a soot layer on a glass surface. The glass surface is coated by sputtered silver and prepared by lithography to form interdigital electrodes (Figure 2). The distance between the electrodes is about 100 µm. This combines the conductivity measurement principle with a controlled and size independent particle collection. However, it is still crucial to test this sensor principle with an independent and reliable method. Therefore a test vehicle will be equipped with the AVL Micro Soot Sensor (photoacoustic aerosol sensor) to validate this promising approach for an on-board particle sensor.

Laboratory investigation of post-combustion nitro-PAH formation

J. C. Wolf and R. Niessner

Chair for Analytical Chemistry, Technical University of Munich, Marchioninistr. 17, 81377, Munich, Germany

Keywords: NPAH formation, Diesel particle filter.
Presenting author email: jan.wolf@mytum.de

Particulate matter dispersed in diesel exhaust gas is a problem in air pollution and due to its known carcinogenic potential it is considered as harmful to humans. This carcinogenic potential is to more than 50 % accounted to polycyclic aromatic hydrocarbons (PAH) and nitro-PAHs (NPAHs) adsorbed on the particle surface (Schauer *et al.*, 2004). For this reasons the application of diesel particulate filters (DPF) has rapidly increased since the year 2000. This technology proved to reduce the total emitted particle mass and therefore also the emitted amount of PAH. Moreover, they may act also as chemical reactors, where PAHs may be converted to more carcinogenic NPAHs as a result of passive regeneration with high amounts of NO_2 (Heeb *et al.*, 2010).

The focus of our investigations is on this possible nitration reaction. Therefore a laboratory simulation setup of an exhaust gas system equipped with a miniaturized DPF (PM-Kat®–like) was constructed. In this setup spark-discharge soot, which is PAH-free, is coated with a submonolayer of benzo[a]pyrene (B[a]P) and directed to the miniaturized PM-Kat®, where it gets trapped. The regeneration of the filter structure can be controlled by temperature as well as the amount of NO_2 or oxygen passing through. Even different regeneration cycles can be simulated with this system, with the advantage, that only one single PAH (here B[a]P) and its reaction products are monitored.

To ensure that the reaction products were exclusively formed within the DPF structure, a special sampling and denuding system had to be developed.

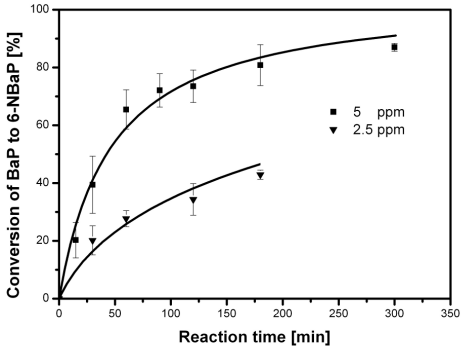

Figure 1.: Benzo[a]pyrene to 6-Nitro-benzo[a]pyrene conversion at 2.5 / 5 ppm NO_2 and 25°C on a quartz fibre filter.

In line with the DPF a heatable KI-based NO_2-denuder was placed to remove the excess of NO_2, which would otherwise cause artifacts on the sampling filter (see figure 1).

This denuder system is capable of removing 100 ppm NO_2 at a flow rate of 5 l/min for three hours with an efficiency $\eta > 98\%$. Behind the annular denuder a second denuder coated with XAD4 resin is placed to collect the gaseous PAH and NPAH. Finally, the particle phase is collected on a quartz fiber filter. Sampling time was one hour. All relevant parts (DPF structure, gas-phase PAH collector and filter) were analyzed for NPAH as well as for PAH.

Analysis was carried out by means of HPLC coupled to a fluorescence detector. The weak fluorescence exhibited by NPAHs required a reduction of the NPAHs to the corresponding amino-PAH (Schauer *et al.*, 2004). Therefore a reduction column densely packed with 5% Pt on γ-Al_2O_3 was placed after the reverse-phase analytical column used for the separation. Eluent was methanol/water and the injection volume was 0.5 µl. A LOD in order of 50 - 300 pg/µl was achieved for 12 different NPAH.

In our experiments 6-nitrobenzo[a]pyrene (6-NB[a]P) was found as major product, with trace amounts of 1- and 3-nitrobenzo[a]pyrene. By measuring the formation of 6-NB[a]P and the decrease of B[a]P at different reaction times and assuming the nitration being the only ongoing reaction, the conversion of B[a]P to NB[a]P could be calculated.

Our results show that DPFs using NO_2-aided regeneration are capable of increasing the NPAH emissions in diesel exhaust significantly.

Financial support by DFG is gratefully aknowledged.

Diesel exhaust undergoes rapid cooling and dilution processes when the exhaust is released into the atmosphere. During these processes, gas-to-particle processes like nucleation and condensation can take place modifying the size distribution and physical and chemical characteristics of the exhaust particles.

Particle volatility studies are a practical way to study the gas-to-particle processes of diesel exhaust. In addition to the emission characterizations, volatility studies can produce information about the particle formation processes and about the technical factors affecting them (e.g. exhaust after-treatment, fuel quality).

For example, in several studies the diesel exhaust nucleation mode is shown to include a non-volatile fraction. The initial formation of nonvolatile nucleation mode particles have been showed to take place at high temperature conditions before the exhaust entered into the atmosphere and the formation is affected e.g. by fuel injection pressure and exhaust after-treatment.(eg. Rönkkö et al. (2007), Heikkilä et al. (2009), Lähde et al. (2011)).

On the other hand, the changes of fuel and lubricant oil sulfur content affect mostly to the emissions of totally volatile nucleation mode particles (Karjalainen et al. (2011)).

In the studies above, the particle volatility has been studied using a thermodenuder (TD) where the semi-volatile particle fraction is first evaporated in the heating part and, after that, collected onto the surface of active charcoal in denuder part. The diesel exhaust nucleation mode studies require that, in addition to the effective evaporation of volatile components, the penetration of small non-volatile particles is high enough. Therefore, we built a TD based on the following designing criteria:

1) TD is able to evaporate all semi-volatile species of diesel exhaust particles
2) Evaporated vapors are efficiently collected into the activated charcoal
3) Flow range of TD is 0-10 slpm and the inlet temperature is 300K or higher.
4) Aerosol cools in the denuder part nearly to the inlet temperature of 300K.
5) TD provides a high penetration for non-volatile particles larger than 3 nm.

Designing of the TD was based on simulations by employing CFD packages of Ansys Fluent and Comsol Multiphysics. Losses of non-volatile particles were simulated as a function of particle size by solving the transport equation for different particle sizes in combination with the flow field and heat transfer equations. Evaporation rates of 10 – 100 nanometer sulfuric acid – water particles with concentration of 10^8 particles/cm^3 were simulated (see Figure 1). It can be seen that the particles evaporate in the heating part. In addition, simulations showed that the concentration of the sulfuric acid was reduced by a factor of 300 in the denuder part. The evaporation efficiencies (Karjalainen et al. 2011) and the non-volatile particle losses (Heikkilä et al. 2009) were tested also by generated particles.

In addition to the simulations and laboratory tests, the TD was used in the diesel exhaust particle studies in engine laboratories and on-road. These field measurements showed that the TD is able to remove the volatile nucleation mode particles and condensates from the soot particles (Karjalainen et al. 2011). In engine laboratory measurements the size-distribution measurements of the non-volatile core mode particles agreed well with the results obtained by using the hot dilution setup. Also the studies related to nucleation mode particle charge supported the results(e.g Lähde et al. (2011)).

In summary, simulations, laboratory tests and real engine exhaust measurements confirm that the TD performs well when it is properly operated; the sample flow is not too large, the temperature is not too low and the nucleation mode particles are not too large.

Presenting author email: souzana@cperi.certh.gr

The direct oxidation of soot by employing catalyst coated Diesel Particulate Filters (CDPFs) or fuel borne catalysts, depends greatly on soot-catalyst proximity. The highest degree of soot-catalyst contact that can be achieved is in the case of fuel borne catalysts. In case of catalyst coated filters, the details of the distribution of the catalytic coating on the channels of the filter, on the one hand, and the evolution of the soot deposit on the catalytic layer, on the other hand, are factors that affect the oxidation of soot and consequently the efficiency of the catalytic system. It has been therefore realized that, for the optimization of such catalytic systems, model-based approaches are required, that could estimate the parameters that govern the oxidation of soot under various conditions (Kostoglou and Konstandopoulos, 2005). The soot oxidation kinetic studies in the literature are primarily focused on the effect of oxygen and the derivation of reaction schemes and secondary on the structural details (Messerer et al, 2006).

In the current work, microstructural models of soot oxidation, based on the generalization of the Two-Layer model for incomplete soot-catalyst contact (Konstandopoulos and Kostoglou, 1998), are developed in order to express the micromechanics of soot-catalyst particle interactions that are observed during soot oxidation on catalyst coated filters and on filters loaded with soot particles that contain fuel borne catalysts at different concentration levels.

An extensive set of controlled experiments (isothermal or with linear temperature increase) using fuel borne catalysts and catalytic coatings has been performed. The experiments analyzed in this work were: (i) soot oxidation under linear increase of temperature on catalytic wall-flow monoliths coated with different amounts of catalyst via an advanced coating technique, the Aerosol Based Deposition (ABD) (Lorentzou *et al.*, 2007), (ii) isothermal oxidation of soot on catalytic filters coated via a conventional and an advanced (ABD) technique and (iii) isothermal oxidation of soot with the aid of different doses of a Ce/Fe based fuel-borne catalyst. In cases (i) and (ii) the model was based on a population balance approach for different classes of soot particles which have different levels of contact to the catalyst sites and on the dynamic evolution of these populations during oxidation, taking into account migration phenomena. In case (iii), the rate of the reaction as a function of conversion changes in such a manner as the temperature and the amount of additive increases that gives rise to a view of a spatial evolution of the additive particles on the surface as well as inside the bulk of the soot particle. The initial aggregation state between the soot and catalyst particles is shown to largely determine the evolution of the system during oxidation. The agreement between the experimental data and the simulated curves that derived from the application of the microstructural model in the case of the oxidation of soot with the aid of different amounts of fuel-borne catalyst is illustrated in Figure 1.

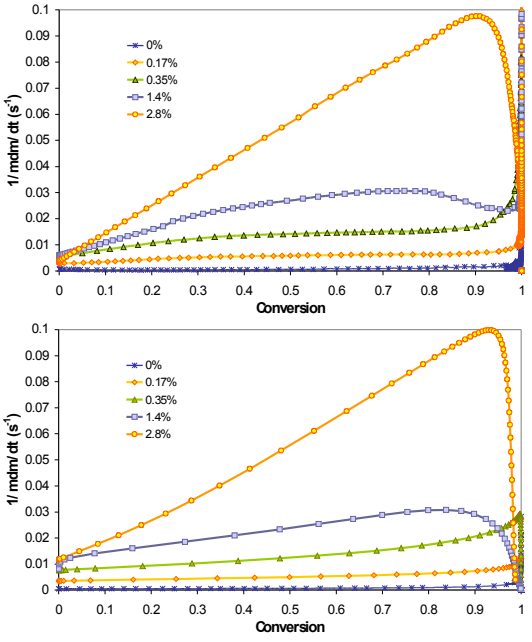

Figure 1. (a) Experimental and (b) simulated instantaneous soot oxidation rate curves as a function of conversion for the case of fuel-borne catalysts

The micromechanical models of soot-catalyst interaction successfully described the experimentally observed behaviour of the catalytic systems during soot oxidation opening the perspective for advanced modelling of the catalytic soot oxidation process.

Abstract

Emulsion fuel is a possible alternative fuel for reduction of diesel engine emissions. Using water/diesel emulsion fuel as a fuel can reduce the emissions of nitric oxide and particulate matters of the exhaust.(Samec et al., 2002; Armas et al., 2005) However, few researches have been carried out on the particle number concentration and energy efficiency from high speed light-duty diesel engine generator fueled with water/diesel emulsion fuel.

In this study, an ultrasonic vibrator with 40-kHz frequency was employed to prepare different water/diesel emulsion fuels (W5S5; W10S5; W15S5: W is water content; S is surfactant content). The experimental system consisted of a light-duty diesel engine generator, Electrical Low-Pressure Impactor (ELPI), Loading, and Fuel Consumption Measuring Device.

The results showed that the exhaust gas temperature was increased as generator loading was increased. However, it was decreased as the water content of emulsion diesel fuel was increased. When the loading was less than 2700 watts, the number concentration might increase as loading was increased. However, as loading was above 3600 watts, the number concentration was decreased. The total number concentration was 1.42×10^{8} #/cm^3 by using super diesel. However, the total number concentration was decreased to 2.99×10^{7} #/cm^3 by using W15S5 emulsion fuel (Fig. 1 & 2). Furthermore, the net diesel fuel consumption was decreased. As a result, using W/O emulsion fuel could increase the engine thermal efficiency by 12 to 34 %.

Presenting author email: souzana@cperi.certh.gr

The most efficient way of reducing the particulate emissions from the exhaust of Diesel engines is the use of Diesel Particulate Filters (DPFs). However, DPFs need to be periodically cleaned (regenerated) from the accumulated soot particles. Two pathways are mainly being investigated for the efficient regeneration of DPFs: the first one involves engine measures and the second one involves the application of catalytic coatings on the DPF. The involved catalysts aim to promote the reactions in the gaseous phase to produce reactive species that can oxidize soot and/or reactions in the solid phase between soot and catalytic particles.

Conventionally, the coating of monolithic structures with the catalytic elements is conducted via impregnation of the supports in a slurry of the catalyst or in a solution containing the catalyst precursors. Alternatively, the coating of monolithic filters can be achieved via aerosol routes by the in-situ synthesis and deposition of the catalytic particles on the DPFs (Karadimitra et al., 2001, Lorentzou et al., 2009). In the past, we have presented a pilot-scale Aerosol Infiltration synthesis and Deposition (AID) unit that involved a thermal spray gun for the creation of the high-temperature catalyst synthesis zone (Lorentzou et al., 2010). The pilot-scale unit employs an in-house atomizer for the atomization of appropriate precursor solutions while the production of the aerosol of droplets is used for the synthesis and the in-situ deposition of catalytic particles on full-scale DPFs. In the present work the high temperature synthesis zone is implemented via the incorporation of a heat exchanger (Figure 1). The droplets are transferred through the specially designed heat exchanger where they undergo evaporation of the solvent, precipitation of the reactants and crystallization to solid particles. The unit was used to integrate the different catalytic components that enhance the gas phase reactions as well as the soot oxidation reaction, into one multifunctional "reactor".

The final oxide particles that are formed are in-situ deposited on a monolithic real-size DPF, located at the exit of the heat exchanger. The coating process is monitored by the development of the pressure drop on the filters as a function of the amount of the deposited material. Initial experiments involved the optimization of the deposition parameters (gas flow and temperature) that affect the droplets' size and the catalyst particle size and morphology. Having defined the optimal unit operating conditions, the microstructure of the coatings on the walls of the filters and the homogeneity of the catalyst layer along the channels of the filters was observed with Scanning Electron Microscopy (SEM).

The performance of the coated DPFs was evaluated with respect to their pressure drop behavior during the accumulation of soot on the filter and to their catalytic activity towards the oxidation of soot and the conversion of gaseous pollutants (e.g. CO, HC and NOx). The evaluation was performed on an engine test bench. The catalyzed DPFs demonstrated enhanced performance when compared to state-of-the-art catalyzed DPFs especially if direct soot oxidation is of concern.

Particulate matter emissions from a winter operation of a modern on-road diesel engine powered by heated rapeseed oil

M. Vojtisek-Lom, M. Mazač, R.E. Lozano

Department of Vehicles and Engines, Technical University of Liberec, Liberec, Czech Republic
Keywords: combustion, diesel engine, rapeseed oil, vegetable oil, biofuels
Presenting author email: michal.vojtisek@tul.cz

Diesel engines powered by liquid fuels are a widely used, time-proven, practical and economical source of motive power for heavier road vehicles and mobile machinery. As the continuing use of traditional petroleum-based diesel fuel is severely threatened by increased world demand for petroleum, dwindling petroleum resources which are often located in politically problematic regions, and global climate changes stemming from the release of fossil carbon into the atmosphere, replacement fuels are being sought. At the same time, ultrafine particles produced during the combustion process in a diesel engine pose a major environmental and human health hazard, notably when released in urban streets. These concerns drive the need for careful evaluation of the effects of new fuels and new engine and exhaust aftertreatment technologies on particle emissions.

Neat vegetable oils are primarily used for the production of biodiesel, which is blended with petroleum diesel fuel. Their use directly as a fuel is minor but increasing mainly in stationary engines. Previous research done on traditional mechanically injected engines has shown that operation on heated rapeseed oil (RO) results in a decrease of particulate matter (PM) emissions at moderate and higher rpm and loads but an increase in PM at low loads (Czerwinski 2008, Vojtisek 2009). The increase in PM emissions was attributed primarily to higher viscosity of rapeseed oil compared to diesel fuel, causing worse atomization of the fuel, and worsened evaporation in the combustion chamber, leading to a less complete combustion; the decrease in PM to the differences in chemical structure of rapeseed oil, notably the absence of aromatics and about 10% by weight oxygen content. The number mean particle diameter was smaller compared to diesel fuel except for high loads, and that the fraction of organic carbon is higher in the PM from rapeseed oil combustion, offering an advantage if an oxidation catalyst is used.

To decrease PM emissions, majority of currently produced diesel engines use a Common-Rail (CR) injection system. In a CR system, multiple injections are performed, with the timing and quantities of fuel injected controlled and optimized for petroleum diesel fuel. While this approach greatly reduces PM emissions when operating on diesel fuel, a question arises as to its performance with vegetable oils for which it is not optimized. Higher PM were reported by Dorn (2007).

In this study, a 4.5-liter, 130 kW, four cylinder, turbocharged Cummins ISBe4 engine, widely used in medium trucks (lorries), with a Bosch CR injection system, was tested on an engine dynamometer during steady-state operation at engine speed and load combinations defined in ESC and WHSC cycles (DieselNet). The engine was operated without any exhaust gas aftertreatment system on diesel fuel, neat biodiesel (FAME) and heated RO. The exhaust was routed in an improvised full-flow dilution tunnel, part of which was located outside of the laboratory. PM mass emissions were measured by the gravimetric method. Particle size distributions in the range of 5-500 nm were measured by EEPS spectrometer (model 3090, TSI, St. Paul, MN, USA). The testing was performed during the winter at outside temperatures 265-270 K and engine intake air temperatures 285-290 K.

The dilution apparatus and its operating temperature were favorable for nucleation and condensation of particles. No efforts were taken to evaporate volatile matter from the particles by a thermodenuder or by diluting with heated air. Therefore, this experimental setup was considered to represent reasonable worst-case scenario of an engine operated during the winter.

The particle number emissions for FAME were typically similar to tens of percent lower compared to diesel fuel in all size ranges. For RO, particle concentrations were between diesel and FAME above 20-30 nm, but markedly higher at lower diameters with a strong nanoparticle peak; these small particles are believed to be organic carbon which would be in gaseous form at higher temperatures. Total particle number emissions for RO were compared to diesel lower at full load but higher at all other regimes. The effect on total PM mass over ESC and WHSC cycles was not uniform and relatively small. With the exception of the nanoparticle peak which is subject to future discussions, no major adverse effects on PM emissions were observed during operation of a modern CR diesel engine on heated RO.

The work was supported by the Czech Science Foundation (grant 101/08/1717) and by the Czech Ministry of Education (project 1M6840770002).

Electrostatic Measurement Techniques have been applied to the characterization of submicron aerosols since 1966. Initially designed for laboratory and ambient measurement tasks only this method has been more or less successfully applied also for emission aerosol characterization, encountering numerous problems. Main issue is the dilution problem, making the use of this method rather complicated and requiring a high level of knowledge to avoid erroneous results. It will be shown, that a rather simple redesign of the method by integration of the dilution system into the measuring device can solve most of the intrinsic problems connected with the characterization of highly concentrated particles suspended in a reactive carrier gas at prohibitive temperature and pressure levels. A few selected examples are presented, outlining the broad spectrum of applications.

Developed in two steps in the late nineties during a cooperation of the Vienna University, the AVL and the GPR-Aerosol Inc. two Systems were designed, the DDMPS for the use during conventional test bed studies featuring two DMAs run in parallel covering the size range from 2 nm to 900 nm with a cycle time of 90 seconds.

Still not fast enough for transient aerosol sources, the system was expanded to 10 DMAs featuring a somewhat poorer size resolution, but a fast cycle time of 200 ms only. This TrDMPS was first built as a prototype at the University of Vienna in cooperation with GPR-Aerosol Inc. in 2000 and is used since to characterize and investigate the dynamic Emission pattern during legal test cycles at Roller test bed facilities throughout Europe and Asia.

In 2005 a commercial version of the 10 DMA-FCE device FAPES was developed by Grimm Aerosol Technology. However, difficulties with the complex plumbing of the device caused severe handling problems.

In 2011, Grimm-Aerosol technology will present a newly designed FAPES, featuring a 12 DMA device with improved size resolution and with an improved pneumatic setup to avoid the known plumbing problems.

Some results of the studies utilizing the TrDMPS and the FAPES leading to discussions of environmental management policies are shortly presented.

Particle-Lung Interactions

Deposition efficiency of micro-size particles in the upper airway of Taiwanese adults

D.J. Hsu[1] and M.H. Chuang[2]

[1]Department of Safety, Health and Environmental Engineering, National Kaohsiung First University of Science and Technology, Kaohsiung, 811, Taiwan
[2]Department of Occupational Safety and Health, Chang-Jung Christian University, Tainan, 711, Taiwan
Keywords: deposition efficiency, upper airway, Taiwanese adults.
Presenting author email: hsuderjen@nkfust.edu.tw

Numerous studies to determine the removal efficiency of the inhaled particles in the nasal region have been performed in the past decades, either by using replicate casts or human volunteers (Cheng et al., 1991; Garcia et al., 2009; Liu et al., 2010). However, most of those studies were primarily based on a limited number of white male subjects (Bennett and Zeman, 2005). Some previous studies also indicated that nasal anatomic and dimensional factor are important in determining the amount of deposition in the nasal passage, and particle deposition data from a demographically diverse group is important (Kesavanathan and Swift, 1998).

The purpose of this study was to obtain particle deposition efficiency in the upper respiratory tract from Taiwanese adults with respect to particle sizes (0.5~20μm) and inspiratory flow rates. Information of nasal geometry of the human subjects were collected to address the racial differences in particle deposition in the upper respiratory tract.

Nine healthy and non-smoker adults (5 men and 4 women) with age ranging from 23 to 45 years old participated in this study. The particle deposition in the upper respiratory tract was measured for particles with aerodynamic diameter between 0.5 to 20μm. To simulate the inspiratory demands at various workload levels, minute volume of 10, 15, 20 and 30 liters were selected, which are in the breathing range for humans of resting to moderate exercise. Three repeated measurements were performed for each subject at a selected inspiratory flow rate. For a single experiment, subjects were asked to hold their breath for 20 seconds and air was drawn a mouth piece in subjects' mouths by a constant pump in the manner of nose-in-and-mouth-out. The particle concentration near the human nose (C_0) and the outlet of the mouth piece (Cout) was measured, and the deposition efficiency (η) was determined by the following equation:

$$\eta = 1 - \frac{C_{out}}{C_0}$$

The particle deposition efficiency obtained in the current study showed a large intersubject variation and no significant correlation was found between the deposition efficiency and gender. The average particle deposition efficiency of the nine subjects was plotted as a function of inertial parameter (d^2Q) and was compared with the data of several in vivo and in vitro studies. As shown, those in vivo studies, which were mainly based on the Western people, had higher deposition efficiency than Taiwanese adults. However, the data from previous replicate cast studies seem to better approximate those of current study, except in the relatively high and low values of inertial parameter.

The work of Kesavanathan and Swift (1998) noted that nostril shape would affect the anterior air flow pattern and an elliptical shaped nostril (i.e., greater E) will have greater particle deposition efficiency. The average E obtained from the present study is 1.59, which is close to that of Koreans (E=1.87) in Hwang and Kang (2003), but much lower than the data from Caucasians and Asians (2.47 and 2.15, respectively) measured by Kesavanathan and Swift (1998). We speculate that the difference in nostril shape between Western people and Taiwanese is one of the causes for such discrepancy. Future study with greater numbers of human subject as well as more detailed information of nasal geometry is suggested to clarify whether the difference in particle deposition efficiency exists between ethnic groups.

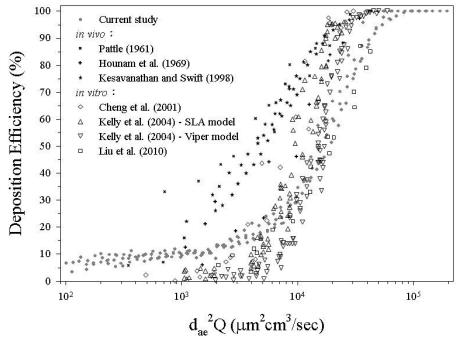

Figure 1. Comparison of the current study with the published in vivo and in vitro data.

Aerosol inhalation study is the best method for respiratory hazard assessment of newly developed materials in animal experiment. But it takes much time and efforts, therefore intratracheal instillation test is used as an alternative.

The hazard of nano-size particle becomes great interest. Titanium dioxide has been recognized as innocent particle but IARC summarized the experimental data and resulted TiO_2 is categorized as "Group 2B". Adverse health effect is depended on the dose as well as its own toxicity. In overloaded condition, the excess adverse effects are observed. Therefore in this study four doses of TiO_2 nanoparticle were intratracheally instilled to Wistar male rats and we try to investigate the dose which induces the overloaded condition.

TiO_2 (P90, Degussa) was ultra-sonicated in disinfected distilled water to smaller particles and the solution was centrifuged. The particle size of TiO_2 in the supernatant was 25 nm detected by dynamic light scattering method. The prepared supernatant was instilled to rats after adjusting the concentration. 0.1mg, 0.2mg, 1mg, 3 mg of TiO_2 nanoparticles dispersed in 0.4ml distilled water were intratracheally instilled to rat lungs. At 3 days, 1, 3, 6, 12 months after the instillation, each 10 rats were dissected. The number of PMN in bronchoalveolar lavage fluid (BALF) from right lungs of each 5 rats was counted. And the deposited amounts of TiO_2 nanoparticles from left lung and two right lungs of each 5 rats were detected by chemical analysis and calculated the biopersistence.

For determination of TiO_2 in rat lungs, dissected lungs were acid digested by H_2SO_4, $(NH_4)_2SO_4$, H_2O_2 with microwave and the Ti concentration in completely digested solution was determined by ICP-AES.

Figure 1 shows the number of PMN in BALF. PMN in BALF of 0.1mg and 0.2mg instilled rats were not increased throughout the observation period after the instillation. In contrast, the PMN number of 1 mg and 3 mg instilled group increase at 3 days after the instillation. For 3 mg instilled group it has continuously increased compared with the other groups.

Figure 2 shows the biopersistence calculated by one compartment model from the average amounts of retained TiO_2 nanoparticles in rat lungs. The biological half times (BHT) of low dose (0.1mg and 0.2 mg) were about four months and almost the same each other. But BHT of 1 mg instilled group increased slightly and that of 3 mg group increased further.

Our results of PMN analysis and biopersistence suggested that approximately 1 mg in lung may be the border zone of overloaded situation for Wistar male rats. Therefore in order to avoid the excess effect, the dose to the lung has to be controlled in animal experiment.

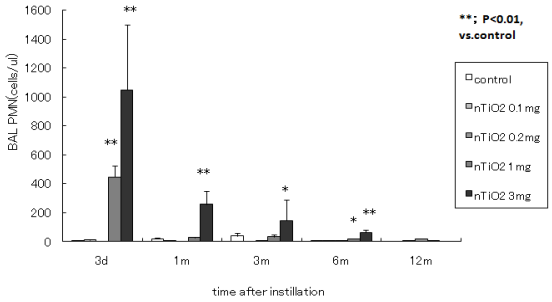

Figure 1. The number of PMN in BALF from rats instilled 0.1, 0.2, 1, 3 mg of TiO_2 nanoparticles at each dissected time.

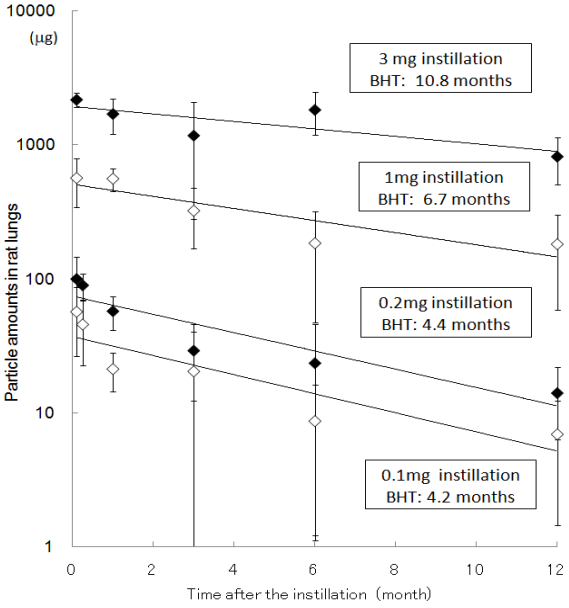

Figure 2. Biopersistence of TiO_2 nanoparticles in rat lungs in 4 different dose instillation test.

In vitro toxicity studies are becoming much more important due to increasing concerns about animal welfare and partly also due to higher costs of *in vivo* studies. We introduce a new device for *in vitro* cell exposure to nanoparticles for cytotoxicity screenings. The system is an attempt to solve one problem most *in vitro* toxicity studies encounter when trying to mimic *in vivo* inhalation studies, namely the lack of representativeness of the exposure to the particles (Teeguarden, 2007) and hence the resulting dose and dose rate. It is conceptualized as a toxicity screening device primarily indicating cytotoxic effects on the human respiratory tract.

The so called Cyto-TP is a thermal precipitator (TP) (Azong-Wara, 2009) for the deposition of airborne nanoparticles on living human epithelial lung cells at the air-liquid interface (ALI). The cellular response to ALI exposure seems to be similar to suspension exposure but occurs at doses significantly lower (Holder, 2008). Cellular response at ALI may be observable at exposure atmospheres with moderate particle number concentrations. The TP deposits particles very smoothly onto the cell surface and therefore does not damage the cells by impact. By using airborne particle exposure the surface chemistry, morphology and size of the nanoparticles do no change in contrast to the use of suspension exposure. Unlike in a similar concept using electrophoresis for particle deposition (Sillanpää, 2008), particles bear their natural charge level. These aspects contribute greatly to a higher representativeness of exposure mode.

The Cyto-TP consists of a hot plate (52°C) and a parallel cold plate (37°C) which hosts the cell cultures as shown in Fig. 1. The aerosol flows between the two plates and particles are deposited onto the cells by thermophoresis. Potential cell stress due to secondary effects is minimized with our device, so cellular response can be related more easily to the presence of nanoparticles in the exposure atmosphere. After exposure the cells can be placed inside a scanning electron microscope for analysis. Additionally CASY cell counting and analysing used to determine the ratio of living and dead cells.

The presentation will describe the first prototype of the Cyto-TP and its design and functionality along with a newly designed experimental approach for cytotoxicity screening. First results of the validation of the Cyto-TP approach with nanoparticles will be presented.

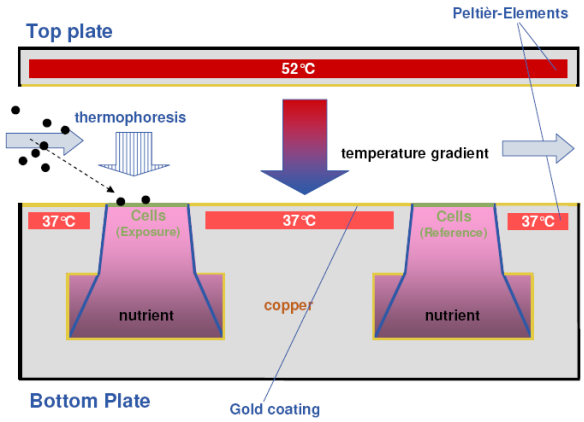

Figure 1. This is a concept sketch of the functionality of the Cyto-TP. The nanoparticles in a laminar flow are deposited onto the cells placed at the cold plate.

The research leading to these results has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement n°211464-2.

Important adverse effects on children health can be caused by exposure to air pollution, namely during the peculiar "susceptibility window" occurring during the first years of life (Clark, 2010). In particular, traffic related pollution adversely affects lung function development.

Between 2007 and 2008, 228 children, mean age 8 years, were enrolled from 2 primary schools, located in different sites, in order to study pollution related respiratory symptoms and/or diseases in different places of Milan with a different traffic-related exposure. The former (School 1) was located near a large park, the latter was located downtown, close to main crossroads (School 2). Daily levels of PM10 and PM2,5 (diameter <10μm and 2,5μm) were measured both outdoor and indoor outside the schools (in the school garden) and within common places (corridors), for 7 consecutive days during 2 different campaigns (winter and spring-summer). Children underwent skin prick testing for inhaled allergens, analysis of exhaled nitric oxid (FeNO) and spirometry.

The distribution of FeNO values was significantly different (p=0,02) between the two schools. In particular, the percentage of children with FeNO values <5ppb in school 1 was higher (almost double) than in school 2. In 73% of children attending the school located downtown FeNO concentration was between 5 and 20ppb.

The percentage of asthma exacerbations in the previous 12 months was higher in children from school 2 (p=0.05). On the contrary, the prevalence of persistent allergic rhinitis in children allergic to grass pollen was higher in school 1 (p=0.03). In particular, the latter children also had a greater activity limitation, due to rhinitis and concomitant conjunctivitis (p=0.03). Interestingly, the highest recorded peak for PM10 occurred between 8:15 and 9:15 a.m., for 3 consecutive days, and was related to children arrival. This peak (>1000μg/m^3) (figure 1) didn't seem to produce specific health effects, likely because of the usual PM10 composition in a park site, with a lower content of toxic or reactive components.

Hospital admissions, because of lower respiratory tract diseases (bronchitis, bronchiolitis, pneumonia) were more frequent during the winter campaign and in school 2, whereas otitis and allergic rhinitis or conjunctivitis, together with asthma, were more severe during the spring-summer period and in school 1 (p<0,05).

Continuous monitoring for 3 years of both children and PM showed that: 1) short duration pollution peaks, even reaching concentrations 20 folds above the fixed limits, have no consequences on children health and were likely induced by children's arrival or movement; 2) there was an enormous daily variability in PM10 concentration, among the daily mean value results, from the average of values, with a very high standard deviation (+30,+1000μg/m^3) and with various peaks; 3) prolonged follow-up for 3 years in this selected group of children didn't show any evident difference in the occurrence of clinically relevant respiratory diseases. On the basis of FeNO values, different degrees of respiratory function and bronchial inflammation were found in the 2 groups.

Traffic could be responsible at least in part for the different air quality, but individual susceptibility and seasonal changes are also major determinants of clinical outcomes. In particular, early exposure during the first years of life could be responsible for future diseases occurring later, during adult life.

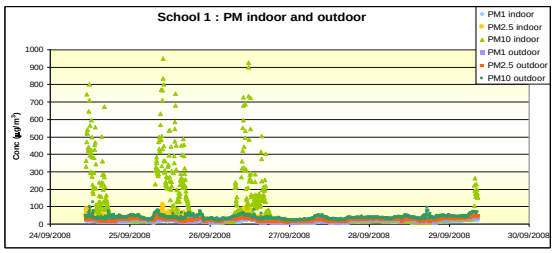

Figure 1. Concentration of PM10, indoor and outdoor, in School 1.

Environmental pollution, mainly due to urban traffic, is responsible for a different air quality in metropolitan areas vs less polluted sites and for a different incidence of respiratory complications and/or reduction of pulmonary function.

Methods: Two groups of 99 subjects were recruited (n=198), on a casual and voluntary basis: the former in Milan, Italy, i.e. a densely populated and polluted metropolitan area, the latter in Aprica, a remote alpine site (1181 m.a.s.l), with low pollution, due to traffic or other pollution sources. PM_{10} (<10 μm) and $PM_{2,5}$ (<2,5μm) were measured by PM detection units during two 2 week-campaigns. Each group was classified in 2 subgroups. The former, aged 30 to 64 y (n=72) , the latter over 65y (n=27). All subjects, well matched for cigarette smoke, sex and age were in good health conditions, asymptomatic and with no previous history of respiratory chronic diseases. All of them underwent spirometry, with evaluation of the following parameters: FVC (forced vital capacity), FEV_1 (forced expiratory volume in 1 second), PEF (peak expiratory flow) and MEF_{50} and MEF_{25}, i.e. maximum forced expiratory flow at 50% and 25% of FVC, respectively. In addition, the thiol redox status, which is crucial to balance oxidative stress and ROS generation, facilated by air pollution, was also evaluated in 2 subgroups of subjects,: the former (n=38, age 82±9y) living in Milan, and the latter (n=42, age 70±8y) living in Aprica. HPLC analysis was performed on blood samples for the evaluation of thiols in plasma and erythrocytes (total and reduced forms PT, PR; ET, ER) and also in exhaled breath concentrate (EBC). In fact, thiol redox status contributes to contrast oxidative stress and ROS generation promoted by air pollution. Namely cystein (Cys), cysteinylglycine (CG), homocysteine (Hcy) and glutathione (GSH) were evaluated both in blood and in EBC.

Results: FEV_1 was <80% in 20 out of 99 subjects in Milan (20,2%), whereas it was < 80% in only 8 out of 99 in Aprica (8,08%). Evident differences were also observed in subgroups of different age: FEV1 resulted <80% in 8 out of 72 subjects under 65 y in Milan (11,1%) and in 2 out of 72 in Aprica (2,8%); and in 12 out of 27 (44,4%) and 6 out of 27 (22,2%) in subjects over 65 y, respectively ($p<0,05$). Concerning thiol analysis, there was no evident difference in the GSH levels between the two populations. In fact, GSH alteration is usually a late event, occurring in severe imbalances and no subject in both groups had clinically evident diseases. On the contrary, PT Cys was 459,8 ±152,2 vs 286,3 ±74,8 ($p<0,001$) and ER Cys 2,5±0,8 vs 1,5 ±0,6 ($p<0,001$), respectively. Finally, data concerning thiol balance analysis from EBC showed: 1) a striking individual variability of the various chromatographic peaks; 2) almost complete absence of reduced species.

Conclusion: inhabitants of areas with different traffic volumes showed significantly different Cys, CG and Hcy levels, even if GSH remains unchanged, suggesting a greater- pro-oxidant effect in more exposed populations, affecting Cys, CG and Hcy levels, before GSH alterations. Analysis of thiol redox balance in plasma and erythrocytes is able to distinguish between more and less exposed subjects and could be a useful diagnostic tool for early detection of subjects at higher risk of health effects from environmental pollution. In particular, thiol analysis in EBC could be a very early marker of redox imbalance, and be used to detect early alterations in predisposed subjects. Air pollutants are weak pollutants, which at usual concentration in Western countries, in the absence of increased individual predisposition to respiratory or cardiovascular diseases do not determine clinically evident health effects after short-term exposure. In particular, PM related diseases are likely due to progressive accumulation of biological and tissue damage, because of oxidative stress and other injuries to human cells. Since most of biological alterations caused by PM exposure are likely to be reversible because of endogenous repair and defense mechanisms of the host, it is suggested that periodical interruption of chronic exposure to metropolitan pollutants with exposure to a better environment (such as an Alpine site), could be of benefit in all subjects with prolonged exposure to PM, namely in those with enhanced individual predisposition to develop clinically evident pollution related diseases.

A plea for a more "doubtful" and "skeptic" approach to the role of intrinsic toxicity of airborn pollutants as the main responsible for observed cardiovascular, respiratory and cancerous diseases or deaths in humans.

Presenting author email: luigi.allegra@unimi.it

Milan, Italy, is one of the most polluted metropolitan areas in Europe, mainly because of oro-metereological conditions, but also because of density of population, traffic, heating, industrial activities.
In Milan, Italy, between 2007 and 2010, a comprehensive approach to health effects of air pollution was designed (Prolife Project).
In particular, a comparison was made between daily pollutant concentration and hospital admission to 5 major city hospital because of respiratory and cardiovascular diseases during years 2007-2008. A total of 53.514 people were recruited. Only a very weak level of association ($p > 0.05$) was found between daily levels of PM10 and PM2.5, NOx and SO2 and acute admission within 48h because of upper respiratory tract diseases, Pneumonia, COPD exacerbation, Asthma, Heart failure, Acute myocardial infarction or Stroke. This weak association could mean that cases and controls were not properly selected. However, it could also mean that what we have supposed to be the causative agent was not, i.e. it could be simply a co-causal factor, or whatever else.

Even if pollutants are not "innocent bystanders" in the occurrence of cardiovascular, pulmonary or systemic diseases for which they are suspected to play a role, they are not likely to be the unique or main responsible for the occurrence of these diseases.

In fact, the evidence that "in vitro studies", or even clinical studies have shown that Particulate Matter (PM), or at least some components (diesel exhaust, PM2.5, ultrafine particles) were able to determine oxidative stress or trigger the occurrence of inflammatory mediators (cytokines, chemokines) is not enough to demonstrate that PM is able to determine, even after long-term exposure, evident diseases in every exposed subject.

In particular, we don't know yet whether the "pollution related disease" is a true toxic disease, i.e. due to the "intrinsic toxicity of xenobiotics", or their pathogenic potential, or a non toxic disease, i.e. a disease occurring mainly or exclusively in a few predisposed subjects, because of individual susceptibility and reactivity.

In other words, we have to clarify better whether the "pollution related disease" is a toxic disease, more similar to a viral or bacterial infection or, on the contrary, it is closer to an autoimmune disease. Autoimmune diseases are diseases in which individual susceptibility, either inherited or acquired, because of personal history and/or previous exposure, plays a major role. This could suggest that inflammation, and in particular autoinflammation, i.e. the peculiar host reactivity, plays a pathogenic role in the occurrence of the disease, and this role is greater than previously suspected and, in particular, greater than the role played by the intrinsic toxicity of the pollutant.

In the absence of an increased susceptibility of the host, it is likely that airborne pollutants are not going to be severely dangerous and "kill" people. In particular, a "weak level of association" in epidemiological studies means that: 1) airborne pollutants, at usual concentrations in western countries are "weak toxic"; 2) intrinsic toxicity perhaps is not the main pathogenic mechanism through which they determine their harmful activity; 3) autoimmune and autoinflammatory mechanisms could fit better and explain more convincely observed findings; 4) current models used in epidemiological studies to estimate risk potential are not adequate to capture the complexity of host-particle interaction; 5) better markers of exposure should be selected, but also more specific markers of effect, which in particular, should be able to capture different levels of molecular, cellular and tissutal damage; 6) a better definition of individual susceptibility, of its origin (genetical, inherited, but also partly determined by host-environment interaction and then acquired), is of paramount importance, as well as the distinct role that exposure to pollutants is going to determine during the perinatal susceptibility window, which is going to give "asynchronous" clinically evident consequences and determine diseases years or decades after exposure.

A major goal of future research will be the detection of sensitive and specific markers of individual susceptibility, which should facilitate the proper treatment and/or prevention of health effects of air pollution in susceptible people.
In conclusion, the lack of adequate metrics of exposure, effect and susceptibility in epidemiological studies evaluating PM concentration and health effects is one of the main responsible for the conflicting results of these studies .A plea for a more doubtful and "skeptic" approach is mandatory, when dealing with PM as unique responsible of presumed health effects simply because of its intrinsic toxic potential.

Deposition of aerosol particles in dosing tubes (endotracheal tubes) used in aerosol drugs therapy for infants.

Ł.Żywczyk[1], A.Moskal[2] and T.R.Sosnowski[3]

[1,2,3]Faculty of Chemical and Process Engineering, University of Technology, Warsaw, 00-645, Poland
Keywords: endotracheal tubes, aerosol therapy, deposition of aerosols.
Presenting author email: l.zywczyk@ichip.pw.edu.pl

Endotracheal tubes are commonly used to improve inhalation of aerosol drugs and keeping a steady transfer of air inspiration and expiration during an operation. Device is projected for patients of all ages. The shape and geometry of the tubes provide adequate penetration of the active ingredient into the respiratory tract, while ease the use of the device. In comparison to the parenteral method, the tubes connected with inhalators release increased dose of drug into the lungs. The tubes prevent from significant loss of drug in the upper airways during the treatment, therefore contribute to work more efficiently than other methods. Sizes of the tested tubes are presented in Table 1.

In this work, the penetration ratio of the particles in the endotracheal tubes has been calculated, which allows to calculate the dose of inhaled drug. The calculation has been proceeded in CFD (Computational Fluid Dynamics) FLUENT. Velocity profile has been extracted and deposition ratios of aerosol particles with different sizes were explored.

Table 1. Dimensions of the endotracheal tubes.

Tube denotation	Length (mm)	Diameter external OD (mm)	Diameter internal ID (mm)
516.30	68	4.6	3.0
520.25	165	4.1	2.5
520.30	165	4.6	3.0
520.35	165	5.2	3.5

Study

The aim of this study is to calculate penetration in four tubes with different geometric dimensions. During the calculations the tube was bent at an angle of 90 degrees. This corresponds to a real arrangement of the tube in the upper airway of a patient. The motion of the particles was modeled by Lagrange approach, with the use of DPM (Discrete Phase Model). The calculations were made for two values of air flow 3 l/min and 5 l/min, corresponding to a real air flow in infant's airways. Temperature of air 310K. Normal pressure was imposed at the inlet to the tube. The diameters of the tested particles were between 1 μm and 7 μm. Density of the particles 1.1 g/cm^3, this corresponds to densities of commonly used inhalation drugs. Mass flux of the particles at the inlet of the tube was $4 \cdot 10^{-6}$ kg/s. I the simulation the particles were affected by the gravity force. For particles considered with less than 2 μm, Brownian motion and Cunningham coefficient, were included.

In order to check the quality of the computer mesh, a measurement of the pressure drop of air for different values of air flow was performed for each tube diameter. The results showed convergence between the assumption in our model and a real pressure drop in laboratory, in the range of used flow.

The results

The penetration in the function of the aerosol particles size was obtained, determined by diameter of the tube and two values of air flows. The results show that independently of an air flow, for each tube size particles with diameter less than 2 μm will easily penetrate into lower airways and therefore are the main component of the rehabilitation fraction. Particles with diameter greater than 2 μm, will deposit on tube wall with various percentage. Previous results show that particles with 2 μm diameter penetrate the lungs (Annapragada, Mishchiy, 2007). Penetration into lower airways is more effective when 3 l/min value of air is imposed.

The results show the function of the distribution of particles sizes, which penetrate into lungs, therefore allow to estimate drug dose and predict effectiveness of the therapy.

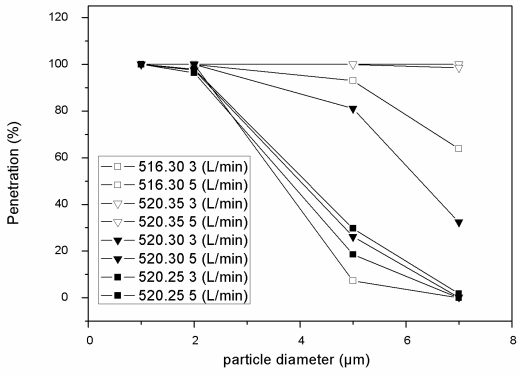

Figure 1.The penetration of the aerosol particles in the function of particle diameter.

The author would like to thank Ph.D. Jan Mazela for providing dosing tubes for experiment.

Keywords: PM, perinatal susceptibility, spirometric values, FeNO
Presenting author email: moltoni@unisi.it

In the present study, hospital admissions to the main pediatric service of Milan were compared with daily and seasonal variations in PM concentration, during 4 consecutive periods: winter/summer 2007, winter/summer 2008.

During 2007-2008, there were in total 440 pediatric admissions for respiratory diseases; 226 (132 M, 94 F) during the winter semester, and 214 (100 M, 114 F) during the summer semester. There were 12.7% asthma or asthma related admissions; 55.8% due to lower respiratory illness, and 31.5 % due to upper respiratory disease. The daily average of PM10 concentration during the 1st semester 2007 was 48.3+/-17.9 mcg/m^3. There were 107 (59.1%) days with at least one hospital admission. The mean daily concentration of PM was higher in days with (n=107) than without (n=74) hospital admissions (p=0.032 or <0.05). Accordingly, children acute admissions were significantly affected by pollution data, with increased admission during winter, namely for upper air tract infections, whereas lower tract inflammation and acute admission for asthma were more frequent during spring-summer.

Between 2007-2008, 228 children, older than 7 y, were enrolled from 2 primary schools, in order to study pollution related respiratory symptoms and/or diseases in different places of Milan with a different traffic-related exposure. The former (S1) was located near a large park, the latter downtown (S2). Daily levels of PM10 and PM2.5 were measured both outdoor (garden) and indoor (corridors) for 7 consecutive days during 2 different campaigns (winter and spring-summer). Children underwent skin prick testing for inhaled allergens, analysis of exhaled nitric oxid (FeNO) and spirometry. The distribution of FeNO values was significantly different (p=0,02) between the two schools: the percentage of children with FeNO values <5ppb was almost double in S1; FeNO was 5- 20ppb in 73% of children from S2. The percentage of asthma exacerbations (previous 12 months) was higher in S2 (p=0.05). The prevalence of persistent allergic rhinitis in children allergic to grass pollen was higher in S1 (p=0.03), the latter children also had a greater activity limitation, due to rhinitis and concomitant conjunctivitis (p=0.03).

It is suggested that: 1) newborn exposure could be one of the most relevant pathogenetic effect of "weak pollutants, with low intrinsic toxicity", as air pollutants actually are at usual concentration in the atmosphere. 2) epidemiological studies evaluating concomitantly pollutant concentration and detectable diseases or hospital admissions usually miss this perinatal damage in foetuses and newborns, not immediately detectable, but is a delayed manifestation. Perinatal damage from air pollution deserves further attention, because it not only includes fetal malformations, birth defects or developmental alterations, but could also be responsible for the increased proportion of individuals who, because of the exposure to pollutants during the "perinatal susceptibility window", and because of epigenetic alterations, due to environmental factors, will turn from previously "unsusceptible" into "susceptible" individuals. The latter could also transfer this susceptibility to future generations, and develop not only asthma at age 4, but also respiratory, cardiovascular or systemic diseases, 20 or 40 y later; 3) since peculiar pathophysiological mechanisms based on individual susceptibility play a major role in the occurrence of pollution related diseases, it is necessary to improve current epidemiological models, adding pathophysiological variables, which could account for tissutal damage, duration and type of exposure, or susceptibility markers. Not only a better knowledge of the "particle side" of the interaction is required, but also a deeper insight into cause and effect relationships and pathophysiologic mechanisms or pathways, i.e. a deeper understanding of the "host side" of the host-particle interaction. A critical re-evaluation could open new avenues, including the design of new models, in which the increasing role of host reactivity is better "weighed", and the possibility that autoimmune or inflammation related mechanisms, instead of purely toxic ones, could be more "fit" to explain clinical outcomes should be carefully evaluated.

The "harmful potential" of PM, evaluated "in vitro" must be used with a great causation as a surrogate for risk assessment in humans

J. Martellucci[1], F Cetta[1] ,V. Guercio[1], L. Moltoni[1], N. Nante[2], R. Messina[2], M. Monti[3] and E. Bolzacchini[4]

Keywords: risk assessment, PM, intrinsic toxicity, individual susceptibility
Presenting author email: jamjac64@hotmail.com

The aim of the study has been to detect new tools, which could be useful for a risk assessment in humans of the possible effects of air pollutants, on the basis of *"in vitro"* studies of host-particle interactions.

Methods: the BEAS-2B (human bronchial epithelial cell-line) and the A549 (human alveolar epithelial cell), but also sperm cells and synoviocytes from humans with rheumatoid arthritis (RA) and osteoarthrosis (OA), were treated after 24-48h with both summer and winter PM_{10} and $PM_{2.5}$ sampled in Milan, Italy. Therefore, either human beings or cell-lines were exposed to the same pollutants and a cross comparison of observed effects, both clinical and *"in vitro"*, could be performed.

Results: A549 cell viability wasn't significantly reduced after summer and winter PM exposure, and summer PM had no significant effects on BEAS-2B viability. Winter PM treatment induced a decrease in cell viability, at the dose of 25 and 50 mcg/cm^2. Moreover, winter PM_{10} induced a 5-fold increase in IL-8 release in treated cells, and summer PM_{10} induced a 20-fold increase in IL-8 expression. BEAS-2B resulted more responsive to PM treatment than A549. Short- term clinical effects in Milan were not related to PM daily concentration.

Comment: "In vitro" studies confirm potential toxicity of PM, but these studies can't be used for clear-cut inferences to humans. In fact, in terms of health or biological effects, one thing is to inhale by breathing diluted particles in a concentration equivalent to the one that can be introduced with a single breath in 1sec and another is to incubate, with a cell line of alveolar cells, particles deposited on filters, which contain aggregated and concentrated particles, that correspond to 60sec x 60min x 24h, i.e. 8640 folds the portion inhaled by a single breath. In particular, in humans each quantity can be partly eliminated, and only partly can rich the alveolar area. In addition, the final response of the human being includes not only the cellular and molecular response, but also includes the response of the "entire organism", which is controlled by volunty and by the central nervous system. In particular, there are 2 main differences between *"in vitro"* and in humans studies: 1)the human being gives not only biological, but also chemical and mechanical responses, which are able to eliminate completely inhaled particles; 2)the model used in analyzing host-particle interactions postulates a dose and effect linearity, whereas observed outcomes in humans show a "no threshold" behaviour. In other words, in humans the prevalent mechanism couldn't be the pure toxic one, i.e. related to the intrinsic toxicity of the pollutants, but a different one. Therefore, whereas in this study a toxic dose related mechanism is postulated, i.e. the greater the dose, the greater the health effect detectable, in humans the causative mechanism is likely different. Anyway, the present approach shows some strengths: by using an immortalized cell line, always the same, we set ideal conditions to evaluate against the same standard variable concentrations of pollutants, length of exposure, mixture composition, possible relevance of differences in "source apportionment" and seasonal variations. Therefore it's possible to detect the response from the same host or different hosts to different "trigger" stimuli. The "harmful potential" includes various types of alterations: inflammation, or cell-cycle perturbation, with cellular death or genetic mutations and then cell transformation. Therefore, the "*in vitro*" models, even if not immediately extensible to humans, may represent a surrogate for the experimental animal, in order to evaluate quantitatively parameters such as: inflammogenicity, mutagenicity, cell cycle alterations. The use of different cell lines and human samples, with different responses, has shown the great importance, not only of the intrinsic toxicity of the toxic agent, but also of the different type of targeted cell in triggering a different response. These differences- related to host response and individual susceptibility- can be one of the possible explanation for the "no threshold phenomenon" and for the inadequacy of the "pure" toxic model, characterized by dose and effect linearity, to capture the complexity of host-particle interactions. At the moment we must frankly admit that an adequate model of risk evaluation- applicable to human health- isn't available, mainly because of the persistent lack of knowledge, concerning pathogenetic and pathophysiological mechanisms, which are responsible for clinical outcomes in humans. Anyway, in an ideal model, 2 different components should be distinguished: the particle-related component and the host-related one, even if we don't know yet the relative importance of each component.

The response of PM concentrations in the UK to changes in industrial and agricultural emissions: implications for the exceedance of Air Quality Standards

E. Nemitz[1], M. Vieno[1, 2], U. Dragosits[1], C.F. Di Marco[1], M. Twigg[1,2] and M.A. Sutton[1]

Keywords: Abatement strategies, air quality, PM (general), ammonium nitrate, ammonium sulphate, precursors, inorganics, chemical transport model

Presenting author email: en@ceh.ac.uk

In the UK, secondary organic ammonium (NH_4^+) salts, formed from the reaction of ammonia (NH_3) with the oxidation products of sulphur dioxide (SO_2) and nitrogen oxides (NO_x), typically account for 20-40% of the $PM_{2.5}$ and 10-30% of the PM_{10}. With increasingly more reliable chemically speciated aerosol data becoming available, it is becoming clear that nitrate (NO_3^-) is a larger contributor than sulphate (SO_4^{2-}) and that it is particularly associated with pollution episodes during which the Air Quality Standards for PM are exceeded (Charron et al., 2006; Harrison et al., 1997). Nitrate formation is favoured by the relatively high emissions of NH_3 from agricultural activity, coupled with a cool humid climate. By contrast, SO_2 emissions have decreased by >80% over the past 15 years.

In this study we are using a high resolution version of the EMEP chemical transport model (EMEP4UK) (Vieno et al., 2010) to predict annual time-series of NH_4^+, NO_3^- and SO_4^{2-} for a number of urban locations, which are analysed in the context of measured PM concentrations.

The skill of the model in predicting NH_4NO_3 concentrations and their response to precursor gas concentrations has been carefully assessed by comparison of long-term trends and hourly variability against data from a number of sources, including: (a) a UK network that measures monthly gas and aerosol concentrations at 33 sites with a denuder / filter-pack sampler (UKEAP), (b) long-term measurements of aerosol composition at the UK EMEP Supersites 'Auchencorth' and 'Harwell' using a MARGA wet-chemistry analyser and (c) campaign-based measurements by Aerosol Mass Spectrometry (AMS) (Nemitz et al., 2011), including measurements in London (Allan et al., 2010).

Model simulations were then performed for several emissions scenarios: experiments were emissions were perturbed within and outside the UK, future emissions predictions, and scenarios in which different levels of agricultural NH_3 abatement (BAT) have been implemented.

Figure 1 compares the model predictions of monthly fine and total nitrate against a Scottish UKEAP measurement site, based on runs of full emissions and only non-UK emissions, showing that a long-term high nitrate event in spring 2003 represented mainly fine nitrate which was formed partly from UK and partly from non-UK precursor gases.

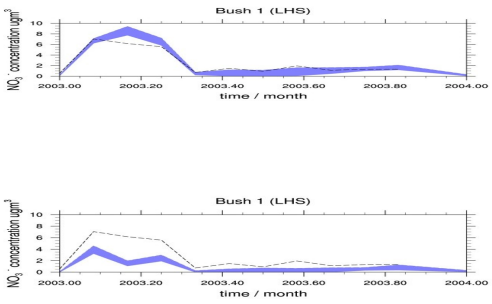

Figure 1. Nitrate monthly surface concentration at the Bush UKEAP site. The dashed line represents the observed nitrate concentration the blue shaded region represents the EMEP4UK model predicted range of fine nitrate (lower boundary) and total nitrate (upper boundary), with the thickness of the shaded area showing the predicted concentration of coarse nitrate. Top graph shows the base run, whereas the bottom graph represents a model run where UK emissions of precursor gases have been removed.

Modelling the effect of variable air exchange rates on indoor aerosol concentrations

James McGrath[1], Miriam Byrne[1], Mike Ashmore[2], Andrew Terry[2] and Sani Dimitroulopoulou[3]

[1] Centre for Climate and Air pollution Studies (C-CAPS), School of Physics, National University of Ireland Galway. Galway.

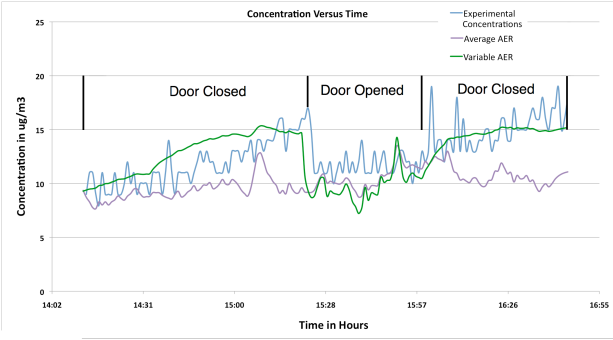
This abstract highlights recent enhancements made to the INDAIR model; INDAIR (Dimitroulopoulou et al., 2006) is an advanced probabilistic modelling tool which can simulate the physical processes determining indoor pollutant concentrations as a function of outdoor concentrations, indoor emission rates and building characteristics. It can simulate the upper percentiles of a population's exposure to air pollutants, or the proportion of the population exposed to concentrations above critical health thresholds.

In simulating indoor aerosol concentration variations, INDAIR makes use of indoor/outdoor air exchange rates (AERs) and inter-room air exchange rates as input parameters. The earlier version of the model uses a 24-hour averaged value for AER, but this approach hides the effect of fluctuations due to variable weather conditions, or door/window opening.. To redress this, the model has now been modified to allow for a variation in AER rates. The new modelling approach uses a text input file, allowing the user to enter start and stop times and the corresponding AER values. This allows the AER to be set to a specific time frame or even allows change on a step-by-step basis if necessary, depending on the requirements.

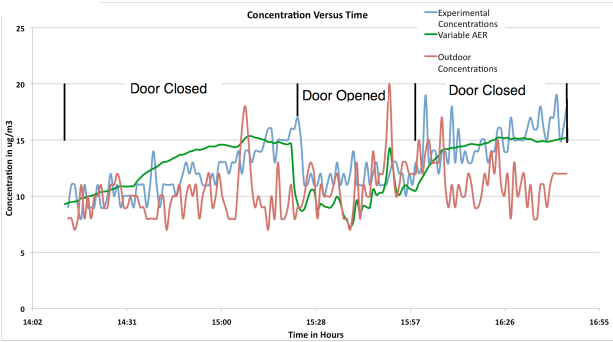
A validation of the improved model has been carried out by monitoring simultaneous indoor and outdoor concentrations of $PM_{2.5}$, using a TSI AM510 Aerosol Monitor. The AER values for a room of dimensions 3.58 m x 4.36 m x 2.67 m (height) were determined (by CO_2 tracer gas decay measurement) under two different scenarios; one where the door was open (AER = 6.227 air changes per hour (ACH))and the second where the door was closed (0.517 ACH). A fixed emission source – a burning candle- was used to help evaluate the concentrations in the room, and to more clearly demonstrate the effect of the change in ventilation. The candle was lit just prior to sampling and remained lighting for the duration of the experiment.

Using the data gathered, the model was run in its traditional format with a fixed AER (mean value 3.002 ACH) and for comparison, with a variable AER, all other input parameters remaining constant.

Graph 1. Measured and simulated particle concentrations for the traditional model with a fixed AER and for comparison, with a variable AER.



Graph 2. Measured indoor concentrations, outdoor concentrations and simulated particle concentrations using the improved INDAIR model in combination .



Conclusion

Overall, it can be seen that the enhancement of using a variable AER in the model shows a better performance than the simulation using a mean AER over the time period. In the enhanced version of the INDAIR model, simulated PM concentrations follow more accurately the approximate profile of the experimental concentrations than the traditional model. This is most evident when the doors are closed, with the reduce air flow, the emissions result in higher PM concentrations in the room which the traditional model under-predicted.

Artificial lung as an alternative for measurement pulmonary deposition *in vivo*.

A.B. Penconek and A. Moskal

Department of Chemical and Process Engineering, Warsaw University of Technology, Warsaw, 00-645, Poland
Keywords: lung deposition, laboratory experiments, pulmonary drug deliver
Presenting author email: a.penconek@ichip.pw.edu.pl

Pulmonary deposition of aerosol particles is an important part of toxicological, epidemiological, medical supplies, especially pharmaceuticals including aerosol-therapy. In the case of drugs administered by inhalation the main way to determine the depth of penetration of the respiratory system *in vivo* is radioisotope labelling of the drug particles by technetium ^{99m}Tc (half-life 6 h). Tc is not harmful to human health but application of this method is controversial, especially in the case of testing newborns or children. The aim of our study was to create a device which enables the precise determination of the deposition of aerosol particles in the bronchial tree. The device allows to determined deposition of inhaled drugs, but also diesel exhaust particles or microbiological particles, without using radiolabelling and *in vivo* methods.

The "Artificial lung" is a set of devices where airflow simulating inhalation and exhalation, is generated by deliberately produces pressure difference (between atmospheric pressure and pulmonary pressure) in a manner most similar to the flow of air in the mammalian lung (Figure 1). The airflow (Q), which is generated, could be described in general approximately by following equation Q=Asin(Bt) (where A, B – proper constants, t – time). This equation was obtained based on analysis of real breathing curves derived from measurements of spirometric.

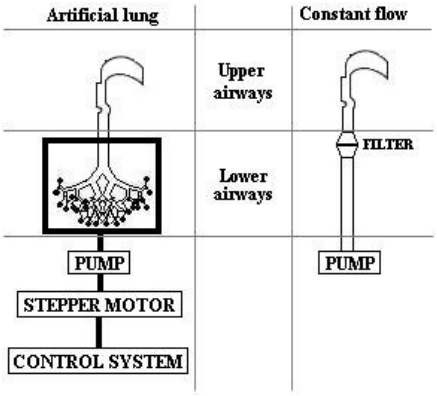

Figure 1. Diagram of measuring system.

Silicone model of the upper airways was developed on the basis of data computed tomography scans and magnetic resonance imaging (Grgic *et al*, 2004). Silicon model of the lower airways was developed on the basis on anatomical data (Weibel, 1963). Pure micronized disodium cromoglycate (*GlaxoSmithKline Pharmaceuticals SA)* was selected as the test material, since it is a drug of common use to treat chronic asthma in children. DSCG (60 ± 7 mg) was contained in gelatine capsule and sprayed in the model of respiratory track using a Cyclohaler DPI. The results were compared with the DSCG deposition in the airways at constant flow (60 l/min) after 4 s time of inhalation. Deposition was determined spectrophotometrically at 340 nm against water as a reference sample.

The results obtained are shown in Figure 2 a, b.

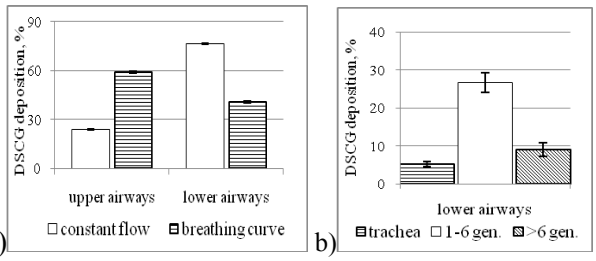

Figure 2. a) Comparison of DSCG deposition in airways for constant flow (60 l/min) and breathing curve (n=3). b) Comparison of DSCG deposition in different parts of lower airways (n=3).

DSCG penetrated beyond 6th generation, represents 9% of taken dose during quite breathing (volume of peak flow 111 l/min). While *In vivo* pulmonary deposition of DSCG (with lactose carrier) are 5,5% (range 1,6%-9,7%) and 17,1% (range 7,8%-28,3%) for flow rate at 60 l/min and 120 l/min respectively (Vidgren *et al*, 1988). Thus our studies are in good relation to *in vivo* studies. However DSCG used in our study did not contain carrier substances which may lead to reduced pulmonary deposition due to cohesion forces between drug particles. It should be noted that study of deposition for constant flow did not produce results corresponding to reality.

Our "Artificial lung" could be successfully used to study the deposition of drugs administered by inhalation, thereby reducing the need for radioisotope. At the same time "Artificial lung" could be used to determine the rate of penetration of the respiratory track harmful particles from polluted environment. This may cause methodological and ethical problems in case of *in vivo* methods.

We would like to thank Mrs Nguyen Q. Huong for making the part of the measurements.

Respiratory airflow in human upper airways

J. Elcner, F. Lizal, M. Forman, J. Jedelsky and M. Jicha

Department of Thermodynamics and Environmental Engineering, Brno University of Technology, Brno, 616 69, Czech Republic
Keywords: Lung, Airflow, PDPA, CFD.
Presenting author email: yelcne00@stud.fme.vutbr.cz

Understanding to airflow during respiratory cycle is prerequisite for assessment of aerosol deposition in upper airways. Respiratory cycle consists of inspiration and expiration phases and its course is imitated by sine-wave function. Our lung model is composite of the larynx, trachea and four generations of branching. Test rig capable to simulate different breathing cycles allowed us to make airflow measurements and compare them with numerical simulation.

Experiment

Phase Doppler Particle Analyser (PDPA) was used for measurements of velocity and diameter of aerosol particles in a realistic optically transparent model, Lizal *et al* (2010). This 1D PDPA system is equipped with Ar-Ion+ Laser ILT 5500A-00. Spectral line 514.5 nm of the CW laser beam with power up to 90 mW and horizontal polarization is split using transmitting optics 58N10 into 2 parallel beams 60 mm distant. Frequency of one of the beams is shifted by 40 MHz. Beam diameter is expanded to 2.5 mm to reduce a probe volume. The transmitting lens focal length is 310 mm. Light refracted by the 1st order is collected using receiving optics 57X10 equipped with three photo-detectors. Focal length of receiving lens is 310 mm and scattering angle 45° used. Signal processor Dantec 58N50 enabled measurement of velocity in range -8 to 24 m/s at 12 MHz bandwidth and in range -2.7 to 8.0 m/s at 4 MHz bandwidth. Maximum droplet size is 44.9 μm. The obtained data are evaluated using BSA Flow Software v2.1.
The test rig consists of the model located in a frame that is attached to the traversing mechanism. Elastic bag is connected to the model input to prevent leakage of aerosol into the environment, and to ensure enough aerosol for both phases of breathing cycle. Aerosol produced by condensation monodisperse aerosol generator (CMAG) is mixed in a static mixer with air from a pneumatic mechanism, which simulates breathing patterns. PDPA measures velocity and size of the aerosol particles.

Table 1. Breathing cycles measured by PDPA

Activity	Tidal volume V_t (l)	Period T (s)	Mean flowrate (l/min)
Resting conditions	0.5	4	15
Deep breathing	1.0	4	30
Light activity	1.5	3	60

Numerical simulation

Polyhedral mesh with prismatic layer with approximately 400,000 cells was generated for the purpose of numerical simulation. Calculations were performed using StarCCM+ program. Unsteady RANS solver with k-omega turbulence model was used. Velocity inlet condition prescribed by time-dependent equation, which simulates the breathing cycle, was set on the input to the model and pressure outlet condition was set at the end of branches.

Results

Comparison of measured and calculated values was made in 16 cross-sections in all generations of the model containing 43 points in total. Figure 1 shows results for resting conditions in axis of trachea 2 cm upstream the first branch.

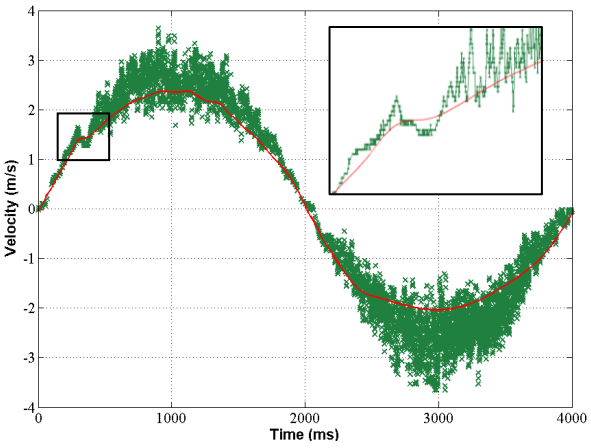

Figure 1. Comparison between experimental and numerical data for resting conditions in trachea.

Development of a Setup for the Purpose of Respiratory Research and Aerosol Deposition in the Lung Using a Novel Active Lung Simulator

M. Forjan[1], K. Stiglbrunner[1], A. Drauschke[1]

[1]Department of Life Science Technologies, University of Applied Sciences - Technikum Wien, Vienna, 1200, Austria

Keywords: aerosol generation, aerosol measurement, lung deposition, modelling, active lung simulator.
Presenting author email: mathias.forjan@technikum-wien.at

Due to the importance of respiratory research in the field of aerosol measurement (for respirable dust, smoke, or nano-particles) a novel active lung simulator represents an ex vivo system for testing respirable substances. The 3R-strategy by Russell and Burch (1959) laid the basis for a philosophy of alternatives to animal models. Further development of mechanical and mathematical lung models becomes even more important due to legal restraints like the Cosmetics Directive (European Commission (1976)). The presented lung simulator with integrated aerosol measurement allows the observation of particle behaviour within the respiratory tract, with fewer legal limitations, because in this case no harmful substances are used on humans or animal models.

Materials & Methods

As core element of the experimental setup a novel lung simulator is used as Stiglbrunner *et al.* (2010) have described. This model allows the simulation of an active, spontaneously breathing human lung. Moreover the device offers both physiological and pathological breathing patterns. An implemented chamber imitates the human thorax and is set under negative pressure. The device allows the use of different lung equivalents, like a latex bag, a primed porcine-, or isolated lung. The created flexible design opens a wide spectrum of possible experimental setups.

For the measurement of the in- and exhaled particles a white light aerosol spectrometer was chosen. In specific, a Promo spectrometer and a Welas 2200 sensor are used, both by Palas GmbH. The measuring range of the Welas 2200 sensor lies in the range of 0.2µm-40µm. This range covers the size spectrum of note, including "inhalable" but also "respirable" aerosols, reaching the lung's alveolar region, like Ruzer and Harley (2005) state. The sensor-spectrometer system by Palas has been chosen, because it allows non-isovolumetric and non filtered sampling.

As this sensor - spectrometer combination permits the use of a broad range of aerosol diameters, different aerosol generators can be used for simulations. Both, monodisperse and polydisperse aerosols can be applied to the breathing lung equivalent.

For programming the GUI and for data acquisition LabView is used. Apart from the implementation of data transfer protocols given by the used spectrometer, the program for the control of the lung simulator is integrated into the system.

Results

The transport of the aerosols is arranged by a horizontal pipe from the generator towards a suction unit. The number concentration can be adjusted by using an additional dry-air inlet. At a T-junction a tube connects the constant aerosol stream with the lung simulator. The lung inhales a volume taken from the aerosol, and exhales into the same pipe, each time passing the sensor.

For the test setting the AGF 2.0 generator by Palas GmbH is used, which is based on a two-fluid-nozzle. This generator produces polydisperse aerosols with a mean diameter of 0.25µm and a maximal diameter of 2.0µm. The aerosol material applied, was DEHS (Di-2-Ethylhexyl-Sebacat). This combination offers a "respirable" aerosol without the risk of hygroscopic behaviour.

Discussion

The experimental setup allows the observation of in- and exhalation processes of a lung equivalent, which will offer an alternative for animal testing, going along with the idea of the 3R-strategy.

Using polydisperse aerosols as first test setting shows results of the degree of separation, but for further research additional measurements applying typical aerosols have to be completed. Such settings can include generators for monodisperse aerosols, like a Sinclair - LaMer generator.

A planned further development will include the use of fresh slaughterhouse ex vivo porcine lungs in order to approximate to realistic anatomical and physiological conditions of the human lung.

We want to thank Leander Mölter, Maximilian Weiss and Fritz Munzinger (Palas GmbH) for their support and cooperation.

Numerical simulation of aerosol deposition and clearance in the large bronchial airways

Á. Farkas[1], I. Balásházy[1], A. Nagy[2]

[1]Health and Environmental Physics Department, Hungarian Academy of Sciences KFKI Atomic Energy Research Institute, 1121 Budapest, Konkoly Thege M. út 29-33, Hungary

Presenting author email: anagy@szfki.hu

Introduction

Knowledge of particle transport and deposition within the airways is important for the assessment of the health effects associated with inhalation of detrimental or therapeutic aerosols. However, mucociliary clearance can modify the primary particle deposition patterns, influencing the particle-tissue interactions and ultimately the health effects of the deposited aerosols. Therefore, simultaneous study of particle deposition and clearance in airways represents a step forward in the elucidation of the health consequences of inhaled aerosols.

In vitro and *in vivo* inhalation and clearance studies have either technical limits or ethical barriers. In these circumstances computational modelling can be a useful tool in revealing the relationships between breathing parameters, aerosol characteristics and airway deposition-clearance patterns. Numerical models can determine the exact trajectories of particles within the airways and thus the locations of their depositions. In addition, numerical methods allow us to model the movement of mucus layer and track the deposited particles transported by the mucus.

The objective of this study was to simulate the coexisting airway deposition and clearance of the inhaled particles characterised by various aerodynamic diameters assuming different breathing modes.

Methods

In this work, state of the art CFPD (computational fluid and particle dynamics) techniques were used to quantify the deposition and clearance of inhaled aerosols in the large bronchial airways. For this purpose the FLUENT CFD code was used. A discrete phase modelling (DPM) technique was applied to track the individual particles in the computed flow fields of air and mucus. Residence time distributions were computed for particles upcleared from the deeper airways and entering a 4^{th}-5^{th} generation model bronchial bifurcation. Modification of deposition patterns as a result of mucociliary clearance was also investigated.

Results

Present computations revealed that while primary deposition patterns are highly sensitive to the particle size, particle clearance is hardly affected by this parameter in the micron-size range. Our simulations demonstrated the existence of a slow clearance area in the vicinity of the peak of the bifurcation. The residence times of the upclearing particles depend on whether they avoid this slow clearance zone or not. Primary deposition patterns are significantly modified by clearance. The high particle accumulation at the bifurcation region (carina), primarily due to impaction, corroborated by a slow clearance area at the same site explains the high frequency of tumours at these locations caused by inhaled carcinogenic aerosols, as reported in early histological studies.

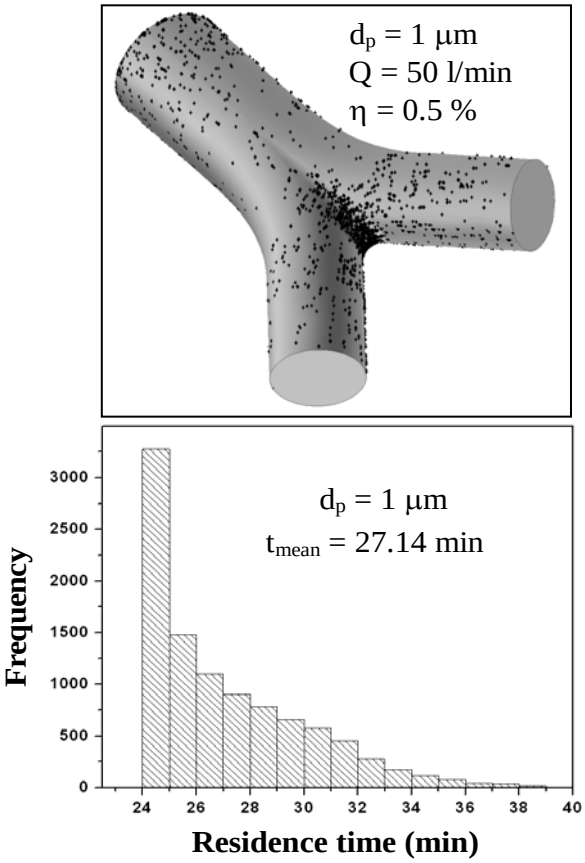

Figure 1. Deposition pattern of 1 μm inhaled particles in the 4^{th}-5^{th} bronchial airway generations assuming breathing conditions characteristic of light physical exercise (upper panel) and residence time distributions of 1 μm upcleared particles in the same airway segment (bottom panel). d_p - particle diameter; Q - flow rate; η - deposition efficiency, t_{mean} – mean residence time.

Regional lung deposition of tobacco smoke constituents

J.McAughey[1] and C. Dickens[1]

[1]British American Tobacco, Group R&D Centre, Southampton, SO15 8TL, UK

Keywords: tobacco smoke, deposition, dosimetry.
Presenting author email: john_mcaughey@bat.com

Tobacco smoke is a complex dynamic aerosol suspended in an equally complex vapour cloud, and is a significant elective source of inhaled particles in the population, despite it being a recognized cause of disease. However, little is known of the regional deposition of smoke and local micro-dosimetry from both its vapour and particle phase constituents. Such data offer context to better understand biologically effective dose and potential modes of action of disease initiation, both in model disease systems and populations.

Measured mass deposition efficiencies of the order of 60-80% for particle species are significantly greater than modelled deposition estimates of 30-40% (Baker & Dixon, 2006). Many authors have suggested that the smoke particles must grow significantly to super-micron diameters, to explain observed patterns of disease in the conducting airways, by a combination of coagulation, hygroscopicity, condensation, and colligative 'cloud-like' behaviour (e.g. Robinson, 2001, Broday, 2003). Others have suggested evaporative losses with increased pulmonary deposition of the smaller residual particles by diffusion (Ingebrethsen, 2006, Kane, 2010).

In this work, a series of measurement tools have been developed to assess deposition by direct measurement of exhaled particles and vapour by electrical mobility spectrometry and selective photo-ionisation time-of-flight mass spectrometry respectively. Measured smoking patterns are then replicated to produce intake estimates with deposition calculated by difference.

In addition, hybrid Computational Fluid Dynamic – Pharmacologically Based Pharmacokinetic models (CFD-PBPK) have been developed to assess local deposition in the upper airways and subsequent systemic uptake; initially for volatile aldehyde species.

Soluble vapour species such as acetaldehyde and acrolein show near 100% retention from modelling and measurement data but particle deposition is significantly lower and related principally to inhalation depth and inhalation cycle time. Particle diameter may also have a role but this may be better reflected by a modified diameter reflecting ageing in the mouth, principally via coagulation, rather than the diameter of fresh smoke. However, consideration of all ageing and growth / evaporation processes of the smoke predict it will remain sub-micron and this is confirmed by size measurements of volume- weighted median diameters of approximately 250 – 350 nm for exhaled smoke.

Thus, a majority of particle mass deposition is calculated to occur in the deep lung via diffusion. However, higher local airway particle and vapour doses occur in the upper airways driven by the smaller surface areas available for deposition. Calculated regional values for particle (tar) deposition as ng.cm^2 of lung surface (per mg tar delivered by the cigarette) are 409 (ET – extra-thoracic), 45 (BB – bronchial), 4.8 (bb – bronchiolar) and 0.1 (AI – alveolar). Transformations of size and concentration data allow equivalent number and surface-area weighted regional deposition to be calculated.

In conclusion, new insight has been gained into local dosimetry of tobacco smoke constituents in the lung through measurement and modelling. Both soluble vapour and particle deposition are driven principally by diffusion processes. Local dose remains highest in the upper airways through the relatively smaller airway surface available for deposition.

Further refinement of deposition and CFD-PBPK models will offer an improved approach to quantitative risk assessment. This will derive from the provision of improved relative dose assessment for *in vitro* models of disease applied to smoke exposure and the a combined dosimetric and mechanistic approach to assessing the impact of technologies designed to reduce selective toxicant dose from smoke.

Implementation of morphometric mouse lung data into a stochastic deposition model

P. Madl, R. Winkler-Heil and W. Hofmann

Department of Materials Research and Physics, University of Salzburg, 5020 Salzburg, Austria
Keywords: mouse lung morphology, particle deposition, modelling.
Presenting author email: pierre.madl@sbg.ac.at

The laboratory mouse is often used as a human surrogate in aerosol inhalation studies. The proposed simulation for aerosol inhalation and deposition calculations represents a significant step forward by reducing animal studies and at the same time speeding up predictions in deposition of particles with a given size.

Due to the lobar anatomical structure of mice lungs that nicely reflect observed differences in bronchial anatomy between different lobes of individual lungs along with intrasubject variability of airway dimensions within a given lobe, makes it possible to construct random airway geometries for Monte Carlo deposition calculations that ultimately enables extrapolation modeling of mouse deposition data to man. Here we present preliminary results of the implementation of morphometric lung data obtained from transgenic mice (Balb/c) into the stochastic lung deposition model originally developed for the rat (Koblinger and Hofmann, 1995).

As a consequence of the more monopodial airway branching in the mouse lung compared to the more dichotomous structure of the human lung, Madl et al. (2010) recommended classifying the mouse lung airways by their diameters and not by generation numbers. The distributions of the geometric airway parameters and the correlations among them are used to confirm the predictions made of Monte Carlo deposition calculations.

Implementation of morphometric mouse data is carried out in two steps. Due to the similarity between the rat and mouse bronchial airway structures, the first approach utilizes an existing rat lung model (Koblinger and Hofmann, 1995) in which relevant morphometric and respiratory parameters are downscaled to mouse size. The second approach applies then real bronchial morphometric data of Balb/c mice (Oldham et al., 2007), such as airway dimensions, termination probabilities and branching as well as gravity angles.

For the acinar region of the mouse, hardly any data can be found in the open literature, except for alveolar diameters and their numbers. Thus in the present version of the deposition model, acinar airway dimensions are downscaled to mouse size, assuming again similarity among mouse and rat acinar structures.

Table 1 summarizes total lung deposition fractions of monodisperse unit density aerosols with three different particle diameters at 25 ml minute ventilation, excluding extrathoracic deposition. The table also lists experimentally obtained deposition fractions (Oldham et al., 2009). Given the preliminary status of the deposition calculations, theoretical predictions for the mouse agree favorably with the experimental evidence.

Table 1. Comparison of total deposition fractions between various computer simulations.

	Diameter	0.5 [µm]	1 [µm]	2 [µm]
depos.[%]	Rat	18.2	20.5	53.5
	Scaled Rat	40.2	45.6	57.4
	Mouse	59.0	71.8	80.0
	Mouse (Exp.)	74.6	72.7	68.8

The distribution of total deposition fractions among bronchial and acinar mouse generations of the Balb/c mouse is illustrated in Figure 1 for 1-µm unit density particles. In contrast to the human lung, the majority of particles are deposited in bronchial generations, exhibiting a distinct peak in generations 6-8.

Although current mouse deposition fractions are still of a preliminary nature – as the code will be further refined – deposition calculations represent a promising tool for the extrapolation of beneficial effects of therapeutic aerosols in humans based on experimental data in mice.

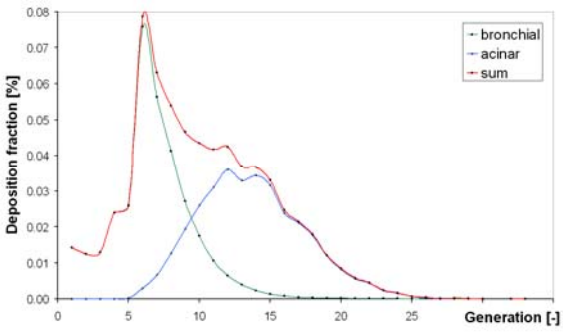

Figure 1. Deposition fractions for a monodisperse aerosol (1 µm) of the Balb/c mouse lung, excluding extrathoracic deposition.

Comparison of stochastic particle lung deposition predictions with experimental data

M.Hussain[1,2] and W. Hofmann[1]

[1]Division of Physics and Biophysics, University of Salzburg, 5020, Salzburg, Austria
[2] Higher Education Commission of Pakistan, 44000, Islamabad, Pakistan
Keywords: lung deposition, experimental, modelling, comparison
Presenting author email: majid.hussain@stud.sbg.ac.at

Deposition fractions predicted by different modelling techniques vary with respect to physical (fluid dynamics of the inhaled air) and biological (lung morphology and respiratory physiology) factors and mathematical modelling technique. Therefore it is always needed to validate the modelling deposition perfection with that of experimental data.

Experimental data on deposition in individual airway generations and lung regions are now becoming available through the application modern techniques (Fleming et al. 2006; Kim et al. 2005-06). Similarly experimental deposition data supplied by deposition studies in surrogate airway models or lung casts (Cohen et al. 1990; Smith et al. 2001) are available for comparison purposes. The purpose of the current study was to compare the experimental measurements with the stochastic modelling predictions using Monte Carlo deposition code IDEAL (Hofmann & Koblinger, 1990) on three levels: (i) deposition per generation (up to 7 generations) (ii) regional deposition; and (iii) total deposition.

In comparison experimental measurements in generations by Smith et al. (1990) were found to be up to 2 times higher than stochastic model predictions for ultrafine particles (see Figure 1). However, comparatively better agreement was found for regional deposition with the studies of Fleming et al. (2006) (see Table 1). The total deposition fraction of Fleming et al. (2006) study is about a factor of 1.5 higher than IDEAL predictions primarily due to their higher alveolar deposition measurements.

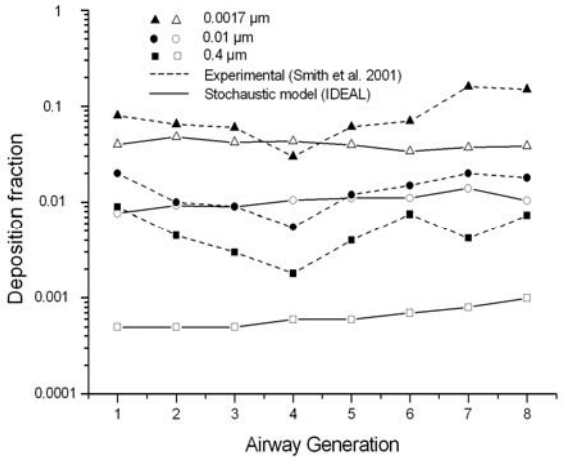

Figure 1. Deposition fraction up to generation 7 for different particle sizes at flow rate of 20 L min^{-1}.

Table 1. Deposition fractions for fine and coarse particle sizes (1.8 and 6.5 µm respectively) predicted by IDEAL code and experimental studies.

Lung regions	Fine particles		Coarse particles	
	IDEAL	Experiment	IDEAL	Experiment
ET	0.03	0.04	0.22	0.27
BB	0.02	0.04	0.12	0.07
bb	0.02	0.05	0.15	0.05
Al	0.20	0.54	0.13	0.41

Comparisons of total deposition predictions by IDEAL are found in excellent agreement with the experimental data of Kim et al. (2005-6) (see Figure 2).

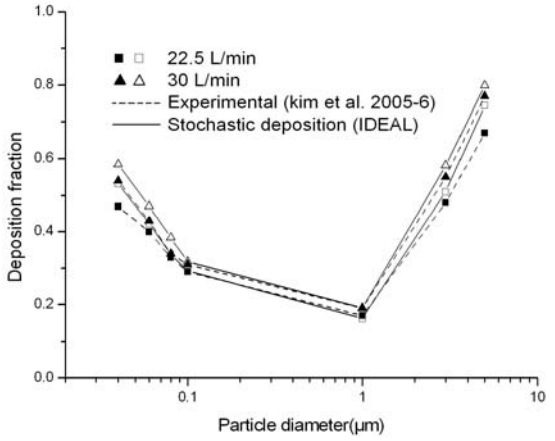

Figure 2. Total lung deposition fraction vs. particle diameter at two different flow rates.

From this comparative study it can be concluded that regional and deposition per generation by experiment vary from stochastic modelling prediction primarily due to difference in lung morphometry used in either studies although a good agreement is found in total deposition fraction.

Single-wall carbon nanotube (SWCNT) is a cylindrical nanostructure substance from wrapping a single graphene sheet. Many reports state that SWCNTs have cyto- and geno-toxicities in vitro studies, and that SWCNTs also have pulmonary toxicities in vivo studies. Some reports also state that SWCNTs do not have toxicities. The discrepancies in reports about toxicity and SWCNT are related to the physicochemical properties of SWCNT including dispersion states, dimensions, metal components, and purification treatment, which affect SWCNT toxicity. Therefore, it is very important to identify the physiochemical properties of SWCNT in order to estimate the harmful effect of SWCNT.
SWCNT was well-dispersed using ultrasonication to conduct an inhalation study. SWCNT was generated using a pressurized nebulizer with liquid suspension of SWCNT in distilled water including Tween 80.

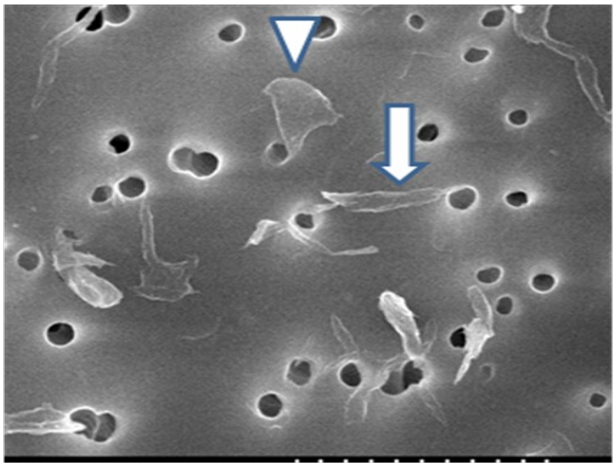

Figure 1 Bundle of SWCNT in the chamber

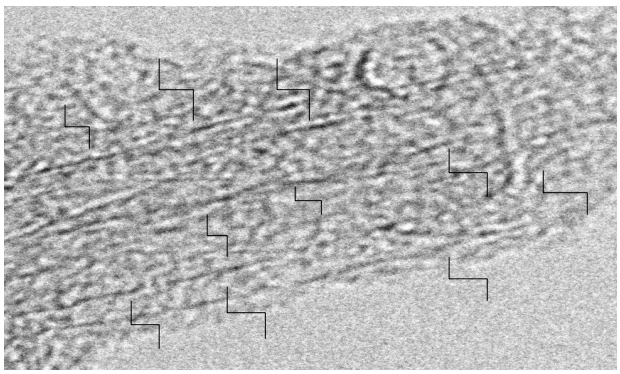

Figure 2 Lots of SWCNT in bundle

Figure 1 and 2 showed well-dispersed SWCNTs in the inhalation exposure chamber. Wistar rats were exposed to the SWCNT (diameter of bundle: 0.2 (1.7) μm; length of bundle: 0.7 (1.7) μm) for 4 weeks. Low and high mass concentrations in the exposure chamber were 0.03 ± 0.003 mg/m^3 and 0.13 ± 0.03 mg/m^3. Agglomerated diameter and mass concentration of nickel oxide nanoparticles (primary diameter: 8.41 nm) as reference material in the chamber was 59 nm and 0.2 mg/m^3, respectively. The rats were sacrificed at 3 days, 1 month, and 3 months after the end of 4 week exposure. The inflammatory responses and gene expression of cytokine-induced neutrophil chemoattractant (CINC) were examined in the rat lungs. There were no increases of total cell and neutrophil counts in bronchoalveolar lavage fluid (BALF), CINC-1, -2 and -3 in the lungs or of BALF in the high and low concentration-exposed groups of SWCNT (Figure 3). Pulmonary infiltration of neutrophils also was not observed in either exposed group through the observation period. On the other hand, neutrophil infiltration and up-regulation of CINC1-2 was observed in nickel oxide-exposed group. Well-dispersed SWCNT did not induce neutrophil inflammation in the lung under the conditions in the present study.

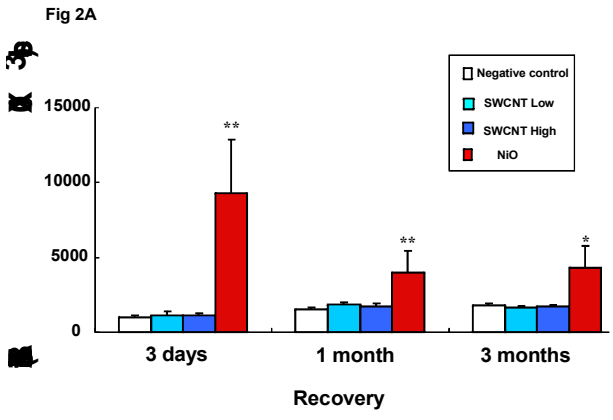

Figure 3 Total cell count in BALF in rat inhaled SWCNT

Both basic and clinical studies have been performed, trying to relate environmental pollution to hospital admissions and/or major respiratory or cardiovascular adverse effects. However, it is always difficult to compare data from "*in vitro*" studies and experimental models in animals to clinically evident effects in humans.

In the present study, hospital admissions to the main pediatric service of Milan were recorded, analysed and compared with daily and seasonal variation in PM10 and PM2.5 concentration, during 4 consecutive periods: winter 2007- summer 2007- winter 2008- summer 2008. Respiratory diseases were classified as follows: asthma or asthma like disorders; upper respiratory diseases (pharyngitis, pharingotonsillitis, otitis); lower respiratory diseases (bronchitis, bronchiolitis and pneumonia).

During 2007-2008, there were in total 440 pediatric admissions for respiratory diseases; 226 (132 males and 94 females) during the winter semester, and 214 (100 males and 114 females) during the summer semester. There were 12.7% asthma or asthma related admissions; 55.8% due to lower respiratory illness, and 31.5 % due to upper respiratory disease. The daily average of PM10 concentration during the first semester 2007 was 48.3 +/- 17.9 $\mu g/m^3$ median 47. There were 107 (59.1%) days with at least one hospital admission. The mean daily concentration of PM was higher in days with (n=107) than without (n=74) hospital admissions ($p=0.032$ or <0.05).

In addition, the human bronchial epithelial cell-line BEAS-2B and the human alveolar epithelial cell A549 were seeded at a concentration of 80.000 cell/well and treated after 48 hours with both summer and winter PM10 and PM2.5 sampled in the main Milan urban area. Cytotoxicity was assessed by HOECHST 33342/91 staining. Viability was calculated as the sum of viable mitotic cells. Release of the proinflammatory cytokine-IL was measured by ELISA assay. Oxidative stress was evaluated by chemiluminescence and genotoxicity was assessed by comet assay.

It was found that, whereas A549 cell viability was not significantly reduced after summer and winter PM exposure, summer PM had no significant effects on BEAS-2B viability, whereas winter PM treatment induced a decrease in cell viability, both at the dose of 25 and 50 µg/ml. In addition, whereas both winter and summer PM2.5produced only a slight increase in IL-8 release, winter PM10 induced a 5-fold increase in IL-8 release in treated cells, and summer PM10 induced a 20-fold increase ($p<0,05$) in IL-8 expression.

In particular, BEAS-2B resulted more responsive to PM treatment than A549. Winter PMs were more cytotoxic than summer PMs; Summer PM10 had a higher proinflammatory potential, which could be partly due to biological components (LPS).

Accordingly, acute admission of children was significantly affected by pollution data, with increased admission during winter time, namely for upper air tract infections, whereas lower tract inflammation and acute admission for asthma were more frequent during the spring-summer season.

In conclusion, in vitro studies using PM10 and PM2.5 sampling from different seasonal samples seem to correlate with clinical data in children exposed to the same type and concentration of PM during winter and summer season.

Even if great caution is required when trying to relate in vitro studies to clinical effects in humans, the present report is the first study in a large urban area trying to compare "*in vitro*" and clinical effects of the same urban particulate material in different seasons of the year.

Mesothelioma incidence is likely not going to decline, despite asbestos ban in Western countries

Keywords: Mesothelioma, exposure, asbestos, individual susceptibility
Presenting author email: paladini@unisi.it

Mesothelioma (MM) is a poor prognosis malignancy, strictly related with asbestos exposure, usually occurring 30-40 years after occupational or non occupational exposure. Recent reports have suggested that "although the MM incidence is anticipated to decline in the coming decade, it may not decrease to background risk levels, given that chrysotile consumption has not been banned under the current legislation and that secondary asbestos exposure from the environmental will continue", and that "although the potency differences with respect to lung cancer or mesothelioma for fibers of various types and dimension are debated", many pleural and peritoneal mesotheliomas have been observed after occupational exposure to chrysotile (Tse, 2010).

At the University of Siena, Italy, during a 12 year- interval, 75 subjects with MM were observed. There were: 53 M, 22F , mean age 65 y, range 43-86 y. In particular, there were 60 pleural MM, 11 peritoneal MM, 1 MM of the pericardium and 2 MM of the tunica vaginalis testis. In particular, a genome wide analysis (array CGH analysis) performed in a small subset of these couples (husband occupationally exposed, but unaffected, and wife unexposed but affected), showed a panel of differently expressed genes, which were partly different from couple to couple, and partly common.

Interestingly, common genes with diverse copy numbers included major histocompatibility genes, genes involved in the metabolism of xenobiotics and genes involved in the inflammatory response (Cetta, 2011). It was shown that, analogously to what occurs for pollution related diseases, also concerning asbestos related diseases, clinical outcomes occur as the final result of host-fiber interaction. In particular, we showed that asbestos related MM occurred in the tonaca vaginalis testis (as primary site), i.e. in a distant site from the portal of entrance of asbestos fibers, and that asbestos fibers have been documented at this level (in other patients). In addition, we observed subjects developing MM more than 45 years after short-term exposure to asbestos (service in the Navy at age 18-20) without any additional occupational exposure. Finally, we observed some couples (husband-long-term occupationally exposed to asbestos and wife non occupationally exposed) with the interesting finding that the non exposed wife developed pleural MM (with asbestos fibers documented in the operative specimen), whereas the exposed husband had neither MM, nor lung cancer, or even overt asbestosis. This points dramatically to the crucial role of individual susceptibility in the occurrence of asbestos related diseases. In particular, after genome wide analysis of blood samples of these couples, we showed that they differed for a diverse expression of a panel of genes, including some of those responsible for major hystocompatibility system, drug metabolizing enzymes and host immune response (Cetta, 2011). These findings dramatically suggest that, whereas most individuals do not develop MM or lung cancer even after a 30-year-occupational exposure to chrysotile, which is the most toxic variant of asbestos, other apparently normal, but highly susceptible people can develop pleural MM after indirect exposure to small quantities of asbestos of whatever structure and composition, or show a mesothelial tumor in a distant, but susceptible site, such as tonaca vaginalis testis. Further ecologic studies and analytical studies, but also pathophysiological and genetic studies are obviously required, before stating which is which, i.e. what is the relative potency of the various asbestos variants and what's the relative role of intrinsic toxicity fibers and of host susceptibility.

However, it is likely that, once that a powerful toxic agent as asbestos has been disseminated in a given community, the decrease to background risk levels is highly improbable, not only because of continuous chrysotile use in other regions (imported as manufacts, even in small quantity), but also because secondary asbestos exposure from the environment will likely continue. In particular, this persistent exposure (after initial introduction) and the long-term persistency of asbestos fibers will be able, even at very low concentrations, to trigger the occurrence of mesotheliomas in genetically susceptible people, the prevalence of which is likely increased also because of the asbestos epidemic. In addition, this should also suggest caution before widespread use of new fibers and new materials, the long-term persistence and long-term effects of which have not been carefully evaluated specifically.

Measurement of damages to exposed populations during concomitant evaluation of PM concentration and health effects usually doesn't consider damage to newborns.

Presenting author email: benoni@unisi.it

In Milan, Italy, between 2007 and 2010, a comprehensive approach to health effects of air pollution was performed (Prolife Project). In particular, the following studies were performed : 1) concentration measurement; 2) comparison between daily concentration of PM and other pollutants and hospital admission; 3) longitudinal studies in frail subpopulations, such as children attending primary school and elderly people living in nursing homes; 4) "*in vitro"* and "*in vivo"* experiments concerning host particle interactions.

The lack of adequate metrics of exposure, effect and susceptibility in epidemiological studies evaluating PM concentration and health effects is one of the main responsible for the conflicting results of these studies (Clark, 2010). In particular, the question of damage to human health by environmental pollutants has never been addressed exhaustively, analysing every possible component – and the specific and proper metrics.

The current paradigm of environmental pollution included acute damage, usually measured as hospital admission for various diagnosis during "pollution peaks" - and chronic damage, i.e. the risk of developing cancer and/or chronic diseases as long -term effects. A dose and effect linearity, due to the intrinsic toxicity of pollutants has been presumed, but never proved, whereas the role of individual susceptibility in the occurrence of the final outcome has never been considered in a proper manner.

The following results were obtained: 1) In a prospective study involving 118 children (63 males and 55 females) attending primary school, close to a park far from vehicular traffic, in 3 consecutive days very high peaks of indoor PM were detected for about one hour (8:15-9:15 in the morning), up to 1000 $\mu g/m^3$ indoor for PM10. There was no evident clinical outcome (increase of asthmatic bronchitis, upper or lower respiratory diseases) or different prevalence of spirometric or FeNO values in any of the 118 children who were evaluated during those days. 2) Functional alterations of human cells incubated in vitro with different types of PM10 and PM2,5 (10, 50, 75 μg/ml) and concentration greatly depended on individual susceptibility and on the pre-existing disease of the host. In particular, semiquantitative functional analysis showed that individual susceptibility of the host was responsible for more than 50% of the final outcome as compared with intrinsic toxicity of pollutants. 3) Comparison of the rate of asthmatic children in 2009 with historical series of 3 decades before, showed an evident increase of susceptible children, likely due to the effects of early life exposure to air pollution, during the critical "susceptibility window" involving the first months of life of newborns (Clark, 2010).

The question of the selection of adequate markers and metrics for epidemiological studies cannot be reduced to a mere controversy among epidemiologists, which should be limited strictly to them and treated only by an improval of statistical method or epidemiological models.

The basic question concerning the determinants of final outcomes and the measure of each component responsible for damage, involving both toxic and harmful processes, but also repair mechanisms, requires a multidisciplinary approach, involving clinicians and pathologists. Namely, the relative power of the damage due to intrinsic toxicity of pollutants, which can be without clinical evidence even at PM concentration of 1000 $\mu g/m^3$ - and that of individual susceptibility deserves further evaluation.
In particular, in the overall analysis of exposed population, the damage to newborns by pollutants usually escapes current evaluation of PM concentration and health effects, which is able to capture only damage expressed as "hospital admission, morbidity and mortality" measured within a 2- day lag. A proper estimation of this damage, i.e. of the increased proportion of newborns - children of non susceptible parents - who will become susceptible to "pollution disease", because of exposure to pollutants in early life, is mandatory because, even if it will be measured some decades later, as a burden of diseases related to PM pollution, it actually is a major component of the total damage from environmental pollution, at a given time, which could also be transmitted to future generations.

Keywords: emissions, wood smoke, health effects of aerosol, combustion particles.
Presenting author email: mikko.happo@uef.fi

Current levels of ambient air $PM_{2.5}$ are associated with mortality and morbidity in urban populations worldwide. At residential areas, wood combustion is one of the main sources of $PM_{2.5}$ emissions. EU has decided to increase the use of biomass energy to 20% on average from the total energy consumption by 2020. This decision will increase the small scale biomass combustion in local heating systems, which also increases the total $PM_{2.5}$ emissions. Therefore, it is crucial to minimize the health risks and to develop safe small-scale heating technologies. However, toxicological properties of particulate emissions from the new heating appliances and fuels are poorly known.

Particulate induced inflammation is one of the main mechanisms behind disease exacerbation in both respiratory and cardiovascular subjects. Particles are also known to induce inflammatory and cytotoxic effects in animals and in cell studies. In this study, inflammatory and cytotoxic responses in bronchoalveolar lavage fluid (BALF) of mice induced by PM_1 samples from different heating appliances were investigated.

The analyzed small-scale combustion appliances were as follows: logwood boiler (old tech), logwood boiler (new tech), stove (old tech), stove (new tech), tiled stove (new tech), woodchip boiler (new tech) and pellet boiler (new tech). Description of gaseous and PM_1 emissions of the investigated biomass combustion systems are shown in the Table 1. Particulate samples (D_p < 1µm) were collected by using a Dekati® Gravimetric Impactor (DGI). Thereafter, the samples were weighed and extracted by using methanol extraction method for subsequent use in toxicological studies.

Healthy C57BL/6J mice were intratracheally exposed to single dose of 10 mg/kg particulate sample. 4 and 18 hours after the exposure, the lungs were lavaged and BALF was assayed for indicators of inflammation (total cell number, IL-6) and tissue damage (total protein, lactate dehydrogenase (LDH)).

Total cell number in BALF was slightly, but not statistically significantly increased 18 h after the exposure to all PM_1 samples. Increase of total cell number was mostly due to migration of neutrophils into the area of inflammation, especially with the new technology samples. In contrast to total cell number, IL-6 concentrations in BALF were found to increase greatly after exposure to PM_1 samples. The highest detected increases were found mostly 4 h after the exposure. Pellet boiler and woodchip boiler samples evoked the strongest and statistically significant increases in IL-6 production. Overall, only low cytotoxic responses were evoked by emission PM_1 samples in mice lungs. Total protein concentration in BALF was not increased from control level after exposure to PM_1 emission samples, excluding pellet boiler sample at the latest time point. In LDH, pellet boiler similarly had the highest response.

Table 1. Mean values for gaseous and PM_1 emissions for the different investigated biomass combustion systems.

Combustion system	0_2 vol% d.b.	CO mg/MJ	OGC mg/MJ	PM_1 mg/MJ

Note. The largest and smallest values are in bold.

In this study, we showed that PM_1 samples originating from different heating appliances, representing old and new technologies, have discrepancies in their ability to induce inflammatory and cytotoxic responses in the mouse lungs. PM_1 samples from new technology appliances induced stronger acute pulmonary responses than samples from old technology devices. However, it is possible that certain chemical constituents of wood smoke, such as PAH compounds, are effecting to lungs via clearance mechanisms or via immunomodulation. This applies especially with samples from old technology heating appliances with high PAH content of the emissions. Moreover, it is noteworthy that modern combustion technology reduces greatly the emission rates and thus, the health hazard caused by particulate emissions.

Prevalidation of the CULTEX method: In vitro analysis of the acute toxicity of inhalable fine dusts and nanoparticles after direct exposure of cultivated human cells from the respiratory tract.

The respiratory tract is a main portal to the human body for inhaled particles and toxic substances. Over the last decade nanomedicine and -chemistry have development with a tremendous pace, not without realising that the safety and risk assessment of nanoparticles will challenge current toxicological approaches. The Cultex® system provides a method for screening such particles for their cytotoxic and therapeutic potency at an air-liquid interface on epithelial cells. The aim of the project is to prevalidate the Cultex® system (Aufderheide and Mohr, 1999) regarding its usefulness as such a toxicological screening tool in a multi-laboratory study.

In our experiments the cell line, A549, which exhibits features of alveolar type II cells but with the production of mucins and with characteristics of bronchial cells, was exposed to different particles. For the Cultex® system A549 cells were seeded on transwells with a semipermeable membrane which allows the separation of two compartments. On the apical side A549 were treated with aerosols, medium was only added in the basolateral compartment. In first studies cells were exposed to clean air and test substances to complete the experimental set-up for further experiments. The main focus was to create a test atmosphere which approaches to the in vivo situation.

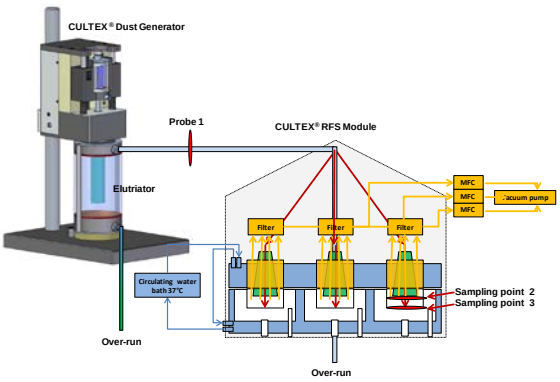

Figure 1: Schematic setup of the Cultex® RFS with three sampling points

The different aerosols are characterized (Figure 1) with regard to the particle size, the generated aerosol mass, the inlet mass and the deposited mass on the cells. The generation of a steady aerosol over a long time and an accurate characterization ensure reproducible dose effect results with cells (Figure 2).

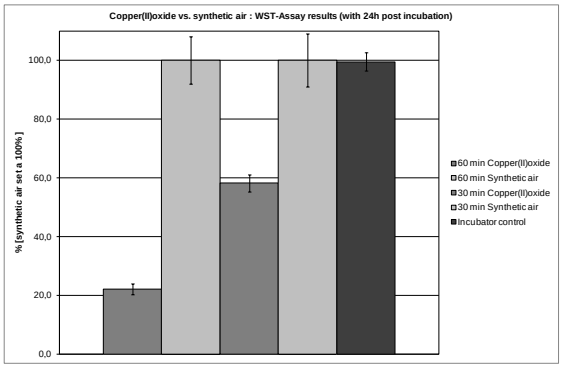

Figure 2: WST-1 results of A549 cells exposed to synthetic air and copper(II)oxide

Keywords: Amazon, Manaus, particulate matter, children health.
Presenting author email: artaxo@if.usp.br

Amazonia is characterized by very low aerosol concentrations during the wet season, with an average PM_{10} of 10 µg/m³ for most of the region. In sharp contrast, during the dry season, concentrations up to about 600 µg/m³ are measured in the Southern and Eastern part of the basin. The health effect of exposure to such high aerosol loading is significant. Another important process occurring now in Amazonia is urbanization, with the city of Manaus growing fast in population.

The objective of the study was to investigate the effects of fine particulate matter emitted from biomass burning on hospitalizations for respiratory diseases in children, at the urban area of Manaus, during the period of 2002 to 2009. The city of Manaus is located in the central portion of the Brazilian Amazon region. Currently has a population of 1.802.525 inhabitants, of which 99.4% lives in the in urban area.

The data for $PM_{2.5}$ were estimated by using the MODIS sensor, with Aerosol Optical Depth (AOD) at 550 nm estimation. $PM_{2.5}$ were derived from MODIS AOD using relationships obtained for several sites in Amazonia were AERONET and MODIS AOD were obtained in parallel with $PM_{2.5}$ measurements. Hospitalization data were obtained from Sistema Único de Saúde database (SUS – DATASUS). Statistical methods were used, with Pearson correlation and multiple linear regression between variables. Significant values were considered with a p-value < 0.05.

It was observed that hospital admissions for respiratory diseases in children, in Manaus, may be more related to weather and humid air conditions, than from exposure to aerosols from biomass burning in the region.

It was observed that the region of Manaus shows quite low PM2.5 concentrations, when compared to the Southern Amazonian region. The annual average of $PM_{2.5}$ levels ranged from 14 to 17 µg/m³, just above the air quality standard established by World Health Organization (WHO) on 10 µg/m³ annually (Figure 1, example of 2009). Over the years, the months between August and November (dry period in the region; burning season), had the highest average levels of $PM_{2.5}$, estimated between 18 to 23 µg/m³. The highest rates of hospitalization were observed during the rainy season, between March and June.

Manaus is located at a wet tropical climate area and presents almost always humid air in its weather normal conditions, with an average relative humidity always above 71%, during the study period, and at nighttime, relative humidity is always close to 100%.

Figure 1 shows the number of hospitalizations for respiratory diseases together with $PM_{2.5}$. Figure 2 shows relative humidity and hospitalizations for 2007. Humidity has a higher effect than aerosol in sharp contrast with health studies in the Southern part of the Amazonian basin.

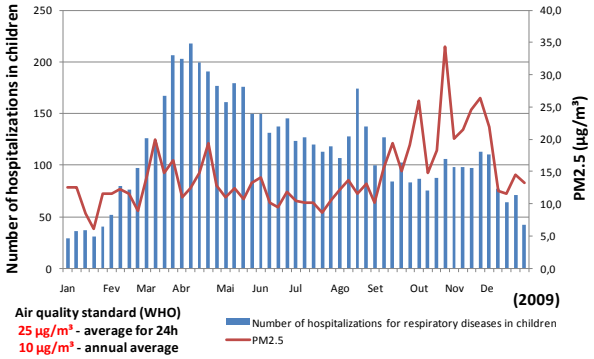

Figure 1 – Number of hospitalizations for respiratory diseases in children and PM2.5 in 2009. Manaus, AM.

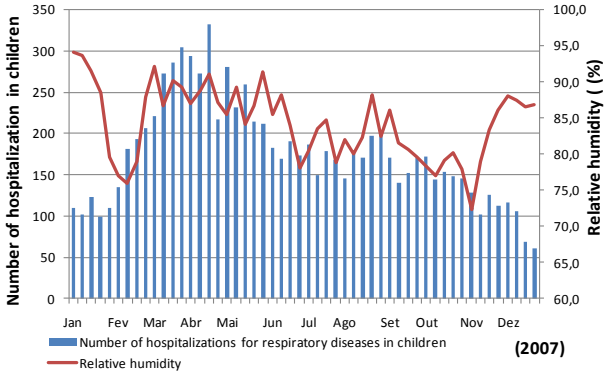

Figure 2 – Number of hospitalizations for respiratory diseases in children and relative humidity in 2007. Manaus, AM.

A novel exposure system for testing the lung toxicity of domestic wood combustion aerosols

S. Mülhopt, C. Schlager, H.-R. Paur

Institute for Technical Chemistry
Karlsruhe Institute of Technology, 76021 Karlsruhe, Germany

Keywords: Exposure, Deposition efficiency, Health effects of aerosols, Human lung cell, Nanoparticles
Presenting author email: muelhopt@kit.edu

Background:

Epidemiological studies show an association between the concentration of fine and ultrafine particles (PM10, PM2.5, PM0.1) in the atmosphere and the rate of mortality or morbidity due to respiratory and cardiovascular disease (Wichmann et al, 2000). The European Union therefore passed the directive 2008/50/EG to decrease the immission of particles. Regulated is the mass of ultrafine particles without considering their source, their chemical composition or their biological potential which is of real interest. Causing one third of the ultrafine particle immissions, domestic heaters are in the focus of interest. Especially the emissions of wood stoves containing a high amount of organic substances should be characterized regarding to their biological potential.

Material and Methods:

For the quantitative assessment of the toxicity of airborne particle emissions from domestic wood stoves the dose–response relationship is tested by *in-vitro* test systems using bioassays of cell cultures as sensor (Paur et al, 2011). To expose human lung cell cultures reproducible at the air-liquid interface towards aerosols the Karlsruhe Exposure System was developed as described in detail before (Mülhopt et al, 2007; Paur et al, 2008). The Karlsruhe Exposure System is a prototype for testing different emission sources. Goal of this project is the development of an exposure system as laboratory equipment optimized for the measurement of emissions from domestic wood stoves.

Results:

The Novel Exposure System is built with dimensions of 60 x 40 cm in base and 60 cm in height (figure 1). It is characterized by determining the deposition efficiency of nanoparticles with the fluorescein sodium dosimetry method (Mülhopt et al, 2009). The reproducibility of the exposure chambers as well as the stability of the QCM online dose measurement are measured and first exposure experiments are performed with A549 cell cultures exposed to filtered air. The data will be presented as well as the first exposure experiment results from small scale biomass stoves.

From Outdoor Particle Concentration to the Health Impact of Aerosol Particles – a Multidisciplinary Modelling Study, Part I

R. Sorjamaa[1], T. Lanki[1], J. Cyrys[2], and O. Hänninen[1]

[1]National Institute for Health and Welfare, Kuopio, 70210, Finland

Both short and long term exposures to particulate air pollution have been shown to associate with morbidity and mortality but the aerosol properties that would explain these effects have remained ambiguous. Particle composition and toxicity as well as particle size distribution ($PM_{2.5}$ and PM_{10}) have been considered as possible explaining factors (Kappos *et al*., 2004). It has been also claimed that the mass metrics $PM_{2.5}$ and PM_{10} alone might not be able to explain the outcome of the epidemiological studies as a change in size distribution would lead to mass metric not being able to predict the lung dose (Harrison *et al*., 2010).

One of the major issues in estimating the exposure is the fact that continuous particle concentrations are measured at urban monitoring stations. As the majority of the Europeans spend approximately 85% of their time indoors, it is important to know how the particle size distributions are modified when infiltrating into buildings.

The current study uses mass-balance approach and aerosol monitoring data collected with electrical aerosol spectrometer (EAS; Mirme *et al*., 2002) to model size specific indoor number and mass concentrations, and compares the results against $PM_{2.5}$ measurements made in Helsinki. Infiltration modelling utilizes data from the literature (Chen *et al.*, 2010) and aerosol physics (Lai and Nazaroff, 2001).

The results show that the accumulation mode particles have the highest contribution to both outdoor and indoor $PM_{2.5}$ mass concentrations and that the contribution of supermicron particles is reduced indoors by the lower infiltration factors.

Particulate matter (PM) and gaseous pollutants inside cultural heritage buildings such as museums and libraries pose a risk to materials. Particles not only cause soiling but are abrasive, provide sites for surface reactions and have a potential to damage artifacts due to their hygroscopic nature (Hachtfield, 2005). In addition ammonium nitrate can evaporate after penetration indoors, generating gaseous ammonia and nitric acid, which can damage works of art (Evans, 1960, Salmon and Cass, 1993).

To determine the composition of PM in the indoor and outdoor environment of the National Library in Prague, size-resolved sampling has been performed during three intensive campaigns in different seasons of year. Particles were collected and segregated into 10 size fractions (0.025-10 μm) using two Berner type Low Pressure Impactors that sampled in parallel from the indoor and outdoor environment. Collected samples were analysed gravimetrically and by Ion Chromatography (IC) giving mass and ionic size distributions. In parallel to PM sampling indoor and outdoor gaseous ammonia and nitric acid were measured using passive diffusion samplers.

Typical mass size distributions were bimodal with minimum at about 1 μm, lower concentrations indoors and submicron range shifted to smaller particles. The typical indoor and outdoor mass size distributions of sulphate, nitrate and ammonium ions are shown in Fig. 1.

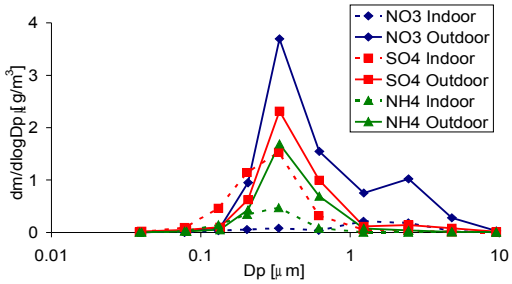

Figure 1. The typical example of indoor and outdoor mass size distributions of sulphate, nitrate, and ammonium.

As can be seen, the ammonium nitrate practically disappeared in submicron fractions of indoor PM. It indicates a shift in equilibrium toward the gas phase, caused by higher temperatures indoors (eq. 1), that can be further driven by deposition of gaseous nitric acid on indoor surfaces (Lunden *et al.*, 2003).

$$NH_4NO_3\ (s/aq) \leftrightarrow NH_3\ (g) + HNO_3\ (g) \quad (1)$$

This can be supported by the results obtained from passive diffusion sampler measurements where indoor concentrations of gaseous nitric acid were very low or below the detection limit during the whole period (Fig. 2).

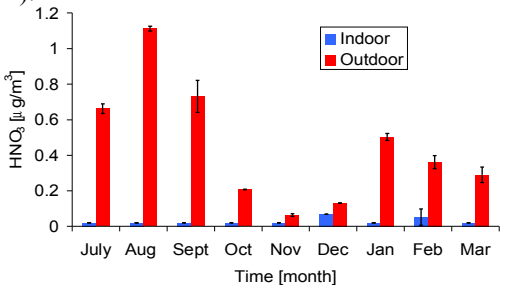

Figure 2. Time series of gaseous nitric acid concentrations.

The evaporation of ammonium nitrate indoors could also explain increased concentrations of ammonia measured indoors (Fig. 3). But, combined effect of ammonium nitrate evaporation and penetration of ammonia from the outdoor air should be considered.

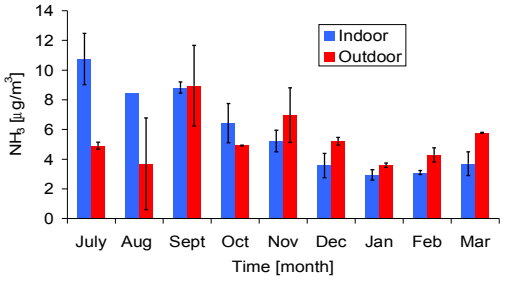

Figure 3. Time series of ammonia concentrations.

Keywords: indoor/outdoor particles, PM_{10}, carbonaceous particles, soluble fraction

Presenting author email: tnunes@ua.pt

Various studies have shown that poor indoor air quality (IAQ) in schools interferes with learning activities and can cause discomfort, irritation, and various short- and long-term health problems in students, teachers and staff. The right to breathe clean air in schools should be recognised as a fundamental health right at all levels: by the European Commission, the Health, Environment and Education authorities in the Member States, and the scientific societies and professional organisations involved in this topic, and also by school staff, students, and the public at large. Previous studies carried out in Portuguese primary schools (SAUDAR, INDOOR) revealed that particulate matter showed systematically higher indoor than outdoor concentrations. Not only PM mass concentrations, but also the composition of particles, particularly the oxidant potential, are thought to be important in assessing health effects. Indoor generated particles are different from those outdoors owing to the different sources and formation processes.

In order to contribute to an integrated understanding of the exposure to PM in school environments and the identification of the main sources and particulate matter composition indoors, a field study started last year. This study involved two primary schools, one in the city centre and another in the peripheral urban area, in an open quarter, with less population density. Comfort parameters and indoor/outdoor concentrations of NO_2, VOCs and PM_{10} were measured. PM_{10} samples were analysed and characterised for the water soluble inorganic ions (WSII), as well for the carbonaceous fractions in their main three components: organic carbon (OC), elemental carbon (EC) and carbonates (CC).

Here we present the results obtained during the first field campaign that occurred between April and June 2010. In each school, daily sampling of indoor/outdoor of PM_{10} during a two-week period was performed in parallel with low volume samplers, excepting the weekend days, when 48 hours sampling time was adopted. The PM samples were collected in pre-baked (6 h at 500ºC) quartz filters with 47 cm of diameter. PM_{10} mass concentration was quantified following the EN 12341 method. After mass weight, the PM_{10} filters were stored in a freezer until chemical analysis. The organic (OC) and elemental carbon (EC) content was analysed by a thermal-optical transmission technique. Two 9 mm diameter filter punches were used in each analytical run, after a previous exposure to an acid atmosphere to remove any carbonate potential interference. Particle carbonates were quantified (two 9 mm diameter filter punches) by the measurement of CO_2 release by NDIR, after sample acidification with orthophosphoric acid. Particulate soluble ions (inorganic cations and anions) were extracted in ultra pure water and analysed by ion chromatography.

Table 1 – Indoor and indoor/outdoor PM_{10} concentrations and percentage of the main particle constituents.

		Urban School		Suburban School	
		Indoor avg ± std	in/out avg ± std	Indoor avg + std	in/out avg ± std
PM_{10} ($\mu g\ m^{-3}$)	w. days	49.2 ± 9.5	2.40±0.88	72.8±28.8	1.84±1.06
	w. end	13.0±4.7	0.74±0.00	20.4±2.4	0.91±0.15

	w. end	26.8 ±1.7		26.5±8.7	

Table 1 shows the average and standard deviation of indoor concentrations and of indoor/outdoor ratios. During weekdays, the indoor PM_{10} concentrations were around twice the outdoor concentrations. Organic carbon was the particulate component contributing most to the indoor PM_{10} concentrations. Its contribution to the aerosol mass increased in both schools during the weekends. Individual particulate components that showed indoor/outdoor ratios >1 were CC, OC, EC, calcium and potassium, with OC and CC showing the highest ratios. EC indoor concentrations observed in urban school were higher than at suburban indoor denoting the influence of higher EC levels in the surroundings of the inner-city institution; however, the average absolute difference in indoor-outdoor is very similar in both schools. A possible indoor source of EC in primary schools could be graphitic pencil regularly used by children. The indoor source of carbonate, calcium and potassium is chalk used in blackboards. Indoor particulate organic carbon sources seem to be mainly related to student room occupancy and their activities, like small particles of paper, skin debris and clothing fibres. Inorganic soluble ions like chloride, nitrate, sodium, ammonium and magnesium showed typically indoor/outdoor ratios <1. These particle components have a probable origin in outdoor air. All the water soluble ions showed pronounced indoor/outdoor concentration ratio decay during weekend periods, with the exception of sulphate.

Smoking neighbours – a possible source to ETS exposure in homes

P. Molnár[1] and S. Johannesson[1]

[1]Department of Occupational and Environmental Medicine, Sahlgrenska Academy at University of Gothenburg, Gothenburg, SE 405 30, Sweden
Keywords: ETS, Indoor aerosols, Submicron particles.
Presenting author email: peter.molnar@amm.gu.se

Background: Living in a home with a smoker makes you exposed to environmental tobacco smoke (ETS). It has been shown that ETS can have negative health effects for both children and adults (Janson, 2004). What about if your neighbours in an apartment block smokes? Can the cigarette smoke penetrate from one apartment to another?

A family (two adults and an infant) complained about cigarette smoke coming from their downstairs neighbours and asked for an investigation regarding the contribution of particles due to the cigarette smoke.

The house is a hundred year old building that has been renovated over the years to improve the energy efficiency (e.g. better insulation and new windows with tighter fitting). After the initial complains, the property manager checked the ventilation system and increased the ventilation rate in the smoker's apartment to create an under pressure compared to the above apartment. However, this measure didn't solve the problem because of the in-wall sliding doors in the apartments. Or more precisely, the space where the doors slide into the walls when opened, were not airtight between the apartments.

Methods: A TSI CPC-3007 was used to count the particle number concentration and placed close to the opening of the sliding doors. In the living room the owner of the apartment, a member from the department and a representative from the property manager were trying to notice any cigarette odour. In the smoking apartment, the owner and two persons from the department were sitting in the living room and smoked according to a predetermined schedule (3 cigarettes followed by another two). This was performed for two settings, first with the windows in the smoker's apartment closed and secondly with two windows opened in the smoker's apartment (to create a draught). The investigated apartment was aired out between the two experiments. Outdoor particle number concentration was measured, before and after the experiments, and the concentration was in the range 9,000-9,600 particles cm^{-3} at both times.

Results: With windows closed in the smoker's apartment only a moderate increase of submicron particles were found (see Table 1) and no cigarette smoke odour was perceived in the living room. About 30 minutes after smoking started downstairs, a faint odour was experienced when sniffing by the sliding doors. After 35 minutes the particle number concentration started to go down again.

In the second experiment when windows were opened in the smoker's apartment, particle number concentration increased during the whole experiment (see Table 1).After about 30 minutes, a 50 % increase was reached, and after about 35 minutes the particle number concentration was doubled compared with pre smoking concentration. Cigarette smoke was perceived in the living room after about 5 minutes and the odour was evident next to the sliding doors. After about 15 minutes the cigarette smoke odour was distinct in the living room and remained so throughout the experiment.

Table 1. Particle number concentration (as 5 min means) for the two experiments (with closed and opened windows) and percentage increase vs. pre smoking.

	Windows closed		Windows opened	
	(# cm-3)	%	(# cm-3)	%
Pre smoking	4095	–	4820	–
+5-10 min	4316	+5	5489	+13
+10-15 min	4440	+8	5147	+6
+15-20 min	4751	+16	5677	+17
+20-25 min	4635	+13	6716	+39
+25-30 min	4623	+13	7228	+50
+30-35 min	4854	+19	10257	+112

Conclusions: Cigarette smoke from a neighbouring apartment can give a substantial contribution to the particle number concentration indoors under certain conditions. This occurred when the windows were open in the smoker's apartment downstairs. The lower air pressure indoors compared to ambient air is then lost in the smoker's apartment while maintained in the other apartment. The cigarette smoke is therefore drawn through the leakages between the apartments.

Keywords: indoor/outdoor particles, health aspects of aerosols, BPA, indoor sources
Presenting author email: grazia.perrone@unimib.it

Bisphenol A [2,2-bis(4-hydroxyphenyl)propane] (BPA) is a likely endocrine-disrupting compound (EDCs) (vom Saal, 2005; Ashby, 2004). BPA is an industrial chemical, a monomer of the polycarbonate plastics and a precursor for a variety of epoxide resins.

Consideration of exposure to EDCs is critical in study of health effects, particularly in relation to indoor environment, which have been identified as an important source of chemical exposures (Colt et al, 1998). People spend a large fraction of their time indoor, and indoor sources of chemicals, coupled with limited ventilation and slow chemical degradation processes, cause increased pollutant concentrations indoor.

The atmospheric occurrence of particle-bound BPA in the indoor and outdoor atmosphere at an urban site (Milan, Italy) has been investigated.

Daily (24 h) PM2.5 samples have been collected (low volume gravimetric sampling: 38.3 l min^{-1}, PTFE filters; according to EN-14907) from September 2007 to March 2008, and sampling took place simultaneously in an indoor and outdoor site. Indoor site was a non-smoking office, and outdoor site was located in the yard of the building where the office was set. To assess the BPA concentration in PM2.5 samples, filters were ultrasonically extracted in methanol (0.4 ml) and analysed by HPLC/(-)ESI-MS/MS (liquid chromatography /negative ion electrospray ionization – tandem mass spectrometry). In this work IDMS method has been used and the analytical procedure was validated: the accuracy, precision and recovery have been evaluated.

	PM2.5	BPA		PM2.5	BPA		PM2.5	BPA
	$\mu g\ m^{-3}$	$ng\ m^{-3}$	$ng\ \mu g^{-1}$	$\mu g\ m^{-3}$	$\mu g\ m^{-3}$	$ng\ \mu g^{-1}$	$\mu g\ m^{-3}$ IN/OUT	$ng\ m^{-3}$ IN/OUT
MEAN	16.9	0.30	18	29.0	0.18	5	0.62	3.3
SD	1.8	0.04	1	3.6	0.05	1	0.05	0.8

Table 1. Comparison between indoor and outdoor concentrations for PM2.5 and BPA. Mean ± SD (standard deviation)

PM2.5 concentrations indoor were lower than outdoor, but higher BPA concentrations were measured in indoor than outdoor. (Table 1). Averaged BPA concentration was 0.30 (± 0.04) ng m^{-3} indoor and 0.18 (± 0.05) ng m^{-3} outdoor. BPA content of PM2.5 was 18 (± 1) ng μg^{-1} indoor and 5(± 1) ng μg^{-1} outdoor.

Indoor air pollution levels are influenced by indoor pollution source and by infiltration of outdoor air. In an indoor environment there are many potential source of BPA from epoxide resins and polycarbonate plastics, but the major source could be the polycarbonate elements of the lamps that, when switch on, warm up by joule effect.

Daily indoor BPA concentration was correlated to daily outdoor BPA (R^2= 0.88) (Fig.1), thus indicating as indoor is strictly influenced by infiltration of outdoor air. The slope of the linear correlation between indoor and outdoor BPA is less than 1 (0.82), suggesting that about 80% of outdoor BPA is transported in the indoor environment.

Nevertheless, the y-intercept of the linear relationship between indoor and outdoor daily concentrations indicate that another source of indoor BPA, not related to the exchange with outdoor, occurred. The level of indoor BPA attributed to indoor pollution source was estimated equal to 0.15 ng m^{-3}, and it contributed to 19% up to 94% of the indoor BPA level we measured.

.

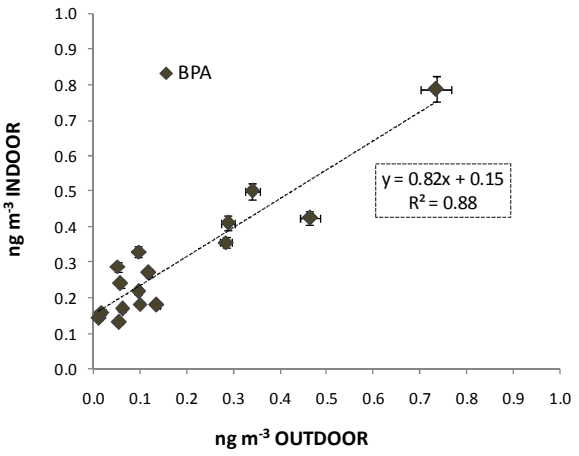

Figure 1. Daily BPA concentration (ng m^{-3}) in PM2.5 samples indoor (offices) versus outdoor.

Keywords: inactivation, H6N1, aptamer
Presenting author email: shinhaoyang@ntu.edu.tw

Most people typically spend around 87.2% of their time indoors (Lance, 1996). Accordingly, indoor air quality is an increasingly important issue. Bioaerosols importantly affect indoor air quality because they cause various respiratory diseases (Eduard *et al*., 1993; Melbostad *et al*., 1994). Higher concentrations of bioaerosols were found in indoors because of higher temperature and relative humidity all round year in Taiwan. Many epidemiological studies have inferred that sick building syndrome (SBS) was related to bioaerosols. Therefore, it cannot be neglected that the problem of indoor air pollution caused by bioaerosols in Taiwan.

This work applied the fibrous filter coated with the aptamer to explore the feasibility of removing avian influenza H6N1 virus bioaerosols. The H6N1 virus bioaerosols are generated from a microbial suspension liquid using a Collison Nebulizer. The H6N1 virus bioaerosols are mixed with a clean air and then are filtered using fibrous filter pretreated with the aptamer. To assess collection efficiency of fibrous filter, several factors were investigated, including the aptamer concentrations, higher and lower relative humidity, and different face velocities. The inactivation efficiency of H6N1 virus bioaerosols was assessed by virus titer before and after filtration. This work will show the results of the feasibility of removal H6N1 virus bioaerosols by aptamer coated on fibrous filter. Otherwise, the effects of different surface velocities, and relative humidity on removing H6N1 virus bioaerosols by the fibrous filter coated with aptamer will be investigated completely in this work. The experimental system was shown in Figure 1.

This study applied the aptamer-filter and non-coated filter to inactivate H6N1 virus bioaerosols at relative humidity (RH) of 30%, temperature of 25 ºC, and face velocity of 10 cm/s (shown in Table 1). The experimental results showed that the virus titer of the H6N1 virus passing through the non-coated filter was 2^6. The virus titer of the H6N1 virus passing through the aptamer-filter was 2^3. It's finding that aptamer could inactivate the H6N1 virus bioaerosols, when H6N1 bioaerosols passed through the aptamer-filter.

Table 1. Comparison of the H6N1 virus titer between through the non-coated filter and aptamer filter.

Testing filter	Virus titer
Non-coated filter	2^6
Aptamer-filter	2^3

This study applied the aptamer-filterr to inactivate H6N1 virus bioaerosols at RH of 30%, temperature of 25 ºC, and face velocity of 10 and 20 cm/s. The results showed that the virus titer of the H6N1 virus passing through the passing through the aptamer-filter at face velocity of 10 and 20 cam/s was 2^3 and 2^4. The results indicated that the inactivation ability of the aptamer would decrease with face velocity increasing.

This study also applied the aptamer-filter to inactivate H6N1 virus bioaerosols temperature of 25 ºC, face velocity of 10 cm/s, and RH of 30% and 90%. The results showed that the virus titer of the H6N1 virus passing through the passing through the aptamer-filter at RH of 30% and 90% was 2^3 and 2^4. The results indicated that the inactivation ability of the aptamer would decrease with RH.

Keywords: aerosol exposure, real-time measurements, source identification
Presenting author email: christina.isaxon@design.lth.se

Although we spend a major part of our lives indoors, there is a basic lack of information considering particles of indoor origin and their impact on human health. Airborne particle measurements are frequently conducted in workplace environments, but very few, designed to find associations between human activities, aerosol concentrations and health outcomes, in residential homes.

The aim of this study is to characterize the air quality in residential dwellings (in terms of time resolved particle mass and number concentrations, size distributions, soot, temperature, relative humidity and CO_2 levels), correlate this data to various indoor activities and study associations between exposure to airborne particles and health effects/symptoms of the inhabitants.

For seven consecutive days time resolved stationary air measurements are conducted in randomly selected homes (N=42) in the area of Lund in southern Sweden. Aerosol instruments used are MiniDISC (University of Applied Sciences, Windisch, CH), Nanotracer (Philips Research) Indoor Air Quality monitor (IAQ3016, Lighthouse), DustTrak (TSI) and a soot monitor (microAeth AE51, Magee Scientific). The instruments are placed at a central location in each home, close to, but not in, the kitchen. All measurements are made during off-pollen season (October-April). CO_2 data is collected and used to calculate the air exchange rate. Petri dishes are used for collection of potential allergens. The habitants are asked to fill in detailed activity log books.

A thorough examination of each home – e g construction year, floor and wall materials, and ventilation system - is conducted according to a structured protocol. In addition, the participants fill in a 9 page translated and modified version of the IUATLD (International Union Against Tuberculosis and Lung Disease) questionnaire covering topics such as current and previous health status, professional history and everyday habits.

After the measurement period a non-invasive medical examination is conducted, including rhinometry, study of tear film break-up time and measurement of NO in exhaled air. During the measurement period ambient air variations were monitored constantly from a station in northern Lund.

. A data classification is carried out by sorting the data into two categories: occupancy time (at least one person present in the dwelling/residence) and non-occupancy time. An example is shown in Figure 1.

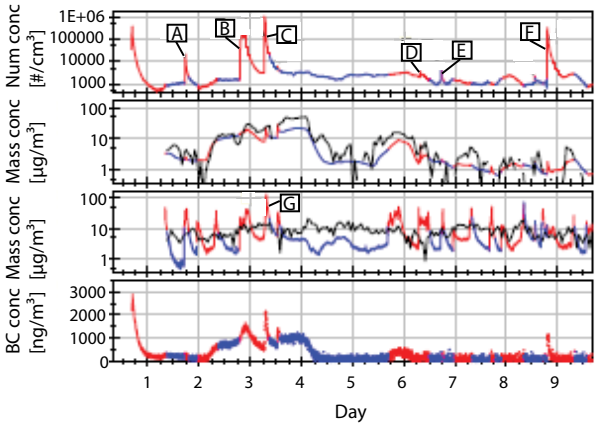

Figure 1. From top to bottom: Number concentrations (MiniDISC), PM_1 (IAQ3016), PM_{10-1} (IAQ3016) and black carbon concentrations (AE51). ug/m^3 denotes reading quantities from the optical instrument, using a density of 2,5 g/cm^3. Red lines denote that somebody was present and blue lines that the dwelling was empty. Black lines are background $PM_{2.5}$ and $PM_{10-2.5}$ respectively. Marked peaks are explained in Table 1 below.

Table 1. Peaks in Fig 1 and their heights above baseline concentration.

Peak	Num conc [#/cm^3]	PM_1 [µg/m^3]	PM_{10-1} [µg/m^3]	Activity
A	20000	0.5	35	Cooking
B	150000	6.8	0	Burning candle
C	1000000	0	0	Burning candle
D	1900	5	5	Cooking
E	2800	0.4	0	Cooking
F	320000	1.1	6.5	Cooking
G	-	15	110	Extinguishing candle

In a major part of the studied homes the concentration of particles, in particular in the sub micron size range, were higher when someone was present. Mean number concentration levels elevated by several hundred percent (indicated by the miniDISC, which is most sensitive for particles 20-120 nm), when someone was present in a dwelling, were not uncommon. The time resolved data in combination with the activity log books made it possible to trace peaks in concentration to a specific activity or usage of a specific appliance. It was also possible to see the relative strength of the indoor aerosol sources.

Keywords: PM, COPD, urban areas, remote alpine sites.
Presenting author email: giaschir@tin.it

Increased concentration of particulate material (PM), mainly due to urban traffic, heating and industrial pollutants is responsible for a different air quality in metropolitan areas vs remote sites and is likely to be responsible for a different incidence of respiratory complications and/or reduction of pulmonary function.

Methods: Two groups of 99 subjects were recruited (n=198), on a casual and voluntary basis: the former in Milan, Italy, i.e. a densely populated and polluted metropolitan area, the latter in Aprica, a remote alpine site (1181 m.a.s.l), with low pollution, due to traffic or other pollution sources. PM_{10} (<10 μm)and $PM_{2,5}$ (<2,5μm) were measured by PM detection units during two 2 week-campaigns. Each group was classified in 2 subgroups. The former, aged 30 to 64 years, (n=72) the latter over 65 (n=27). All subjects, well matched for cigarette smoke, sex and age were in good health conditions, asymptomatic and with no previous history of respiratory chronic diseases. All of them underwent spirometry, with evaluation of the following parameters: FVC (forced vital capacity), FEV_1 (forced expiratory volume in 1 second), PEF (peak expiratory flow) and MEF_{50} and MEF_{25}, i.e. maximum forced expiratory flow at 50% and 25% of FVC, respectively. Data were expressed as the percentage ratio between measured and theoretical values (m/t%).

Results: m/t% of FEV_1 (index of bronchial patency), both in under 65 and over 65 subjects, was lower in Milan that in Aprica subjects (**Table 1** and **Table 2**).

Table 1: m/t% in subjects age 30-65 years

	Milan	Aprica	p (t test)
FEV_1 m/t%	96	103	<0.01
MEF_{50} m/t %	75	97	<0.0001
MEF_{25} m/t%	54	78	<0.0001

Table 2: m/t% in subjects age 65-89 years
In particular, FEV_1 was <80% (value borderline

	Milan	Aprica	P (t test)
FEV_1 m/t%	69	88	NS (p=0.052)
MEF_{50} m/t %	68	86	NS (p=0.073)
MEF_{25} m/t%	44	66	<0.0001

between normal and abnormal data) in 20 out of 99 subjects in Milan (20,2%), whereas it was < 80% in only 8 out of 99 in Aprica (8,08%), (**Table 3**).

Evident differences were also observed in subgroups of different age: FEV1 resulted <80% in 8 out of 72 subjects under 65 years in Milan (11,1%) and in 2 out of 72 in Aprica (2,8%); and in 12 out of 27 (44,4%) and 6 out of 27 (22,2%) in subjects over 65 years, respectively (p<0,05) (**Table 3**).

Table 3: FEV_1 changes (< 80%) Milan vs Aprica

FEV_1 < 80%	Milan	Aprica
Total subjects	20 (20%)	8 (8%)
Subjects < 65y	8 (11%)	2 (28%)
Subjects >65y	12 (44%)	6 (22%)

Consistently, MEF_{50} and MEF_{25}, suggestive of the "smaller airway diseases", i.e. of a sub-clinical pathological entity somehow preceding chronic obstructive pulmonary diseases (COPD), were found (m/t%), both in under 65 and over 65 subjects, higher in Aprica than Milan inhabitants (**Table 1** and **Table 2**). In particular, in 30 out of 85 Milan subjects vs 18 out of 85 Aprica subjects, they were below the threshold (<65% for MEF_{50} , and <50% for MEF_{25}), which are considered borderline between normal and abnormal values (p<0,001) (**Table 4**).

Table 4: MEF_{50} and MEF_{25} changes (<65% and 50% respectively) Milan vs Aprica

MEF_{50}<65%, MEF_{25}<50%	Milan	Aprica
Total subjects	30 (35 %)	18 (21 %)
Subjects < 65y	17 (27 %)	3 (5 %)
Subjects >65y	13 (56 %)	15 (65 %)

Conclusion: Present data, even if preliminary, suggest that in the polluted metropolitan area of Milan, inhabitants are more prone to a "COPD march" than in the low pollution alpine site of Aprica. In particular, not only in severely symptomatic subjects with evident respiratory diseases, but also in clinically asymptomatic individuals, it is possible to detect significant difference in respiratory function because of different levels of air pollution. Since PM related alterations are partly reversible because of repair and defense mechanism of the host, periodical interruption of chronic exposure to metropolitan pollutants with exposure to a better environment (such as an Alpine site) could be of benefit.

Surface Area Deposition Index for Jet Engine PM Exhaust

D.E. Hagen[1], E.A. Black[1,2], P.D. Whitefield[1], and P. Lobo[1]

[1]Center of Excellence for Aerospace Particulate Emissions Reduction Research, Missouri University of Science & Technology, Rolla MO, 65409, USA
[2]College of Natural & Applied Sciences, Missouri State University, Springfield MO, 65897, USA
Keywords: Aircraft plumes, combustion aerosols, lung deposition, hygroscopicity.
Presenting author email: hagen@mst.edu

A major portion of atmospheric particles found in both urban and rural areas consists of carbonaceous material derived from both biogenic and anthropogenic sources. Particulate matter (PM) from on-road vehicular traffic has been correlated to increases in mortality and morbidity. PM from jet engine exhaust (JEE) falls into a similar size range, but its inhalation health impacts have been less well studied. JEE PM has unique properties with respect to deposition, retention kinetics, and clearance pathways in the human respiratory system, and is composed of sizes that readily travel gas streamlines that penetrate the deepest regions of the lung; this is a concern as deposited JEE PM in these regions could potentially cross the blood-membrane barrier and migrate into the bloodstream.

In two field campaigns PM size distribution and hydration data was acquired by the Missouri University of Science & Technology Center of Excellence for Aerospace Particulate Emissions Reduction Research (Missouri S&T COE), at Hartsfield-Jackson Atlanta International (ATL) and Oakland International (OAK) airports (Herndon et al 2008; Whitefield et al 2007). JEE PM was sampled downwind of active taxi- and runways during normal airport operations. The sample locations were selected adjacent to airport runways at distances of 100 m or greater from take-off sites, and chosen so JEE plumes would be transported by prevailing winds to a sampling probe feeding the diagnostic instrumentation. For both campaigns aircraft tail numbers were recorded for identification of airframes and engine types. Weather conditions were also monitored and recorded continuously throughout testing periods.

Using the JEE PM data collected during plume studies performed down-wind of active runways at ATL and OAK, lung deposition probabilities of JEE PM (as a function of particle size) can be determined using the International Committee of Radiological Protection (ICRP) lung deposition model. Surface area is the characteristic PM parameter most strongly correlated with health impacts (Stoeger et al 2006). Using the deposition probabilities and size resolved number distributions, a Surface Area Deposition Index (SADI) was developed. This new parameter, SADI, characterizes JEE PM lung deposition as the surface area of deposited PM per kilogram fuel burned. SADI allows for equitable comparison among various jet engine types while also proving a surface area metric for meaningful health impact correlations. An example of the variation in SADI for engine type CFM-56 observed at OAK is shown in Fig. 1.

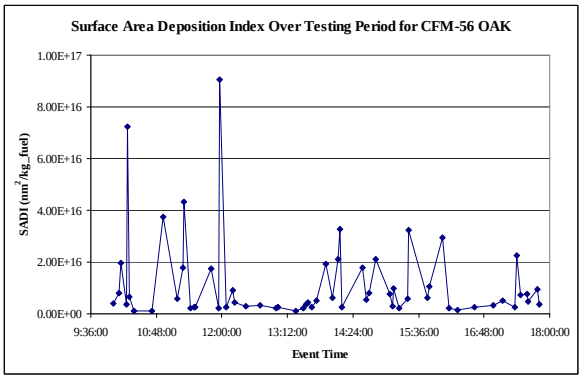

Fig. 1 Surface Area Deposition Index for CFM-56 engine type observed at OAK

Two interesting conclusions to this preliminary study are that statistically significant differences among engine types are not observed in SADI, and variations in SADI are not correlated with temporal changes or changes in meteorological conditions.

EAB was sponsored by the Airport Cooperative Research Program (ACRP 11-04: Graduate Research Award Program on Public-Sector Aviation Issues) administered by the Transportation Research Board of the National Academies (Project Manager: Larry Goldstein). Protein Nitration and Health Effects

K. Selzle, Y. Zhang, H. Yang, and U. Pöschl

Department of Biogeochemistry, Max-Planck Institute for Chemistry, Mainz, 55128, Germany
Keywords: ambient air pollution, health effects of aerosols, enhanced allergenicity due to protein nitration
k.selzle@mpic.de

Proteins account for up to ~5% of urban particulate matter, influence the physiochemical properties of atmospheric particles, and play a major role as airborne allergens (Franze, Weller et al. 2003)

Lots of studies indicated that proteins could be nitrated by the NO_2 and O_3 gas in atmosphere and the nitration took place at tyrosine (Franze, Weller et al. 2005). Several studies suggested that nitrated protein might cause and enhance allergic disease and asthma (Gruijthuijsen, Grieshuber et al. 2006).

The chemical mechanisms and molecular processes that lead to adverse health effects of NO_2 and O_3 are, however, still poorly understood. We suggest that protein nitration by air pollutants plays a major role in the increase of allergies in the western countries besides nutrition effects and excessive hygiene practices.

In this study, liquid chromatography and tandem mass spectrometry (LC-MS/MS) was used to characterize several proteins in their native and nitrated form.

Native protein bovine serum albumin (BSA) and native chicken ovalbumin (OVA) were nitrated by tetranitromethane (TNM) in liquid phase and NO_2 and O_3 in gas phase and characterized by The observed nitration patterns show how the site selectivity of protein nitration depends on the nitrating agent, reaction conditions, and molecular structure of the protein (Zhang, Yang et al. 2010)With regard to immunological questions it might be of special interest that the most efficiently nitrated tyrosine residue within the OVA protein (Y107) is part of human as well as murine IgE epitopes of ovalbumin and is also found in a human ovalbumin T cell epitope (Untersmayr, Diesner et al. 2010).

The experimental results show that further investigation on protein nitration is required. Our future plan is to investigate different nitration agents which are relevant in immunological pathways as well as in the atmosphere (peroxynitrite, peroxyacetylnitrate (PAN)).

This work was supported by the Max-Planck Society (MPG), the International Max-Planck Research School for Atmospheric Chemistry and Physics (IMPRS) and the Max-Planck Graduate School (MPGC).

Pigeons as Source of Airborne Circoviruses

G. Jereb[1], U. Krapež[2], Š. Pintarič[2] and A. Dovč[2]

[1] University of Ljubljana, Faculty of Health Sciences, Zdravstvena pot 5, 1000 Ljubljana, Slovenia
[2] University of Ljubljana, Veterinary Faculty, Gerbičeva 60, 1000 Ljubljana, Slovenia

Keywords: bioaerosols, pigeons, *Circovirus*
Presenting author email: gregor.jereb@zf.uni-lj.si

With pigeon's colonized attics as well as pigeon lofts represent rather dusty environment, therefore different dust particles (aerosols) could be found in such locations. These aerosols originates mainly from pigeons and consists of pigeon's excreta and feather dust (known also as bloom), another source is also grain feed. Consequently also different bio-aerosols are present in rather high concentrations in such locations. According to the results of preliminary study (Jereb et al., 2010) as well as literature data, free-living pigeons are commonly infected with different microorganisms (Dovč et al., 2004; Haag, 2008), also several zoonotic ones. Among others, pigeons (especially young ones) are often infected with avian circoviruses of the genus *Circovirus* (Bougiouklis, 2007). The role and influence of circoviruses on pigeons is not yet fully elucidated, however connection with immunosuppression and several different clinical signs is established (Marlier and Vindevogel, 2006). Influence of circoviruses pathogenesis on humans is not excluded as well (Bougiouklis, 2007).

In presented study therefore presence of circoviruses in pigeons as well as presence of circoviruses in air sample from pigeons loft and from with pigeon's colonized attic was investigated.

Samples of air were obtained using a Merck MAS-100 NT bio-aerosol sampler based on the impaction principle. Sampler aspirates air through a perforated plate on to standard 90mm agar poured Petri dishes. The aspirated volume was a constant value of 100 liters per minute and 300 x 0.6mm sampling head (perforated lid) was used with declared impaction speed <20m/s. Additionally, Coriolis Delta Air sampler - aspirated volume of 100 liters per minute (cyclonic air sampler), based on a cyclone type device that selects and captures airborne particles and transfer them into a liquid sample, was used.

In 2006 cloacal and tracheal swabs and in 2009 the air in with pigeon's colonized attic was analyzed on presence of circoviruses using PCR (Duchatel et al., 2009). According to preliminary results 75% of tested feral pigeon's excreted circoviruses through cloacae and 62% of them excreted virus through trachea. The air in the attic where feral pigeons lived was positive for the presence of circoviruses. Method for detection of virus was identical in all cases.

Based on preliminary results further analyzes will be performed among several pigeon breeders and their breed pigeons. Also air in pigeon's loft will be further assessed on presence of circoviruses with aim to correlate presence of circovirus in pigeons and air.

Aerosol Chemistry

Synthesis and Surface Area evaluation of Solid Core Porous Shell Particles

G. Kastrinaki[1,2] and A.G Konstandopoulos[1,3]

[1]Aerosol &Particle Technology Laboratory, CERTH/CPERI, P.O. Box 60361, 57001, Thessaloniki, Greece
[2] Department of Mechanical Engineering, University of W. Macedonia, 50100, Kozani, Greece
[3] Department of Chemical Engineering, Aristotle University, PO. Box 1517, 54006, Thessaloniki, Greece
Keywords: porous nanoparticles, nanoparticle oxides, aerosol spray pyrolysis.
Presenting author email: georgiak@cperi.certh.gr

A solid particle (core) that is surrounded by a porous shell is a morphology than can be used to protect the core material from unwanted interaction with molecules that exceed the pore shell size (protection) and/or to maintain it until the temperature conditions intrigue the core material to be released out from the porous shell walls (controlled release). The particle's selective reactivity and release characteristics make Solid Core Porous Shell Particles (SCPSP) interesting for energy, environmental and medical applications. The size of: the core, the shell and the shell pores are important parameters in order to control the protection and release characteristics of the particles. The present work is a study of SCPSP synthesis and surface area evaluation of particles with various core sizes.

SCPS particles with metal oxide core and silica porous shell were synthesized by Aerosol Spray Pyrolysis (ASP) (Karadimitra et al., 2001). An aqueous silicate and surfactant precursor solution is atomized into micro-sized droplets by an air assisted atomizer. The droplets are carried via air inside a heated (400^{o}C) tubular reactor and the produced particles are collected on a glass fiber filter located at the exit of the reactor.

In the silica droplet, the surfactant is located towards the external surface (Ward, 2003) forming micelles, which self assemble into ordered structures, while the water-ion solution is captured in the core undergoing crystallization of the ions when the concentration reaches saturation point. Calcination of the synthesized particles at 450^{o}C for 5hrs removes the surfactant leaving the final product particles with a porous shell behind.

The SCPSP morphology and the core size of the particle can be adjusted by the precursor solution and the synthesis conditions (Kastrinaki et al., 2009). The particles were characterized by Transmission Electron Microscopy (TEM), X-Ray Diffraction (XRD), BET and Induced Couple Plasma (ICP) Analysis.

TEM images revealed the core shell morphology. The nanostructured particles had an outside ordered porous shell with metal oxide trapped in the core. XRD analysis showed that the core metal oxide is nano-crystalline whereas the porous shell is mostly shown to be amorphous with ordered porosity. Porous particles were characterized via BET analysis with respect to their surface area and pore size distribution. The BET pore sizes agree with the sizes measured from the TEM images, while the ICP analysis shows the increased metal percent for the larger cores.

For a constant pore size of 2nm the precursor solution moles varied from 0.1-0.33/1 metal/Si ratio and the impact on the final particle is the control of the core size. The surface area of the particles is measured by BET analysis and the surface area vs the core size is depicted on Figure 1, where particles with larger cores (smaller porous shell areas) show smaller surface areas.

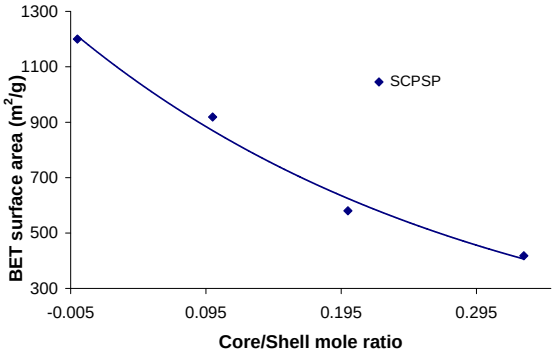

Figure 1. BET surface are with the core/shell ratio for the solid core porous shell particles.

Uniformly porous particles with 2nm pore size were also synthesized, in order to evaluate the surface area of porous particles without a core. The uniformly porous particles depict a high surface are of 1200 m^2/gr, which decreases with the incorporation and further increase of the core size.

Mathematical formulations were used in order to calculate theoretically the surface area of the SCPSP in correlation with the core size measured from the TEM pictures and to compare it with the surface area measured from the BET results.

Physicochemical transformations and photochemical reactions of high-disperse pesticide chemicals

Yuri N. Samsonov

Institute of Chemical Kinetics and Combustion, 630090, Novosibirsk. Russia,
Keywords: aerosol chemistry, evaporation, particulate matter, pesticide particulates, photochemical reaction
samsonov@kinetics.nsc.ru

The high-disperse substance state is a natural phenomenon. Many hundreds of millions of tons of particulate matter enter the atmosphere annually from both the natural and anthropogenic sources. Anthropogenic impact is caused by heat-and-power engineering, motor fuel exhausts, and the application of pesticide chemicals in agriculture. The chemical reactions which occur permanently in the environment with particulate pollutants (reactions with OH radicals, nitrogen oxides and ozone, direct or induced photodecomposition and photo-oxidation, (photo)catalytic reactions) result in their chemical conversions. As the reagents (OH, O3, and others) arise in the atmosphere due to the action of sunlight, the term "photochemical reaction" applies often to all chemical reactions in which these reagents participate. Decomposition under sunlight seems to be very important for many chemical pollutants being in a high-disperse state in the environment (pesticide particles levitated in the air or settled on foliage, thin films of pesticide chemicals spread over leaf surface). The photochemical stage of decomposition, which generally is a many-stage chemical process, can sometimes predetermine the overall decomposition rate of pesticide particulates. The light absorbed inside a particle/film induces here chemical reactions. There is the lack of reference data on the intra-particle absorption of light preceded and/or followed by physicochemical and chemical changes in the particulate matter. The photodecompositions of polymeric films and pesticide residues on foliage concern partly these problems. It is worth noting, however, that the polymeric films are the relatively "thick" things (5-10 μm and thicker) with the given chemical compositions and bulk structures (Rabek, 1996). As will be shown below, both the composition and structure of fine pesticide particles and films, especially in ambient conditions, are specific, changeable and often irreproducible.

The high-disperse state reveals specific features for the rates and mechanisms of physicochemical transformations and photochemical reactions, which differ from the processes in coarse dispersal matter and, even more, in ordinary liquid and solid "test-tube" assays. The point is that, due to the fast evaporation of some chemical components (e.g., solvents) out of a fine particle/film, its size, chemical composition and phase state are changing permanently. This can cause the solidification and stratification of intra-particle matter resulting in a very slow diffusion of reagents within particle/film body, and other specific physicochemical and chemical changes. In this regard, the chemical reaction in a fine particle/film is not a certain elementary chemical act, but a succession of the above physicochemical and chemical events depending on the particle size (film thickness) and the bulk structure, but the expressivities of the above-listed factors can be diverse and spontaneous under different conditions.

The kinetics and the mechanisms of the direct and sensitized photochemical decompositions of several pesticide chemicals have been experimented as applied to the aerosol particles 0.12- 1.3 μm in diameter settled on glass plates and films 0.03 – 0.5 μm thick on plates. The plates with the particles and films exposed to a long irradiation, which simulate sunlight photolysis of pesticide residues on plants. Although the settled particulates are not the perfect imitation of the pesticide particles levitated freely in the air, they can simulate slow physicochemical and photochemical reactions in the high-disperse pesticide substances. In this regard, it is impossible to experiment over a long time with the freely levitated particles in both the laboratory and ambient conditions due to either fast deposition in a laboratory chamber or fast dissipation in the air. The mechanisms of (photo)chemical reactions of high-disperse pesticide chemicals are hypothesized including the complexing mechanism, the two-quantum photochemistry, and the oxidation by singlet oxygen.

Phase transformation of evaporating solution droplets of immiscible polymers

V. Rajagopalan, E. A. Grulke and A. K. Ray

Department of Chemical Engineering, University of Kentucky, Lexington, KY 40506, USA
Keywords: polymer blend particle, multicomponent droplet evaporation, VOAG.
Presenting author email: akray@engr.uky.edu

Polymer blends have wide range of applications (e.g., opto-electronic devices, organic solar cells) that often require microparticles with uniform properties. In many cases, the polymers are incompatible with one another and thus separate into distinct phases. Conventional methods based on melt blending and miniemulsions can reduce the extent of phase separation in many polymer blends, but are limited to polymer pairs in certain property ranges. There is a need for a synthesis method that can blend immiscible arbitrarily polymer pairs. Blended microparticles produced by evaporating solution microdroplets, containing two immiscible polymers dissolved in a common solvent, are expected to exhibit a high degree of phase uniformity under conditions where the timescale of solvent evaporation is lower than that of polymer diffusion and self-organization. In such a situation, the phase separation is inhibited within the atto- to femto-liter volume of the droplet, and homogeneous blends of immiscible polymers can be produced.

We have examined multicomponent polymer particles produced from highly monodisperse microrordroplets that were generated using a Vibrating Orifice Aerosol Generator (Devarakonda et al. 1998; Gao et al. 2007). Equal proportions of two highly incompatible polymers, polystyrene (PS, Mw=280,000) and polyvinyl chloride (PVC, Mw=75,000), were dissolved in a common solvent, tetrahydrofuran (THF), to get a desired total polymer concentration in the solution in the range of 2 to 4 wt%. Droplets were generated from the homogeneous solution; in addition to THF, ethanol was added in varying amounts to reduce evaporation rates of the solution droplets. The morphology of the polymer blend particles produced from the droplets of various composition was studied by an SEM (Hitachi SEM-3200N). To obtain the distribution of each component inside the particle, samples were placed in Beem capsules, embedded in Spurr's resin, and kept under vacuum for 48 hours. They were then polymerized at 60^0C for 48 hrs, and finally, sliced thinly on a Reichert-Jung Ultracut E microtome. The thickness of the slices was about 60 nm. The slices were placed on copper grids and examined in the FEI Tecnai Biotwin 12 transmission electron microscope (TEM). An Energy Dispersive X-ray Analysis (EDS) (coupled with SEM) was performed for the presence of chlorine. All the samples were coated with a thin layer of Gold and Palladium before using them under the SEM.

The SEM micrographs of polymer particles show that the particles are of spheroidal shape and often have indentations. Even though the initial droplets generated by the VOAG have the same size, the final solid particles have varied morphologies. This is due to nonuniform drying conditions inside the experimental chamber. Surface hollows and indentations observed in the particles can be attributed to the rapid drying of the droplets. Even though the physical characteristics of the particles were not uniform, the objective was to study the extent of phase separation or the lack of it thereof. The elemental difference between PS and PVC is the presence of chlorine in PVC. This prompted us to do EDS on the thin slices of the blend particles that were prepared using the microtome. The slices were about 60 nm thick with diameter of about 12 μm. Each analysis was done over an area of 3x3 μm^2. The EDS spectra from various locations of a particle clearly show primary and secondary peaks of chlorine. For particles produced from solutions with THF as the sole solvent, chlorine peaks were observed to have approximately the same intensity. This suggests that the distribution of chlorine is more or less uniform throughout the cross-section. Thus, qualitatively, PVC and PS are dispersed uniformly in the particle.

The results of this study show that uniform polymer blend microparticles can be produced by rapid evaporation of microdroplets. The morphology of the final particles that form after the solvent evaporation depends on the initial droplet size, polymer concentration, solvent volatility, and temperature. Future studies would involve more quantitative measurements. The mapping of chlorine in the samples are needed to fully ensure that the particles produced are indeed uniformly blended microparticles.

Diethylamine and new charged particles formation

T.-E. Parts, A. Luts, and U. Hõrrak

Institute of Physics, University of Tartu, Ülikooli 18, 50090 Tartu, Estonia

Keywords: aerosol chemistry, air ions, particle size distribution, trace gases.

Presenting author email: tiia-ene.parts@ut.ee

Volatile organic compounds (VOCs), particularly amines may play substantial role in the new particle formation (NPF) processes (e.g., Bzdek *et al*, 2010). Diethylamine (DEA), chemical formula $(C_2H_5)_2NH$ or $C_4H_{11}N$, is one of the VOC, emitted into the atmosphere from a variety of sources including meat cooking, biomass burning, motor vehicle exhaust, industrial processes, and marine organisms (e.g., Facchini *et al*, 2008).

Previously we reported some results about DEA affecting the mobility spectra of one second aged small positive air ions (Parts and Luts, 2004). Now we have measured the mobility spectra of negative ions by our modified experimental set-up, which allows to observe the changes in ion formation processes through time scale from about 1 second (*young ions*) up to ~20 seconds (*old ions*). Ions are produced by radioactive ^{243}Am source. We study the ageing of air ions concurrently by ion mobility spectrometry (AIS, Airel Ltd) and mass spectrometry (API300 TQ MS) to find out the characteristic differences in spectra (compared to background), induced by enhanced concentration of diethylamine, and to propose some of the ion species typical for the obtained spectra.

Diethylamine is a chemical compound with high proton affinity, therefore, it behaves in different way regarding the positive or negative ions chemistry. For positive ions the proton transfer reactions are important For negative ions, in our present study, the attachment reactions of DEA to negative ions should appear.

The results of AIS measurements reveal that the relative effect of DEA on the size distribution of negative ions depends on air ion age (Figure 1). Addition of DEA reduces the amount of the smallest (<0.65 nm) young ions and increases the concentration of smallest old ions. DEA also decreases the mean size of old cluster ions. The concentration of charged particles with diameters above 7 nm has a trend to rise.

In the AIS spectra we also observed some increase in the percentage of the intermediate ions with a diameter from 1.5 to 4 nm. So, it appears that DEA can generate new aerosol ions. But, presumably, more than 20 seconds is needed to generate larger particles.

Mass spectra measurements show that addition of DEA into the air also changes ion composition for both young and old negative ions. When to compare with the background, the new peaks appear at *m/z* 198, 261 and 334. The MS/MS analysis of the peak *m/z* 198 confirms that $NO_3^-(HNO_3)$(DEA) should be responsible for such a mass. The small peak at *m/z* 261 (198+63) could be $NO_3^-(HNO_3)_2$(DEA), and the latter at *m/z* 334 (261+73) the ion with one extra DEA molecule $NO_3^-(HNO_3)_2(DEA)_2$.

Some aspects concerning the spectra of positive ions, obtained in the same experiment, are also discussed.

The electron-excited chemistry of sulfur dioxide oxidation induced by UV irradiation of air with trace O_3 and SO_2 is considered. The importance of this mechanism is evaluated based on recent laboratory experiments on SO_2 oxidation in a laminar tube with air induced by UV irradiation (Berndt et al., 2005, 2006, 2008). The formation of GSA has been attributed to known neutral chemistry mechanism starting from the reaction of SO_2 molecules with OH radicals which is a typical SO_2 oxidation route in atmospheric conditions.

Our results show that under respective conditions the route of SO_2 oxidation involving electron excited oxygen molecules may present an additional source of gaseous H_2SO_4 production to known OH-radical mechanism (Sorokin, 2010).

During the above experiments the fractions of charged particles were also observed. Their concentrations in a size range bigger than 2 nm were measured to be essentially smaller than that of neutral particles. Based on this result, it was concluded that the ion induced nucleation was a minor importance in these experiments. However, the large time-scale characteristics are an important particularity of these experiments. The gas flow time spends were about 290 and 90 s respectively for UV irradiated section followed by the UV free section. All measurements were performed at the outlet of UV free section. It is likely, that the charge neutralization combined with the particle wall losses in UV free section may essentially change the charged particles size distribution in comparison with those that was formed to the end of the UV irradiated section.

In our topic the ion chemistry of sulfur dioxide induced by UV irradiation of O_3-SO_2-H_2O gases followed by formation of neutral particles via the ion-ion recombination is considered. We show that the observed size distribution of neutral particles may be partially explained by nucleation of neutral sub 2 nm particles induced by ion-ion recombination. In this mechanism, the ions play a key role in an enhancement of both the GSA generation rate and nucleation of neutral particles.

In total, here we try to give some new insights to related mechanisms. An influence of UV irradiation on SO_2 oxidation seems to be important in atmosphere and certainly may provide an additional external source affecting the aerosol formation.

Importance of aerosol phase and water uptake for understanding organic aerosol oxidation

P.J. Gallimore, F.D. Pope, P. Achakulwisut and M. Kalberer

Centre for Atmospheric Science, Department of Chemistry, University of Cambridge, CB2 1EW, UK
Keywords: Aerosol chemistry, Organic acids, Hygroscopicity, Mass spectrometry, SOA
Presenting author email: pjg48@cam.ac.uk

The composition and size of atmospheric aerosol is important with respect to radiative forcing and human health. The chemical processing of organic aerosol by gaseous oxidants helps to determine the atmospheric properties of this important subset of aerosols.

We will present an experimental investigation of the response of maleic acid aerosols to ozone under conditions of variable relative humidity and temperature. Maleic acid is a dicarboxylic acid containing a double bond and is used here as a model for aged organic aerosol in the atmosphere; highly oxygenated dicarboxylic acids constitute a large fraction of the tropospheric organic aerosol budget.

Two experimental techniques are combined in this investigation. An Electrodynamic Balance (EDB) is used to levitate single particles with an initial dry radius of 10-20 μm and assess changes in particle size and mass (due to water uptake and/or loss of volatile ozonolysis products) and phase (liquid or solid) during and after chemical processing with ozone. Particles were exposed to 0.6-1.6 ppmv ozone for 1 hour in a temperature-controlled chamber. The phase of the particle, dependent on the relative humidity, was controlled by a variable humidity N_2 flow. Experiments lasted over 24 hours.

An aerosol flow tube was used to investigate the chemical composition of processed maleic acid aerosol with offline ultra high-resolution mass spectrometry (UHR-MS). The aerosol had a mean dry particle diameter of 180 nm and concentration of $1x10^8$ cm^{-3}, before exposure to ozone up to 200 ppmv in a reaction vessel for up to 5 hours.

The response of particles to ozone is found to depend strongly on the environmental relative humidity; pure maleic acid aerosol exhibits deliquescent behaviour and the phase of the particles (solid or liquid) during ozonolysis is important for understanding the oxidation process. Under dry ozonolysis conditions, glyoxylic acid is the only aerosol-phase product observed. The aerosol hygroscopicity and volatility shows a moderate increase compared to pure maleic acid.

If deliquesced particles are exposed to ozone, additional reaction pathways requiring water become available and many oxidation products are observed. Maleic acid can become significantly depleted after processing, leading to an aerosol composed primarily of high O:C ratio products. The hygroscopicity of such particles is observed to increase significantly compared to maleic acid and volatile product loss is observed.

Furthermore, particles exposed to ozone under dry conditions appear to undergo additional processing upon deliquescence; volatilisation is observed only after a full deliquescence event and after multiple relative humidity cycles the hygroscopicity closely resembles particles obtained from wet initial ozonolysis conditions.

Our experimental hygroscopic growth curves for maleic acid indicate water uptake before the onset of full deliquescence. Ozonolysis of the solid-phase aerosols in this RH region (60-80%) indicates that significant chemical processing occurs including formation of products requiring water (Figure 1). Hence water uptake, as well as particle phase, is a key factor in organic aerosol oxidation.

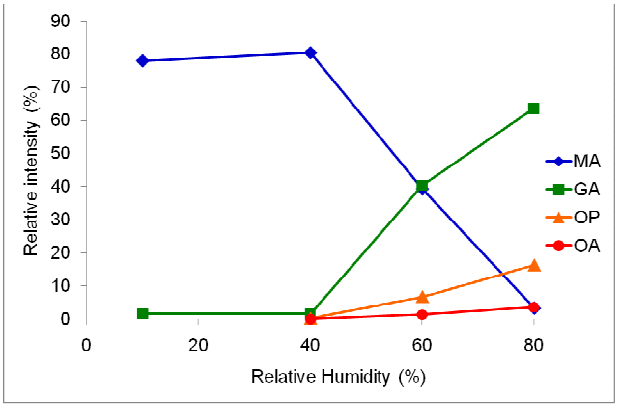

Figure 1: Chemical composition of maleic acid (MA) aerosol processed with ozone (200 ppmv, 3 hours) as a function of relative humidity. Glyoxylic acid (GA) is formed in low yields under dry conditions but becomes a major aerosol component above 60% RH, where pure MA shows water uptake. 2,3-dioxopropanoic acid (OP) and oxalic acid (OA) are only observed in this region.

In summary, the chemical composition and mass of oxidised maleic acid aerosol is found to depend strongly on the relative humidity during and after ozonolysis. The complete history of the processed particle is important, with dry processed particles exhibiting a "memory effect" upon deliquescence. We will propose a chemical mechanism consistent with the observations, placing emphasis on the key role of water uptake in understanding the chemical and physical processing of organic aerosol. The implications of these chemical differences for global aerosol populations, formation of gaseous oxygenated volatile organic compounds, and the cloud nucleation behaviour of the aerosols will be provided.

Gas uptake and chemical aging of amorphous semi-solid aerosol particles

Manabu Shiraiwa[1], Markus Ammann[2], Thomas Koop[3], Ulrich Pöschl[1]

[1]Max Planck Institute for Chemistry, Department of Biogeochemistry, Mainz, Germany
[2] Paul Scherrer Institute, Villigen, CH-5232, Switzerland
[3] University of Bielefeld, Faculty of Chemistry, Bielefeld, Germany
Keywords: bulk diffusion, amorphous semi-solid, ozone, protein
Presenting author email: m.shiraiwa@mpic.de

Atmospheric aerosol particles may occur as solid or liquid or as a mixture of both depending on their compositions and ambient conditions. Carbonaceous combustion aerosol particles such as soot and related substances are known to be solid and undergo chemical reactions at the surface rather than in the bulk (black or elemental carbon, graphene, polycyclic aromatic hydrocarbons). Until recently, secondary organic aerosol (SOA) particles formed in the atmosphere from condensable oxidation products of volatile organic compounds were assumed to be liquid. Virtanen et al. (2010), however, showed that biogenic SOA particles formed in plant chamber experiments and in new particle formation events over boreal forests can adopt an amorphous semi-solid state. Many organic substances, including carboxylic acids, carbohydrates and proteins, tend to form amorphous phases upon cooling or drying of aqueous solution droplets. Depending on viscosity and microstructure, the amorphous phases can be classified as glasses, rubbers, gels, or highly viscous liquids (Mikhailov et al. 2009).

Here we demonstrate how molecular diffusion in the condensed phase affects the gas uptake and chemical transformation of semi-solid particles. Flow tube experiments show that the ozone uptake and oxidative aging of amorphous protein is kinetically limited by bulk diffusion. The reaction rate depends on the diffusion coefficients of both the gaseous and the condensed phase reactants, which can be described by a kinetic multi-layer flux model (Shiraiwa et al. 2010) but not by the traditional resistor model approach of multiphase chemistry (Pfrang et al. 2010). Based on numerical simulations, we present first spatial and temporal profiles of the concentration and reaction rate of ozone and reactive amino acid residues in an amorphous protein matrix. The chemical lifetime of reactive compounds in atmospheric particles can increase from seconds to days and more as the diffusion coefficients decrease over ten orders of magnitude from liquid to solid state. These results and related recent studies demonstrate that the occurrence and properties of amorphous semi-solid phases challenge traditional views and require advanced formalisms for the description of organic particle formation and transformation in atmospheric models of aerosol effects on air quality, public health, and climate.

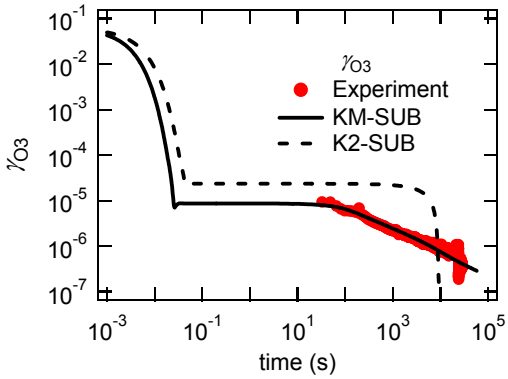

Figure 1. The KM-SUB modeling results of ozone uptake experiments with amorphous protein at 42 ppb O_3. Experimental data and modeled γ_{O3} and surface and bulk accommodation coefficients ($\alpha_{s,O3}$, $\alpha_{b,O3}$).

Heterogeneous uptake of HO_2 onto submicron aerosol particles

The hydroxyl (OH) and hydroperoxyl (HO_2) radicals, together known as HO_x, play an important role in atmospheric chemistry by controlling the oxidative capacity of the troposphere. HO_x radicals determine the atmospheric lifetime and concentrations of many trace reactive species, such as NO_x, O_3 and volatile organic compounds (VOCs). Tropospheric OH reactions with reduced trace atmospheric gases, such as SO_2, NO_x and VOCs, lead to the production of inorganic and secondary organic aerosol mass. Therefore, the ability to accurately predict atmospheric concentrations of HO_x radicals from a detailed knowledge of their sources and sinks is necessary to gain a complete understanding of atmospheric chemistry.

Several recent field studies have observed significantly lower steady-state concentrations of HO_2 radicals than predicted using box models (Sommariva, 2006; Kanaya, 2007). Modeling studies have suggested that heterogeneous HO_2 reaction with atmospheric aerosol particles can be an important HO_x sink (Martin, 2003, Tie, 2005). However, relatively few laboratory studies have been performed to determine the kinetic parameters for HO_2 loss onto aerosols, and thus the impact of this mechanism on HO_x levels is unclear. To bridge this gap in knowledge, we conducted laboratory experiments to measure the HO_2 uptake kinetics onto submicron aerosol particles that are representative of tropospheric aerosols.

HO_2 radicals were produced by the photolysis of water vapour in the presence of O_2 and the FAGE (Fluorescence Assay by Gas Expansion) technique was used to monitor HO_2 uptake kinetics onto aerosol particles in an aerosol flow tube setup. The FAGE technique is a highly sensitive laser induced fluorescence based detection method that has been utilized here so that kinetic experiments could be performed under low HO_2 concentrations, i.e. $[HO_2] < 10^9$ molecules cm^{-3}. Particle size distributions were measured with a Scanning Mobility Particle Sizer (TSI). The reaction time between HO_2 radicals and aerosol particles was varied by translating a movable injector. Aerosol particles were produced either by atomizing dilute salt solutions or by homogeneous nucleation.

First order rate coefficients of heterogeneous HO_2 loss were measured as a function of aerosol surface area and were used to calculated reactive uptake coefficients (γ). The mass accommodation coefficient of $\alpha = 0.8 \pm 0.2$ was determined by measuring HO_2 uptake onto Cu(II)-doped ammonium sulfate aerosols. Reactive uptake coefficients have been determined for aqueous and solid submicron NaCl and $(NH_4)_2SO_4$ particles and several organic acids with a wide range of hygroscopicities as representative models for atmospheric aerosols. HO_2 uptake coefficients on solid particles were below detection ($\gamma < 0.004$), whereas on aqueous aerosols uptake was significantly larger ($\gamma = 0.02 - 0.05$). Experiments are currently being conducted to study both temperature and humidity dependent uptake kinetics as well as HO_2 uptake on more chemically complex environmentally relevant samples. These results suggest that particle phase should be taken into account when modeling the impact of HO_2 uptake on aerosols as a HO_x sink.

SPACCIM model studies of tropospheric aerosol-cloud interactions with the extended multiphase chemistry mechanism MCM-CAPRAM

A. Tilgner, P. Bräuer, R. Wolke and H. Herrmann

Department of Chemistry, Leibniz-Institut für Troposphärenforschung,
Permoserstr. 15, Leipzig, 04318, Germany

Keywords: aerosol modelling, multiphase chemistry, aerosol cloud interaction, organic aerosols
tilgner@tropos.de

A great variety of organic compounds is emitted into the troposphere and is then oxidised by complex multiphase degradations leading to secondary organics which partition between the tropospheric gas and aqueous phase incl. deliquescent aerosol particles and cloud droplets. Oxidised organics play a key role in tropospheric chemistry and account for a substantial fraction of tropospheric aerosol mass. Multiphase processes in fog droplets, cloud droplets and deliquescent aerosol particles can potentially alter the physico-chemical composition of the tropospheric aerosol on a global scale (*Ravishankara, 1997*). However, the chemical multiphase processing, i.e. secondary formation and aging mainly of organic aerosol constituents remains poorly considered in current multiphase chemical mechanisms and models.

In order to model complex tropospheric multiphase chemical interactions of cloud droplets and deliquescent aerosol particles, chemical mechanisms with a detailed description of chemical processes in both the gas and the aqueous phase are required. Hence, the Master Chemical Mechanism (MCM v3.1, *Saunders et al. 2003*) and the Chemical Aqueous Phase RAdical Mechanism (CAPRAM3.0; *Tilgner and Herrmann, 2010)* were recently coupled aspiring to a near-explicit multiphase chemical mechanism (see *Herrmann et al., 2010a*). In order to study the organic aerosol cloud processing in more detail, this mechanism was integrated into the model framework SPACCIM (Spectral Aerosol Cloud Interaction Model, *Wolke et al. 2005*). This parcel model SPACCIM combines a complex microphysical and multiphase chemistry and therefore allows for complex multiphase chemistry modelling of aerosol–cloud interactions focusing on organic aerosol constituents.

As demonstrated by a scoping study, about 60% of the MCM gas phase compounds (about 2100 species) are very water-soluble compounds which might efficiently partition into the aqueous phase and perhaps participate in the chemical aerosol–cloud processing. For those species there is a need to implement their phase transfer and their aqueous phase chemical processes in multiphase mechanisms such as MCM-CAPRAM.

Aiming at a future near-explicit chemical multiphase mechanism with an equivalent description of the organic aerosol chemistry in both the gas and the aqueous phase, the phase transfer for the most soluble MCM compounds has been implemented in the coupled MCM-CAPRAM based on both measurement data (see e.g. *Sander, 1999*) and estimation methods (e.g. *Raventos-Duran et al., 2010*). The latter were needed because measured phase transfer parameters, such as Henry coefficients, gas phase diffusion coefficients and mass accommodation coefficients are not available for most of the organic compounds. Furthermore, hydrations and dissociations were added to the mechanism. Furthermore, the CAPRAM mechanism was updated with recently published kinetic data (e.g. *Herrmann et al., 2010b*) and an extended C_3 chemistry (*Bräuer et al., 2011*).

SPACCIM model studies have been performed for different environmental conditions using a non-permanent cloud scenario. The model studies were carried out to investigate multiphase chemistry and the partitioning of organic compounds in tropospheric deliquescent aerosol particles and cloud droplets in more detail. The model studies were focused e.g. on the influence of organic acids for the aqueous phase acidity, multiphase chemistry of tropospheric oxidants. The model results are analysed including time-resolved reaction flux analyses in order to identify important multiphase oxidation pathways leading to the formation of organic aerosol constituents such as substituted mono- and diacids.

Clouds play a crucial role in the chemistry of the atmosphere, occupying, on average, ~ 15 % of the volume of the lower atmosphere (Lelieveld & Crutzen, 1990). Modelling studies have shown that aqueous phase chemistry in clouds can influence gas phase radical chemistry and in turn can cause significant reductions in the oxidative capacity (e.g. Lelieveld & Crutzen, 1991; Kreidenweis et al., 2003) and, hence, removal rate of VOCs. A number of aircraft projects have identified significantly reduced HO_2 concentrations when flying through clouds that exceeds the depletion expected due to the reduction in radiation alone (Olson et al., 2004; Commane et al., 2010). These experimental observations are relatively sparse, however, and until recently a comprehensive study to validate model predictions has been lacking.

Here we report preliminary measurements of OH and HO_2 radicals made during the HCCT (Hill Cap Cloud Thuringia) project that took place at Mt. Schmücke, Thuringia in Germany during September/October 2010. The University of Leeds Fluorescence Assay by Gas Expansion (FAGE) instrument was located at the summit of Mt. Schmücke and made near-continuous measurements of the radicals at the top of a 22 m tower. The site was regularly influenced by clouds throughout the measurement period and co-located measurements of liquid water content were made at the site enabling the influence of this microphysical parameter on the radical budget to be determined. On average, the photolysis rate of O_3 to form $O(^1D)$, the primary daytime source of HO_x radicals, was ~ 65 % lower in-cloud relative to the out of cloud observations. The HO_2 concentrations were significantly depleted in cloud, with concentrations ~ 90 % lower relative to the out of cloud observations; an OH signal above the noise of the instrument was not observed during cloud events. These results suggest that heterogeneous processes in clouds do perturb the gas-phase radical chemistry. Further investigations into the dependency of the uptake efficiency on the different microphysical and chemical conditions encountered during the different cloud events will also be presented.

The authors are grateful to the Leipzig Institute for Tropospheric Research for financial support to participate in HCCT, and to Prof. H. Herrmann and others for logistical support. Phase Transitions and Separation of Mixed Organic-Inorganic Particles

M.L. Smith, A.K. Bertram, S.T. Martin

School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, USA

Keywords: phase transitions, secondary organic material.

Atmospheric particles containing both organic and inorganic components can transition between solid and aqueous phases in response to fluctuations in ambient relative humidity. These particles can also phase separate into multiple liquid phases depending on the amount of particulate water, the organic volume fraction (ε), and the chemical properties of each component. The parameterization recently developed by Bertram et al. (2011) predicts that aqueous phase separation is more likely to occur as the O:C of the organic material is decreased. Liquid-liquid phase separation in mixed particles should allow inorganic material to deliquesce and effloresce as it does in its pure state. In the absence of phase separation, organic molecules can cause significant deviations from pure inorganic behavior.

The deliquescence and efflorescence behavior of laboratory generated organic-ammonium sulfate particles were investigated using a 1×3 tandem differential mobility analyzer. Organic material was generated via α-pinene dark ozonolysis (O:C = 0.39-0.44; Smith et al. 2011) and isoprene photooxidation (O:C = 0.67-0.74; Smith et al., in preparation).

The deliquescence and efflorescence relative humidities (DRH and ERH, respectively) of all particles containing α-pinene dark ozonolysis products ($0.0 < \varepsilon < 0.96$) deviated less than 5% RH from the DRH and ERH of pure ammonium sulfate.

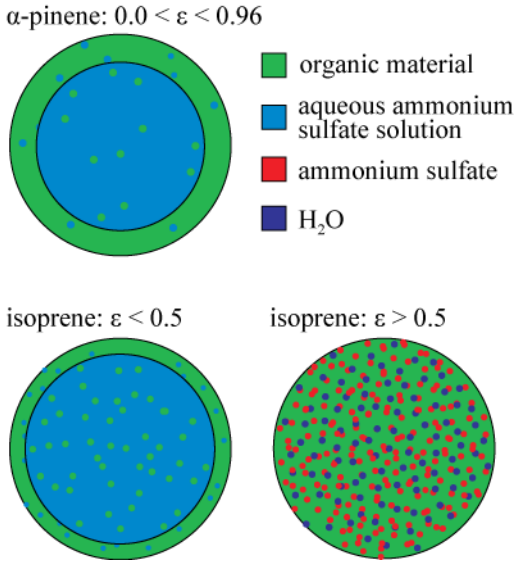

Figure 1. Illustration of the proposed dependence of aqueous phase particle morphology on VOC precursor and organic volume fraction.

The minimal influence of the organic material on the hygroscopic properties of ammonium sulfate suggests that two liquid phases are present in aqueous particles at the water activities of the DRH and ERH. A small negative correlation between both DRH and ERH and organic volume fraction was observed, implying that mixing between the two phases was increased slightly as the organic volume fraction was increased.

The organic material generated via isoprene photooxidation induced greater deviation from pure ammonium sulfate behavior than the α-pinene dark ozonolysis products. The DRH of mixed particles decreased by up to 10% RH, while the ERH decreased by > 20% for particles of high organic volume fraction. The implication is that isoprene photooxidation products are miscible with the aqueous inorganic phase, and can therefore significantly alter the hygroscopic behavior of ammonium sulfate.

These combined results show that phase separation and its subsequent impact on hygroscopic properties vary among VOC precursors and oxidation method. Additionally, the O:C of the secondary organic material emerges as a useful predictor of aqueous phase morphology, with more pronounced phase separation observed for organic material of lower O:C.

The presented material is based upon work supported by the National Science Foundation under Grant No. 0925467 and a Graduate Research Environmental Fellowship from the Global Change Education Program of the Department of Energy.

Laboratoire de Physico-Chimie des Processus de Combustion et de l'Atmosphère (PC2A), UMR CNRS 8522, Université Lille 1, Cité Scientifique - Bâtiment C11, 59655 Villeneuve d'Ascq, France

Keywords: aerosol chemistry, sea-salts, multiphase processes
raluca.ciuraru@univ-lille1.fr

INTRODUCTION

Sea-salt particles are the principal constituent of aerosol particles in the marine boundary layer. Although the dominant mass fraction of marine aerosol is inorganic sea salt, organic matter also contributes to the overall mass. It has been reported that marine aerosols contain an organic fraction being mainly made up of fatty acids. Resulting from biological activity, it is assumed that fatty acids are ejected into the atmosphere along with sea salt and are found in the particles or on their surface [(1)]. In the marine boundary layer, the fatty acids detected in the sea-salt particles whose chain contains between 14 and 19 carbon atoms, are mainly tetradecanoic acid, palmitic acid and stearic acid [(2)]. Once in the atmosphere, these particles are oxidized by collisions was gas-phase radicals. Although OH radicals are the main daytime oxidants, halogen atoms may significantly participate to the oxidation processes especially in the marine boundary layer.

The chlorine atoms ($Cl^{\cdot}$) may represent the major oxidant of the troposphere at dawn at low concentrations of OH radicals. Chlorine atoms have been detected in high concentrations not only in the marine boundary layer, but also at long distances from the coast [(3)]. Chlorine atoms are the products from the photolysis of chlorine species and their concentrations can be up to 10^6 atom.cm^{-3} [(4)]. It has been reported that $Cl^{\cdot}$ reacts more rapidly than OH radicals with hydrocarbon compounds [(4)]. A recent review [(5)] focused on the heterogeneous oxidation of atmospheric aerosol particles has reported measurements of high value for uptake coefficient by radicals ($\gamma \geq 0.1$).

In order to contribute to a better understanding of the heterogeneous reactivity between these aerosol particles and chlorine atoms, kinetic studies has been developed in our laboratory.

EXPERIMENTAL

The aim of this work is to study the kinetics of reactions between $Cl^{\cdot}$ and palmitic acid, one of the most abundant fatty acid of particulate organic matter in the marine boundary layer. These heterogeneous reactions on model substrates have been investigated in a laminar wall flow tube reactor. The principle is to put the gas phase, containing $Cl^{\cdot}$ in contact with the solid surface into a coated wall flow tube reactor. The heterogeneous reactions of chlorine atoms on palmitic acid film, deposited on the internal surface of the reactor, are investigated at low pressure (~1 mbar). The chlorine atoms are generated by a microwave discharge in a mixture of molecular chlorine diluted in helium and detected at the exit of the reactor by a quadrupole mass spectrometer.

The measurement of the first order rate constant, k, is achieved by changing the contact time between the surface and the gas, using a movable injector. From the rate constant, we determine the uptake coefficient, γ, which represents the ratio between the number of gas molecules removed by the condensed phase and the number of gas molecules striking the interface per unit time.

RESULTS

The initial uptake coefficient measured for those heterogeneous reactions is found to be fast, ranging between 10^{-2} and 10^{-1}.

We observed a rapid formation of hydrogen chloride which corresponds with the disappearance of chlorine atoms. These studies have shown that the production of HCl and $Cl^{\cdot}$ consumption is accompanied sometime by consumption or a formation of Cl_2.

In this work, the surface of the film was studied by time-of-flight secondary ion mass spectroscopy (TOF-SIMS) in order to identify the products formed on the palmitic acid surface after exposition to $Cl^{\cdot}$.

To our knowledge this is the first study to investigate the reactivity between chlorine atoms and palmitic acid films.

Further experiments are planned, including identification and quantification of new products formed in the condensed phase by GC/MS.

Aerosols in Geoengineering

Injection of sulfur compounds into the stratosphere by using modified commercial aircrafts

A. Laakso, H. Kokkola, A. Laaksonen, K. E. J. Lehtinen, H. Korhonen
Finnish Meteorological Insitute, Kuopio, 70211, Finland
Keywords: sulfate aerosols, aicraft plumes, stratospheric aerosols, modelling

Predicted rapid climate change has increased the need to affect and slow down global warming especially by reducing emissions of greenhouse gases. However, global efforts to reduce emissions have not been sufficiently successful. Emissions of greenhouse gases are still increasing faster than ever before and there is no quick reversal in sight for this trend. Because of this, alternative methods have been brought out as means to slow down global warming. These methods are called geoengineering.

Geoengineering methods aim to increase the reflectivity of the Earth or remove greenhouse gases from the atmosphere. Several technical methods to limit climate change have been suggested, e.g. orbital mirrors placed in stationary solar orbit filtering sunlight reaching the Earth's atmosphere, seeding sea salt aerosols to brighten marine clouds to reflect more solar radiation back to space, massive reforestation as a mean to reduce atmospheric CO_2 by its uptake by trees, fertilization of ocean by iron, and the proposal that resurfaced the interest in geoengineering, to inject sulphur into the stratosphere to form sulphate aerosols that also reflect solar radiation back to space. Because of the stability of the stratosphere the lifetime of the sulphate aerosol is 1-2 years, when in the troposphere it is only a few days. Thus much less sulfur would be required in the stratosphere to achieve similar cooling as the tropospheric sulfate aerosol and aerosols also have time to spread throughout the lower stratosphere. Estimated 5 Tg S yr^{-1} of stratospheric sulfate would be continuously required to compensate the warming caused by a doubling of CO_2 (Crutzen, 2006).

Numerous methods have been proposed for delivering sulfate aerosol precursors, e.g. military or tank jets, modified artillery, and high altitude balloons. One method that has not been considered in previous studies is to deliver sulphate aerosols to the stratosphere would be to use commercial aircraft that could be modified to fly in the lower stratosphere. One previous example of such vehicles are supersonic transport (SST) aircraft. It has been estimated that one SST emitted 9000 kg of SO_2 per year (Zhao, 1995). In stratosphere, SO_2 is oxidised sulphate which forms sulphate particles with characteristic sizes of several tenths of a micron. It has also been estimated that by using a fleet of 500 SST, the resulting particle concentration at steady state would vary between 35-380 cm^2. If emitted sulfur forms small particles soon after combustion, the concentration would be larger than if sulfur condenses on the existing background aerosol after dispersion and conversion to H_2SO_4 (Fahey, 1995). It is also possible that we can get even larger concentration by enhancing aircraft fuel with sulphur compounds. If we enchanced fuel sulphur contents of 1 per cent by weight, then annual consumption of approximately 100 Tg of fuel (which is used by current aviation) could emit 1 Tg of sulphur. 1 Tg of sulphur would eventually generate roughly 4 Tg of sulphate aerosols (Rasch, 2008). This method can be assumed to have relatively low cost since stratospheric sulfate production would be a by-product of air transport.

There are some constrains which have to be taken into account if commercial aircrafts are used to inject sulphur to the stratosphere. Firstly, most of the current flight routes are in the northern hemisphere and this would limit the aerosol forcing mostly to the northern hemisphere. Secondly, stratospheric travel altitude is feasible only the sufficiently long flights.

The aim of this study is to examine, if it is plausible to reduce radiative forcing by adding sulfur compounds to stratosphere using modified commercial aircrafts and current flight routes above oceans. We will investigate if we get the desired effect with the current number of flights or sulphur concentration of aircraft fuel, or do we have to make changes to the flight routes. Also, we will estimate local climate change and possible undesirable effects such as depletion of stratospheric ozone. The simulations will be made using aerosol-climate model ECHAM5.5-HAM2.

Geoengineering the Earth's Climate – An assessment of potential effectiveness and side-effects

A. K. L. Jenkins, P. M. Forster

School of Earth and Environment, The University of Leeds, Leeds, LS2 9JT, United Kingdom
Keywords: aerosol cloud interaction, sea salt, cloud microphysics, climate effect.
Presenting author email: eeaklj@leeds.ac.uk

Geoengineering is "the deliberate large-scale intervention in the Earth's climate system, in order to moderate global warming" (Shepherd, 2009).

Clouds have a significant influence on the Earth's climate system. In addition to playing a crucial role in the hydrological cycle, clouds directly affect the radiation budget of the Earth with a net cooling effect of 13 Wm^{-2} (Ramanathan, 1989).

We undertake modelling experiments into a geoengineering scheme that proposes the manipulation of marine stratocumulus clouds. The scheme (Salter, 2008) proposes using wind-driven vessels to spray sea-water into the marine boundary layer in order to increase the cloud condensation nuclei (CCN) concentration. By the first indirect aerosol effect (Twomey, 1974), this is intended to increase the planetary albedo, and hence create an additional cooling.

Several previous investigations have considered the effects associated with an increased CCN located at particular sites (Jones *et al*, 2009, Rasch *et al* 2009). These studies have widely ranging outcomes, particularly in regional precipitation, with high dependence on the location and extent of geoengineering. The CCN concentrations assumed in these studies may however have been overestimated (Korhonen *et al*, 2010).

It is known that the cellular structure of marine stratocumulus clouds is highly sensitive to background CCN concentration and liquid water path (Wang *et al*, 2011). The flux and size distribution of the sprayed sea-water, as well as the concentration and composition of background aerosols will be critical to changes in cloud characteristics and behavior.

We use the WRF-Chem model to investigate these effects at a regional scale (250 km by 250 km), using data from the VOCALS campaign. In development of previous work in this area we look at detailed aerosol cloud interactions and their local modification of stratocumulus.

Results are highly dependent on background conditions and injection methodology, with sea-salt injection producing either an increase or reduction of cloud albedo.

We comment on the significance of our results for the implementation of geoengineering by modification of marine stratocumulus clouds with sea-spray.

Sensitivity Studies on the Role of Particle Sedimentation and Subscale Microphysics within a Geoengineered Stratosphere.

F. Benduhn[1] and M.G. Lawrence[1]

Department of Atmospheric Chemistry, Max-Planck-Institute for Chemistry, Mainz, Germany.
Keywords: Stratospheric aerosol, Aerosol modelling, Sedimentation, Subscale processes.
Presenting author email: francois.benduhn@mpic.de

Within the present study some key uncertainties related to the injection of sulphur into the stratosphere as a technique for global scale geoengineering are assessed.

Sedimentation has been regarded as a potential key process which limits the lifetime of stratospheric aerosol (Rasch et al., 2008). Thus, a careful representation of this process seems necessary. The most frequently used representation of this process, namely the up-stream or upstream differencing model, presents the disadvantage of being highly numerically diffusive, thus potentially leading to a misrepresentation of the process, especially in the presence of strong vertical concentration gradients and limited vertical resolution. For this reason, a new scheme with strongly reduced numerical diffusion was developed. The scheme follows a pseudo-equilibrium approach at each grid-box interface by splitting the grid-box aerosol mass distribution into two separate columns, each representative of the mixing ratio of the neighbouring grid cell. The location of the split is chosen appropriately to represent the total tracer mass in the grid cell. Under ideal conditions the scheme is entirely non-diffusive, since the amount of aerosol mass transported in one step does not depend on the amount that was transported during the preceding time-step from grid boxes above, but rather from the same grid-box. However, due to its semi-equilibrium assumptions, the scheme tends to underestimate transport during non-equilibrium situations, e.g. during the build up of an aerosol plume in the stratosphere. In order to accommodate for that effect, the new scheme was combined with the Walcek (2000) advection scheme. The Walcek scheme cannot be used for particle sedimentation without some modifications. As aerosol size discrepancies in the vertical entail that sedimentation is not a monotonic process, the monotonic fixer was not included in the scheme. Aerosol sedimentation fluxes assessed with the modified Walcek scheme are compared to those obtained with the new scheme, and the largest value is then chosen within the combined scheme.

Comparisons with simple analytical solutions demonstrate the effectiveness of both the new scheme and its combined variant to the Walcek scheme to accurately represent particle sedimentation with very little numerical diffusion. 3-D sensitivity studies were carried out with the global chemistry-climate model EMAC (Joeckel et al., 2006). A monodisperse particle distribution (with deactivated particle microphysics) is used in order to evaluate the impact of sedimentation on stratospheric aerosol lifetime. Sedimentation is found to have little impact on the resulting aerosol burden in the troposphere as wet removal processes prove to be more effective. Also, except for large micrometre size particles, sedimentation appears to have little impact on the global burden of the geoengineered stratospheric aerosol, which seems to be mainly driven by large-scale stratosphere-troposphere exchange. However, especially under low vertical resolution conditions, the new schemes very effectively limit diffusive upward transport of particles into the upper stratosphere, thus also limiting the interaction of the aerosol with the local radiation balance, atmospheric circulation and chemistry. Under 3-D conditions the discrepancies between the new scheme and the modified Walcek scheme are shown to be very small.

Another uncertainty which we are investigating is the role of subgridscale aerosol microphysics as related to stratospheric geoengineering. Aerosol microphysical processes are most relevant under conditions of high particle number concentrations (Turco and Yu, 1997, Pierce et al., 2010). For geoengineered particles these circumstances take place just after their injection into the stratosphere. These circumstances cannot be captured by a global general circulation model. The EMAC model is therefore to be implemented with appropriate injection functions that take into account preliminary subscale microphysics. For this purpose we are testing a newly developed function that estimates the time lag between the injection and the handover to the global model as a function of the injection scenario that has been chosen, and first results will be shown.

Atmospheric aerosols - Aerosol Processes and Properties

Radiative forcing from aerosols measured at a coastal site in the Mediterranean

A.R. Esteve[1], V. Estellés[1,2], M.P. Utrillas[1] and J.A. Martínez-Lozano[1]

[1] Department of Earth Physics and Thermodynamics, University of Valencia, Burjassot, 46100, Spain.
[2] Department of Fundamental and Experimental Physics, University of La Laguna, La Laguna, 38207, Spain.
Keywords: atmospheric aerosols, optical properties, aerosol radiative forcing.
Presenting author email: Anna.Esteve@uv.es

Aerosol particles directly affect the Earth's radiative balance through the scattering and absorption of the incident solar radiation (Charlson *et al.*, 1992; Kiehl and Briegleb, 1993). This effect, caused by anthropogenic aerosols, has been termed direct aerosol radiative forcing and may currently have an influence of potentially the same magnitude but in the opposite direction as greenhouse gas forcing (Intergovernmental Panel on Climate Change (IPCC), 2007).

In this work, the aerosol optical properties measured during the year 2009 at Burjassot (Valencia, Spain) (latitude = 39.508°, longitude = -0.418°, 60 meters above sea level) were used to estimate the radiative forcing of anthropogenic aerosols at this coastal site in the Mediterranean. The measured optical properties include the total aerosol scattering (σ_{sp}) and backscattering (σ_{bsp}) coefficients measured using a TSI Model 3563 three-wavelength integrating nephelometer, and the Aerosol Optical Depth (AOD) obtained using a CIMEL CE318 photometer.

First, the Radiative Forcing Efficiency (RFE), which is the amount of the radiative forcing produced by anthropogenic aerosols that increases the optical thickness by one unit, was calculated using the following equation (Haywood *et al.*, 1995):

$$RFE = -DS_0 T_{at}^{\,2}(1-A_c)\omega_0\beta\left\{(1-R_s)^2 - \left(\frac{2R_s}{\beta}\right)\left[\left(\frac{1}{\omega_0}\right)-1\right]\right\}$$

where D is the daylight fraction (changes with latitude and season), S_0 is the solar constant (1370 Wm^{-2}), T_{at} is the atmospheric transmission (0.76), A_c is the mean fractional cloud amount based on data of the 1984-2002 period from the International Satellite Cloud Climatology Project (ISCCP) (Calbó and Sanchez-Lorenzo, 2009), ω_0 is the single scattering albedo, β is the average upscatter fraction (calculated from the backscatter fraction derived from the nephelometer measurements), and R_s is the surface reflectance (0.2).

The monthly variation of the RFE shows a clear variation during the year, ranging from -14 Wm^{-2} in February to -22 Wm^{-2} in July, with a mean value for the whole period of -19 Wm^{-2}. These negative values correspond to cooling effects.

To obtain the Radiative Forcing at the top of the atmosphere (TOA), RFE values were multiplied with the aerosol optical depth provided by the CIMEL CE318 photometer. Radiative forcing at the TOA (Figure 1) shows also a clear variation during the year, ranging from -1.2 Wm^{-2} in December to -4.9 Wm^{-2} in July, with a mean value for the whole period of -3.1 Wm^{-2}. These values are a bit higher but opposite in sign to the forcing induced by the greenhouse gases and estimated to be equal to 2.4 Wm^{-2} (Houghton *et al.*, 1995), and show the important direct role of aerosols in this site of the Mediterranean coast.

Presenting author email: yuanchung.lin@gmail.com

Since spring, 2000, China's dust storms have repeatedly affected Taiwan's air quality and such incidents will only become more frequent given the trend in global climate change. These storms bring lots of sand, dust, and industrial waste from China, increasing the concentration of air pollutants in the atmosphere (Han et al., 2007). With increasing interest in and concern about climate change-related air pollution (Jacob and Winner, 2009; Pang et al., 2009), rising interest has been directed to exploring the dust storms.

Trajectories could reflect the large-scale atmospheric transport characteristics of air mass arriving at Taiwan. They were not only necessary for estimating the long-range transport of pollutants, other chemical species, but also provided a better understanding of airflow patterns (Pongkiatkul and Oanh, 2007). The transport pathway of air masses was determined using backward trajectories from the hybrid single-particle Lagrangian integrated trajectory (HYSPLIT 4)
model. The Asian dust storm event observed in north Taiwan on 3–4 March, 2008 was intense and extensive. Four-day backward trajectories during the period 28, Feb 2008–2, Mar 2008 were shown in Figure 1. The air parcel came from Mongolia, the Gobi desert, and the Losses Plateau, which are the major source regions of Asian dust. The air parcel moved over Shanghai on 29, Feb 2008 and 1, Mar 2008, respectively, and arrived in Taiwan on 3, March 2008. It passed across Shanghai and the East China Sea, and then southwest to north Taiwan. In contrast, four-day backward trajectories calculated before the dust storm during the period 24, Jan 2008–28, Jan 2008 were shown in Figure 2. One air parcel came from south Japan and moved over the Pacific Ocean on 25, Jan 2008–27, Jan 2008, and arrived in Taiwan on 28, Jan 2008. Other air parcels came from Siberia, passed across the border between Mongolia and Inner Mongolia Autonomous Region, Shenyang, the Huanghai Sea, the East China Sea and then southwest to Taiwan. Most backward trajectories calculated before the dust storms are in oceans. Accordingly, the influence of dust and sand before the dust storms is lower than that during the dust storms. Three kinds of trajectory pathways (from 1000, 2000, and 3000 m above model ground level (AGL)) were measured. Sun et al. (2001) also suggested that dust from gobi deserts in Mongolia and China can be entrained only to an elevation of <3000 m in most cases, after analyzing 40-year dust storm data. This NOAA's HYSPLIT trajectory map shows an aerial view of the paths of an air parcel and a vertical view of its movement at three different altitudes. The circles, squares, and triangles lying on each line indicate the position of the air parcel. This backward-trajectory analysis indicates that the prevailing winds at the three altitudes in our sampling period originated in desert areas of China and the air parcel arrived at our sampling site.

Keywords: aerosols, lidar, vertical profile
Presenting author email: pedrose@uv.es

It is now well documented that atmospheric aerosols strongly impact the Earth's radiation balance and climate through the direct scattering and absorption of solar radiation and through their influence on clouds. The aerosol impact depends on the size of the aerosols, on their composition and on how the aerosols are vertically distributed, particularly when dust is present. The estimation of the aerosol direct radiative forcing from measurements at the ground level requires the columnar aerosol optical properties and the aerosol vertical distribution. This demands simultaneous measurements with Sun-photometer and lidar, but this is not always the situation. Even when lidar instrumentation is available, the different schedules of the instruments make the synchronicity (±1 hour) very scarce. In this work we evaluate the influence of the aerosol vertical profile on the aerosol forcing at the Earth's surface and at the top of the atmosphere.

Materials and methods

The aerosol vertical profiles were obtained with a lidar instrument was developed by the Polytechnic University of Catalonia, Barcelona, Spain. It is based on a frequency-doubled Nd:YAG laser delivering simultaneously pulses of approximately 160 mJ and 7-ns duration at 1064 and 532 nm (Rocadenbosch, 2002).

The aerosol radiative forcing can be estimated from the change in the net flux either at the top of the atmosphere or at the surface, with and without aerosols. The employed procedure is based on the one described in Niranjan et al. (2007). The optical and radiative properties of the aerosols are downloaded from the AERONET network DS2 data pool at level 1.5 (AERONET, 2011) and fed into the Santa Barbara DISORT Radiative Transfer (SBDART) model (Ricchiazzi et al., 1998) to derive the aerosol radiative forcing in the shortwave range. SBDART employs the discrete-ordinates solution for the radiative transfer and includes multiple scattering in a vertically inhomogeneous, non-isothermal, plane parallel atmosphere. The ground albedo influences the diffuse radiation, particularly the area of 1-2 square kilometers around the measurement site. Therefore, the AERONET-derived ground is also included as an input data.

Results

A total of 25 different aerosol vertical extinction profiles (see Figure 1) were obtained with the well-known Klett-Fernald-Sasano inversion (Klett, 1984; Fernald, 1985; Sasano 1984) constrained with Sun-photometric aerosol optical depth values measured Barcelona (Spain), in the period 2007-2008. Desert dust intrusions were avoided for this study.

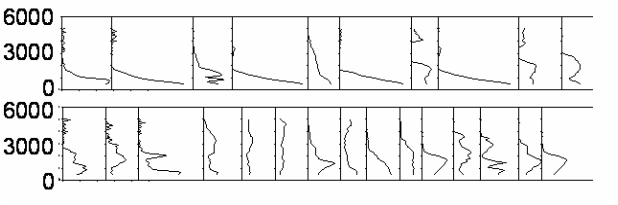

Figure 1. Lidar-retrieved aerosol vertical extinction profiles in Barcelona, Spain, during 2007-2008.

For the simulations we used for all the aerosol profiles the same optical properties and optical thickness of the profile that showed the higher aerosol load (aerosol optical thickness of 0.397), in order to maximize the aerosol effect on forcing. For the comparison we used the average of the 25 profiles, mathematically very similar to an exponential variation.

The results show that when considering the same size and composition of the aerosols, as well as the same aerosol load, the instantaneous forcing at the top of the atmosphere for the 25 profiles deviates less than ±2% with respect to use the average profile. The corresponding deviation for the forcing at the bottom of the atmosphere is less than ±0.1%. This opens the possibility of using an aerosol exponential profile obtained by averaging the available profiles, when there is no lidar data simultaneous to Sun-photometric measurements and in absence of desert dust intrusions.

Global model studies of aerosol indirect effects assume that the cloud droplet number concentration (CDNC) in clouds is given by an adiabatic formation rate. This approach tends to overestimate CDNC, as subsequent entrainment and mixing of dry air in cloud columns are not considered. The goal of this study is to assess the sensitivity of CDNC to diabatic activation (i.e., including effects from entrainment and mixing of dry air) and its first order tendency on indirect forcing and autoconversion rate.

The modeling framework used for this study is the NASA Global Modeling Initiative (GMI). GMI is a global 3D chemical-transport model specifically developed for impact assessment studies. CDNC is calculated using the physically-based prognostic parameterization of *Barahona and Nenes* [2007, hereafter BN07], which parameterizes the effects of entrainment mixing on CDNC through the use of an "effective" entrainment rate. BN07 is an extension of the works of *Nenes and Seinfeld* [2003] and *Fountoukis and Nenes* [2005]; entrainment results in a lower maximum supersaturation and CDNC. Sensitivities are examined under three different meteorological fields from the NASA GEOS4 finite volume GCM (FVGCM), the NASA GEOS1-STRAT (GEOS) and the NASA GISS II' GCM (GISS). Computed CDNC is used to calculate the effective radius. The CLIRAD-SW solar radiative transfer model is used online to calculate the cloud optical depth (COD) and the shortwave fluxes from the surface to the top of the atmosphere (TOA). COD is calculated as a function of the effective radius. Evaluation of modeling results (i.e., cloud droplet effective radius, cloud optical depth) is done against satellite products from Moderate Resolution Imaging Spectroradiometer (MODIS) platform.

Diabatic activation results in lower CDNC than adiabatic treatments of the process. The largest decrease in CDNC (by up to 75%) was found in the Tropics and in zones of moderate CCN concentration (Figure 1). This leads to a global mean effective radius increase between 0.2-0.5μm (up to 3.5 μm over the Tropics), a global mean autoconversion rate increase by a factor of 1.1 to 1.7 (up to a factor of 4 in the Tropics) and a 0.2-0.4 W m^{-2} decrease in indirect forcing (Figure 1). The spatial patterns of entrainment effects on droplet activation tend to reduce biases in effective radius (particularly in the Tropics) when compared to satellite retrievals. This, and the diabatic nature of ambient clouds suggest that entrainment effects on CDNC should be considered in GCM studies of the aerosol indirect effect.

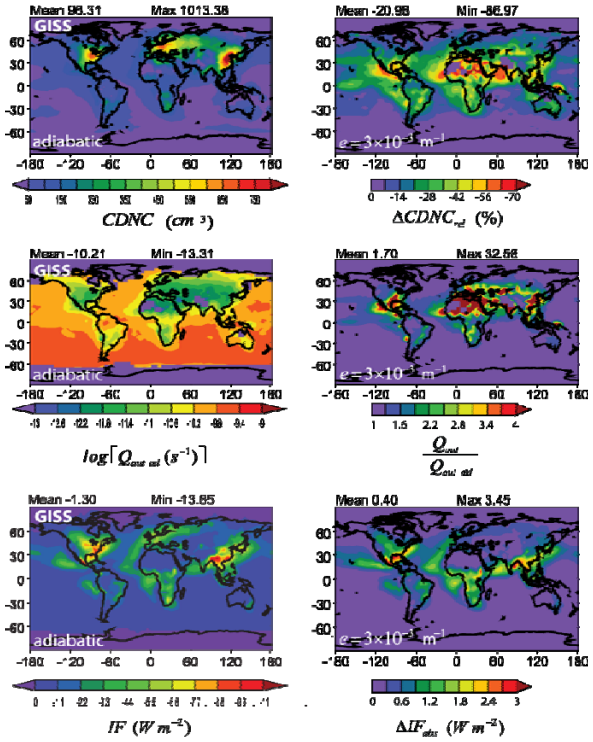

Figure 1. CDNC, autoconversion rate *Qaut*, andindirect forcing (IF) under adiabatic activation (i.e., $e = 0$) (left panels) and corresponding changes for e=3x10^{-3} m^{-1} under GISS meteorology (right panels)

Spatial variability of the direct radiative forcing of biomass burning aerosols in the Amazon Basin and the influence of surface reflectance

E.T. Sena[1], A.L. Correia[1], P. Artaxo[1] and J.V. Martins[2]

[1]Institute of Physics, University of São Paulo, São Paulo, SP, 05508-900, Brazil
[2]Department of Physics, University of Maryland, Baltimore Count, MD, 21250, USA
Keywords: Amazon, radiative forcing, remote sensing.
Presenting author email: artaxo@if.usp.br

In the present work, we used remote sensing techniques in order to obtain the shortwave direct radiative forcing at the top of the atmosphere (TOA) over the Amazon Basin. We analyzed data from 2000 to 2009 acquired by the radiometer CERES (Clouds and the Earth's Radiant Energy System) (Wielicki, 1996) and by the spectrometer MODIS (Moderate Resolution Imaging Spectrometer) aboard Terra satellite during the biomass burning season peak. Due to the high spatial coverage of those sensors it was possible to obtain the spatial distribution of the shortwave radiative forcing at the TOA over the Amazon.

The study area was limited between the latitudes 3ºN – 20ºS and between the longitudes 45ºW – 65ºW plus an additional area between 3ºN – 11ºS and 65ºW – 74ºW. In order to analyze only the direct shortwave aerosol effect we used only cloud-free sky conditions as designated by the MODIS sensor. The full area under analysis was divided in 0.5º x 0.5º (latitude / longitude) cells according to Patadia, 2008. The cell size was chosen so as to maximize the amount of valid pixels inside each cell and minimize its surface reflectance heterogeneity. For each cell we calculated the linear fit of the shortwave radiation flux at the TOA against the aerosol optical depth (AOD). Figures 1 and 2 show the spatial distribution for the average radiative forcing and the average AOD during the months of August and September of 2005 and 2008, respectively.

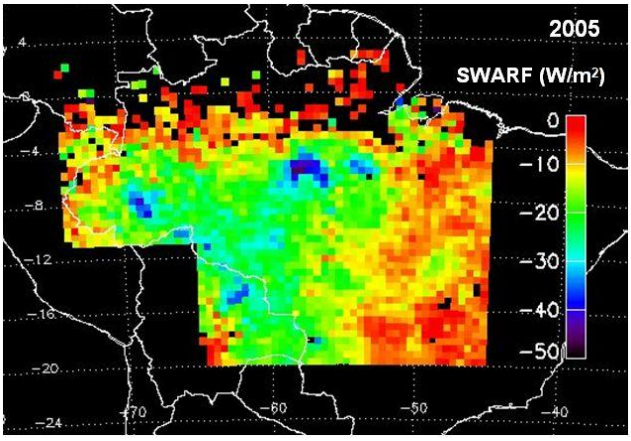

Figure 1: Spatial distribution of the shortwave radiative forcing at the TOA over the Amazon during the biomass burning season of 2005.

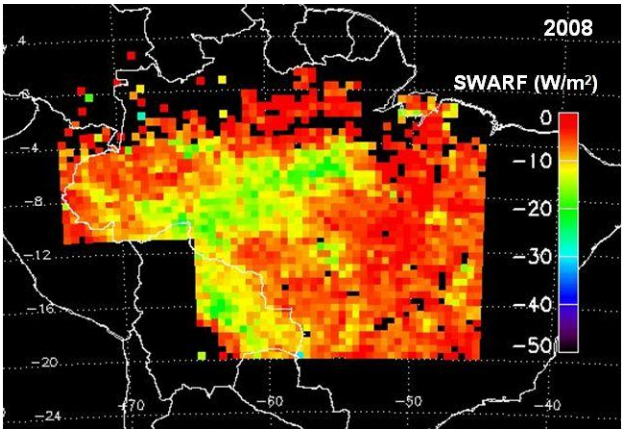

Figure 2: Spatial distribution of the shortwave radiative forcing at the TOA over the Amazon during the biomass burning season of 2008.

The results shown in Figures 1 and 2 indicate that the aerosol radiative forcing at the TOA presents large spatial and temporal variations during the biomass burning season.

As an attempt to understand the impact of land use change in the region we have also studied the behaviour of the radiative forcing with the reflectance at 2.1 μm. It was possible to verify that as the surface reflectance increases the radiative forcing efficiency becomes less negative, with distinct patterns for surface reflectances below and above 8%.

The influence of several other parameters, such as water vapour amount in the atmosphere, solar zenith angle and surface type were studied separately, and presented important contributions in the shortwave radiative forcing of aerosols at the TOA.

This work was supported by FAPESP.

Atmospheric aerosols – Specific Aerosol Types

Spatiotemporal distribution of light-absorbing carbon in Stockholm

P. Krecl[1,2], A.C. Targino[3] and C. Johansson[1]

[1]Department of Applied Environmental Science, Stockholm University, Stockholm, SE-11418, Sweden
[2]Now at School of Earth and Environment, University of Leeds, Leeds, LS29JT, United Kingdom
[3]Universidade Tecnológica Federal do Paraná, Londrina, Paraná, 86036-370, Brazil
Keywords: black carbon, $PM_{10}/PM_{2.5}$, urban aerosols, air quality.
Presenting author email: p.krecl@leeds.ac.uk

Carbon-containing particles have deleterious effects on both Earth's climate and human health. In Europe, the main sources of light-absorbing carbon (LAC) emissions are the transport (67%) and residential (25%) sectors (Kupiainen and Klimont, 2007). Information on the spatiotemporal variability of LAC particles in urban areas is relevant for air quality management and to better diagnose the population exposure to these particles. This study reports on results of an intensive field campaign conducted at four sites (a street canyon site, a kerbside site, an urban background site and a rural station) in Stockholm, Sweden, during the spring 2006.

Light-absorbing carbon mass concentrations (M_{LAC}) were measured with custom-built Particle Soot Absorption Photometers (PSAP) (Krecl *et al.*, 2010). The spatiotemporal variability of M_{LAC} concentrations was explored by examining correlation coefficients (R), coefficients of divergence (COD), and diurnal patterns at all sites. Simultaneous measurements of NOx, PM_{10}, $PM_{2.5}$, and meteorological variables were also carried out at the same locations to help characterize the LAC emission sources.

Hourly mean and standard deviation M_{LAC} concentrations ranged from 0.36 (rural) to 5.39 μg m^{-3} (street canyon) and from 0.50 to 3.60 μg m^{-3}, respectively. Concentrations of hourly LAC between urban sites were poorly correlated (Table 1) and even for daily averages (R<0.70), combined with highly heterogeneously distributed concentrations (COD>0.30) even at spatial scales of few kilometers. This high variability is connected to the distribution of emission sources and processes contributing to the LAC fraction at these sites.

Table 1. Correlation coefficients between hourly M_{LAC} time series measured at the four sites.

R [-]	Kerbside	Urban back.	Rural
Street canyon	0.62	0.48	0.23
Kerbside		0.50	0.27
Urban back.			0.78

At urban sites, M_{LAC} tracked NOx levels and traffic density well and mean $M_{LAC}/PM_{2.5}$ ratios were larger (26-38%) than at the background sites (4-10%). The results suggest that vehicle exhaust emissions are the main responsible for the high M_{LAC} concentrations found at the urban locations whereas long-range transport (LRT) episodes of combustion-derived particles can generate a strong increase of levels at background sites.

Figure 1 displays the weekday concentrations at the different locations relative to the concentrations at the urban background site (100%). For M_{LAC} and NOx, 70-75% of the concentrations were generated in the urban area whereas only 35% of PM_{10} and 5% of $PM_{2.5}$ corresponded to local urban sources. Regarding the kerbside and street canyon stations, M_{LAC} and NOx levels were 310-660% relatively higher than urban background levels whereas PM_{10} and $PM_{2.5}$ concentrations were 130-230% higher relative to the urban background level.

To decrease pollution levels at urban and urban background locations in Stockholm, we recommend abatement strategies that target reductions of vehicle exhaust emissions, which are the main contributors to M_{LAC} and NOx concentrations.

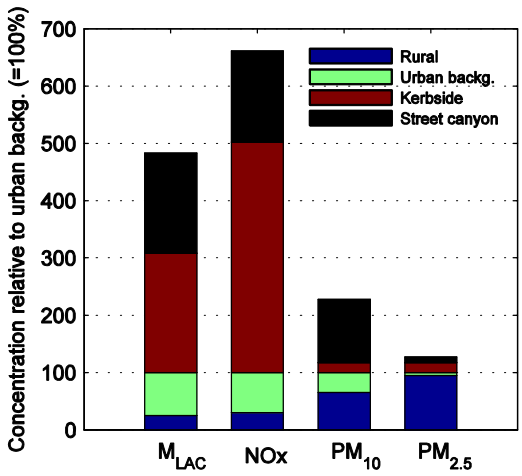

Figure 1. Comparison of weekday M_{LAC}, NOx, PM_{10} and $PM_{2.5}$ levels at the four sites relative to urban background concentrations.

Abstract

Carbonaceous fraction of aerosols impacts the local air quality and climate in several complex ways such as by changing the energy budget of Earth-Atmosphere system and by participating in cloud formation thus changing the cloud optical properties and lifetime (Ramanathan 2007, IPCC, 2007). In last two decades carbonaceous aerosol were linked with change in hydrological cycle leading to draughts and floods in various parts of south Asia (Ramanathan, 2005). However, the role of carbonaceous aerosol in climate change is poorly understood and its quantification is associated with large uncertainties (IPCC 2007, Ramanathan 2005). In Indian context the better understanding of carbonaceous aerosol and their impact on local air quality and climate require a great effort in terms of aerosol measurement and characterization in various parts of India. Therefore, this study was focused on temporal (April 2010 to June 2010) measurement of aerosol and determination of organic and elemental carbon at urban background site of Delhi.

The urban back ground site was ~30 m above the ground level on the roof of administrative building of IIT-Delhi. Fine aerosol mass ($PM_{1.0}$, $PM_{2.5}$) was collected separately during day and night time to investigate the link between aerosol concentration with regional meteorology and long range transport in dry season (from April, 2010 to June, 2010). The particles ($PM_{2.5}$) were analyzed for organic carbon and elemental carbon using thermal optical reflectance (DRI model).

The construction activities for common wealth game in various part of Delhi city resulted in many dust dominated days in the city leading to low $PM_{1.0}/PM_{2.5}$ ratio in April (monthly average 0.6±0.2, n=5) (Table 1). Higher aerosol concentrations were observed during night time compare to day in all the months (Table 1). The higher aerosol concentration during night time could be because of low temperature, low mixing height and calm condition resulting in accumulation of aerosol in the lower troposphere. The average carbonaceous aerosol concentration was highest in April and lowest in June. This paper presents the detail analysis of trends in carbonaceous aerosol concentrations and their possible links with regional meteorology and long range transport.

Table 1 Monthly averaged day and night concentration of $PM_{2.5}$ and $PM_{1.0}$

Month	Average aerosol concentrations (µg/m³)				Ratio	
	$PM_{1.0}$		$PM_{2.5}$		$PM_{1.0}/PM_{2.5}$	
	Day	Night	Day	Night	Day	Night
April	70±35	108±33	144±119	194±106	0.6±0.2	0.6±0.2
May	98±57	118±72	131±60	156±70	0.7±0.2	0.7±0.1
June	109±59	167±115	167±115	199±99	0.7±0.2	0.8±0.1

Particulate carbonaceous matter (PCM) has been observed to contribute significantly to ambient particulate matter concentrations in a wide range of environments, even over remote ocean regions. However, the inherent complexity of the PCM has proved it difficult to quantify and resolve to a compound level. In addition, secondary processes along with chemical processing in the atmosphere, ensures an ever changing nature of PCM, rendering quantitative source apportionment highly challenging. Carbon isotope analysis offers a method for quantitative source apportionment of three principal sources of PCM due to their unique isotopic signatures: i.e. marine, continental (non-fossil) and fossil fuel sources (Ceburnis et al., 2011). In addition, source specific tracers can facilitate an even more detailed source including separation between primary and secondary sources (Gilardoni et al., 2011).

The EMEP monitoring programme along with the EUCAARI project conducted two intensive measurement periods in fall 2008 and spring 2009, focusing on carbonaceous aerosol using both on-line and off-line chemical analysis. In the present study, we report the results from off-line chemical analysis at the Mace Head station (Ireland) where ^{13}C, ^{14}C and ^{15}N were determined in $PM_{2.5}$ filter samples collected according to the quartz-behind-quartz sampling approach along with OC, EC and levoglucosan. Five weekly samples were collected in fall 2008 and four (weekly) samples in spring 2009. Contribution of marine, continental non-fossil, and fossil fuel sources to TCp (particulate TC) is summarised in Table 1, showing the dominance of the continental non-fossil source. An attempt was made to separate continental non-fossil sources into biomass burning (BB) and natural terrestrial sources (BG) by the use of the biomass burning tracer levoglucosan, however, a question remains whether levoglucosan can be an equally good tracer in fresh and aged carbonaceous aerosol for reliable BB source apportionment.

Apart from the source apportionment some new insights were obtained by the determination of stable nitrogen isotope (^{15}N) in spring 2009 samples and stable carbon isotope (^{13}C) in front and back-up quartz filters. A statistically significant difference in nitrogen isotope ratios was obtained between anthropogenically perturbed samples (4.82‰) and clean marine samples (-1.24‰), clearly showing that clean and polluted samples exhibit not only distinct stable carbon isotope ratios but also for nitrogen, as already suggested by Myazaki *et al.* (2010).

Table 1. Contribution of carbonaceous matter sources by dual carbon isotope analysis.

	TC_p, μgC/m^3	Marine μgC/m^3	Cont. non-FF μgC/m^3	FF μgC/m^3
F 1	0.80	0.080	0.58	0.14
F 2	3.02	0.091	2.43	0.50
F 3	0.30	0.053	0.21	0.030
F 4	0.16	0.025	0.071	0.069
F 5	0.16	0.057	0.025	0.076
S 1	0.09	0.053	0.004	0.032
S 2	0.13	0.062	0.050	0.021
S 3	0.75	0.037	0.61	0.11
S 4	2.05	0.21	1.52	0.33

F – Fall 2008, S – Spring 2009, Cont. non-FF – continental non-fossil, FF – fossil fuel.

Stable carbon analysis of the front and back quartz filters suggested that gas phase compounds adsorbed on the back filter, and considered to be responsible for the positive sampling artefact, are "lighter" in terms of stable carbon isotope (~1‰). It can not yet be concluded whether this finding is due to isotopic fractionation or simply is source dependent.

Our findings suggest that continental non-fossil sources are stronger than previously thought and thus should be adequately considered in models.

After the red sludge disaster in Hungary during the autumn of 2010 a marked increase in the mass concentration of atmospheric aerosols in the red sludge hit area around the town of Devecser was observed. A mobile measurement station, which includes our recently developed multi-wavelength photoacoustic instrument (4λ-PAS) (Ajtai et al, 2010) was installed at the heart of the red sludge covered area. With the 4λ-PAS the optical absorption properties of the atmospheric aerosols and especially the light absorbing carbonaceous matter (LAC) was monitored with high time resolution and it was possible to deduce certain conclusions about the chemical composition and possible sources of the atmospheric aerosols.

Although the optical absorption spectra of LAC components are typically almost completely featureless in the visible, nevertheless they have fairly characteristic variations in the UV wavelength region, therefore multi-wavelength measurements (especially of they include wavelengths in the UV) have the potential for their efficient spectral identification (Andreae and Gelencsér, 2006). We have developed a multi wavelength photoacoustic instrument, which operates at four wavelengths (266nm, 355nm, 532nm, 1064nm) which cover the UV, VIS and NIR spectral regions. The wide wavelength range, the in-situ high sensitivity measurements, as well as the non-site specific, generally applicable calibration procedure makes this instrument an indispensable tool for spectral identification of the carbonaceous matter of atmosphere under various field conditions.

In this work we present the results of our field measurements at the red sludge covered area at Devecser shortly after the disaster, which are based on the absorption measurements by the 4λ-PAS and as a reference a commercially available seven wavelength Aethalometer. The analysis of the measured optical absorptions is based on the use of the Angström exponent nomenclature and especially wavelength dependent Angström exponents were used in order to achieve a better fit of the calculated curves to the measured data. From the measurements it can be concluded that during traffic lockdown period biomass burning was the dominant source of aerosols, and aerosols from the red sludge were change the spectral behaviour only during mornings when there was a reduced intensity of biomass burning. Dust from the red sludge appears to have a very sharply increasing optical absorption toward the UV. As soon as the traffic lockdown was removed traffic aerosols became dominating the atmosphere (Fig.1.). Chemical analysis and particle size measurement was found to support the interpretation of the absorption measurement.

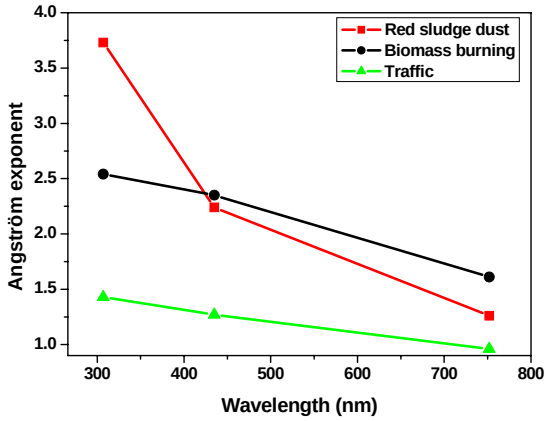

Figure 1. The identified source related spectral features during the field measurements at the area of red sludge disaster.

Presenting author email: Robert.Bergstrom@smhi.se

The EMEP MSC-W chemical transport model (Simpson et al., 2007) has been extended with a new organic aerosol (OA) scheme based on the Volatility Basis Set (VBS) approach (Donahue et al., 2006).

Four different VBS-based schemes, based on the OA models of Lane et al. (2008), Shrivastava et al. (2008) and Murphy & Pandis (2009) have been tested. The models include SOA formation from anthropogenic and biogenic VOC. Reactions of semivolatile OA species in the gas phase with OH may lead to a shift of the reacting OA to lower volatilities (aging of the OA).

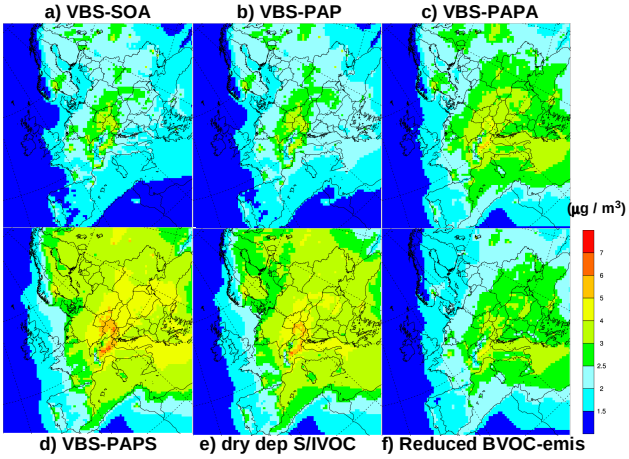

Figure 1. Calculated yearly average total organic aerosol (µg/m^3) for 2008, using different model setups: (a, VBS-SOA) includes a 4-bin VBS-based scheme for SOA formation from anthropogenic and biogenic VOC. Primary organic aerosol (POA) emissions are assumed non-volatile; (b, VBS-PAP) VBS-SOA + partitioning and aging of POA emissions. The emitted POA is distributed over different volatilities (9-bin VBS) and partitions between the gas and particulate phases. The emissions are assumed to be accompanied by emissions of low-vapour pressure gases. Aging reactions for POA in the gas phase are included, using the reaction rate $k_{OH\text{-}POA}=4\times10^{-11}$ cm^3 molecule^{-1} s^{-1}; (c, VBS-PAPA) VBS-PAP + aging of anthropogenic SOA (ASOA), using the reaction rate $k_{OH\text{-}ASOA}=1\times10^{-11}$ cm^3 molecule^{-1} s^{-1}; (d, VBS-PAPS) VBS-PAP + aging of both ASOA and biogenic SOA (BSOA), using the reaction rate $k_{OH\text{-}SOA}=4\times10^{-12}$ cm^3 molecule^{-1} s^{-1}; (e) As (d), but with dry deposition of gas-phase SOA and POA; (f) As (d), but with BVOC emissions reduced by a factor of three.

We present results from model runs, on the European scale, testing various assumptions regarding the emissions and aging reactions of the semi-volatile OA. Some sensitivity tests regarding BVOC emissions and dry deposition of semi-volatile species were also performed. Results are compared to measurement data from several European campaigns, including the EUCAARI-project.

The model results are very sensitive to the assumptions regarding the volatility of the POA emissions and the aging reactions. Several different alternatives need to be explored and detailed comparisons of the model results to chemically speciated observation data (especially source apportionment data) are needed to constrain and validate the model and emissions.

Chemical composition and δ^{13}C values of OC and EC in the size-segregated aerosol particles

A. Garbaras, R. Bariseviciute, K. Kvietkus, J. Sakalys, J. Didzbalis, R. Skipityte and V. Remeikis
Institute of Physics, Center for Physical Sciences and Technology, Vilnius, LT-02300, Lithuania
Keywords: Stable carbon isotopes, Cascade impactor, AMS, PM and source apportionment
Presenting author email: garbaras@ar.fi.lt

Research on the origin and evolution of the chemical composition of aerosol particles is important for understanding the climate change, environmental pollution and environmental self-cleaning processes. Atmospheric aerosol absorbs and reflects radiation from the Sun and heat radiation from the Earth, thus changing thermal balance of the planet. Aerosol absorbs gases, chemical elements and compounds, influences water condensation processes, stimulates photocathalytical reactions and has influence on the global chemical processes in the atmosphere [Ceburnis et al., 2005.]

Organic matter, ammonium, sulphates, nitrates, chlorides in the atmospheric aerosol particles were measured with the Quadrupole Aerodyne Aerosol Mass Spectrometer (Q-AMS). Sampling with the MOUDI impactor and δ^{13}C measurements of total (TC), elemental (EC) and organic (OC) carbon in different aerosol size intervals were performed in parallel to AMS measurements in Vilnius city. At the Preila background station only sampling with the MOUDI impactor was performed. The carbon isotopic ratio of aerosol particles were measured with the EA-IRMS system (FlashEA 1112 - ThermoFinnigan delta plus advantage) [Garbaras et. al., 2009]. TC, EC and OC isotopic data comparison in Vilnius (urban) and Preila (background) showed that (Fig. 1):

a) TC in Vilnius varied from -27 to -24 ‰, while in Preila from -28 to -26 ‰;

b) EC in Vilnius varied from -31 to -26 ‰, while in Preila from -28 to -25 ‰;

c) OC in Vilnius varied from -22 to -28 ‰, while in Preila from -28 to -27 ‰.

Carbon isotopic analysis shows that the aerosol particles in the accumulation and coarse modes had the same source, and this source was different for Vilnius and for Preila. Carbonates were present in Vilnius in coarse mode probably from the road sprinkle with the mixture of sand an a salt.

Carbon isotope ratio measurements in size-resolved aerosols allow identifying aerosol sources more precisely, especially if OC and EC separation is performed. Combination of QAMS data with δ^{13}C is a promising tool for the aerosol particle source apportionment.

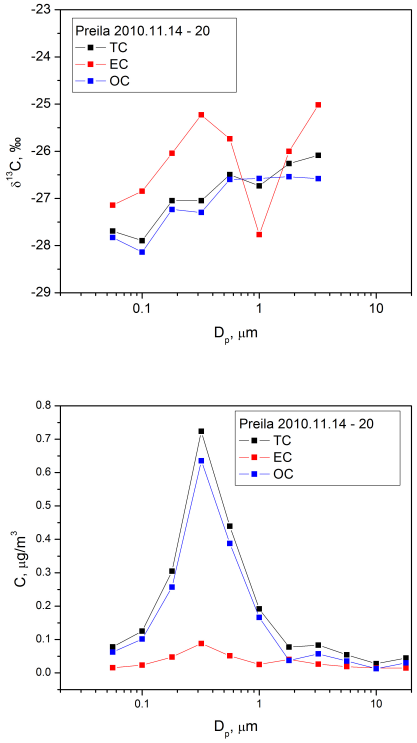

Figure 1: δ^{13}C and concentration of TC, EC and OC in aerosol particles, collected with the MOUDI impactor at Preila background station, Lithuania.

.

Aerosols are important for the Earth's climate and have a negative impact on human health (Pope and Dockery, 2006). Carbonaceous particles (total carbon, TC) are a major fraction of the fine aerosol and are classified into the subfractions elemental carbon (EC) and organic carbon (OC) (Jacobson *et al.* 2000). EC originates from fossil-fuel combustion and biomass burning. OC can be emitted directly as primary organic aerosol from biogenic sources, wood burning and fossil fuel combustion or can be formed in the atmosphere as secondary organic aerosol (Szidat *et al.* 2006).

Analysis of the radioactive isotope ^{14}C is a unique tool for distinguishing fossil and non-fossil sources of carbonaceous aerosol, because ^{14}C in fossil fuels is completely depleted whereas other sources have a contemporary ^{14}C level (Szidat *et al.* 2006). The $^{14}C/^{12}C$ content in the EC and OC fractions provides a quantitative and unambiguous measurement of the fossil/non-fossil carbon, thereby directly addressing a major uncertainty in the present understanding of organic aerosol sources.

Previous ^{14}C analyses have been performed on aerosol filters with a sampling time ≥12h. This study presents the first ^{14}C measurements performed on high time resolution (3-4 h) filter samples. As a result a diurnal pattern with the fossil and non-fossil composition of carbonaceous aerosols can be resolved.

Filter sampling was conducted during the CalNex-2010 field campaign from the 15th of May to the 16th of June 2010 at the California Institute of Technology (CALTECH), located about 20 km northeast of downtown Los Angeles using high-volume samplers with PM_1 and $PM_{2.5}$ inlets with a time resolution of 3, 4 and 24h.

Separation of the EC and OC fractions is carried out using the THEODORE system (Szidat, *et al.* 2004b) and a Sunset ECOC Analyzer. The evolving CO_2 is cryo-trapped and sealed in glass ampoules for ^{14}C measurements which are then performed with the mini radiocarbon dating system MICIDAS (Ruff *et al.* 2007) at the Swiss Federal Institute of Technology ETH Zürich.

First results from PM_1 filters for TC for the 4th of June (see Figure 1) show a distinct diurnal variation for TC with a peak for fossil TC in the early afternoon. The non-fossil fraction stays roughly constant between 2 and 3 µg/m^3 throughout the day. During high concentrations the fossil fraction of TC is very high indicating that the increase of the TC values in the early afternoon mainly stems from traffic related emissions. During low concentrations the non-fossil fraction constitutes ~50% of TC even though the Los Angeles area is strongly influenced by traffic-related emissions. This indicates that biogenic, biomass burning, cooking or other contemporary carbon sources also significantly affect the total carbon budget in urban areas. Trends in the fossil and non-fossil composition of aerosols in the Los Angeles area will be further analyzed by ^{14}C measurements of the EC and OC fraction and by comparison with aerosol mass spectrometry (AMS) and other data measured during the CalNex-2010 field campaign.

Transformation by aging processes of soot particles from laboratory combustion experiments

J.K.Brooke[1], J.B.McQuaid[1], B.J.Brooks[1], S.Osborne[2] and J.M.Wilson[1]

[1]Istitute for Climate and Atmospheric Science, University of Leeds, LS2 9JT, UK

Keywords: Carbonaceous aerosol, Biomass burning, Optical properties
Presenting author email: eejkb@leeds.ac.uk

Black carbon is the most abundant light absorbing particle in the atmosphere; it is an efficient absorber of solar radiation in the atmosphere and re-radiates the energy in the form of thermal energy and results in localised heating in this area, Buseck and Posfai (1999). Emissions of black carbon are a global phenomenon associated with incomplete combustion activities from fossil fuel and biofuel whilst with an estimated 40 % of global emissions of black carbon are from biomass burning, IPCC (2007).

The atmospheric lifetime of black carbon is short, and a reduction of BC emissions may be an effective method of mitigating climate change; such a reduction in BC emissions would equally benefit health and air quality. The lifetime of black carbon is dependent on the aging processes and deposition rates Schwarz *et al* (2006).

The aging process of soot consists of a change to the morphology and size distribution of soot particles; compaction of fractal aggregates of soot with time has been reported as a method of aging, Lu *et al* (2008) whilst hygroscopicity of soot particles has an important influence on their lifetime, Weingartner *et al* (1997). The aging process is not well understood, with changes in size distribution of soot, in models being poorly represented. An experimental set-up has been developed to observe changes the size distribution of soot particles as the particles age.

Laboratory experiments enable properties of soot particles to be characterised under controlled conditions, which remove the problems associated with field studies; variation in combustible material, burning conditions and atmospheric processes. Laboratory experiments enable a simplification of complexities of the combustion process.

The set-up involves a combination of two well proven systems; Optical particle counter (OPC) and Scanning mobility particle sizer (SMPS), an instrument combination which enables a wide range of particles to be observed (20 nm to 1 µm). Environmental Scanning Electron Microscopy (ESEM) will be used to examine the 3-dimensional shape of soot particles in order to understand soot surface topography and composition as particles age under varying reaction conditions.

Reaction chambers (280-L) are constructed and experiments are carried out with particles of known size and charge to determine wall loss rates which will be compared to theoretical predictions. Aerosol wall-loss rates are determined by observing changes to aerosol particle concentrations with time in the reaction chamber, McMurry and Grosjean (1985).

Preliminary experiments have been carried out to determine the initial polydisperse size distribution for a range of biofuels and hardwoods. Figure 1a shows the size distribution data of freshly emitted (240 s) soot from biofuel eugenol, as measured by the OPC. The difference in optical diameter and aerodynamic diameter for the eugenol soot is highlighted in Figure 1b.

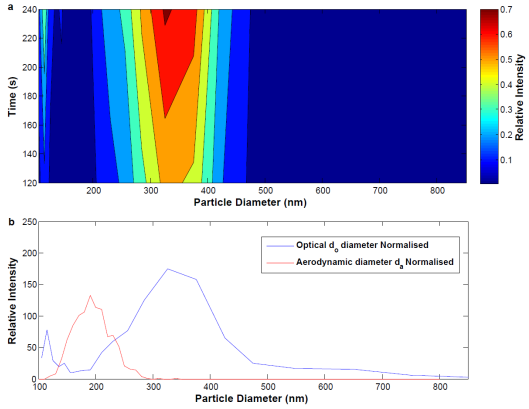

Figure 1 (a) Polydisperse size distribution of freshly emitted biofuel, eugenol, with evolving burn time as measured using an OPC (b) Normalised optical diameter d_o vs. normalised aerodynamic diameter d_a

Future work will involve quantifying changes to the size distribution as soot age increases inside a sealed reaction chamber monitored by OPC, SMPS and SEM. Results from these investigations will be applied into the Global Model of Aerosol Processes (GLOMAP) in order to improve the representation of black carbon aging in the model.

Gaseous and fine particle emissions from the combustion of agro-forestry pellets in a residential boiler

V.K. Verma[1], S. Bram[1,2] and J.De Ruyck[1]

[1]Department of Mechanical Engineering, Vrije Universiteit Brussel, Pleinlaan 2, 1050 Brussel, Belgium
[1,2]Department of Industrial Sciences and Technology, Erasmushogeschool Brussel, Nijverheidskaai 170, 1070 Brussel, Belgium

Keywords: agro-forestry pellets, $dust_{DINplus}$, $dust_{Isokinetic}$, multi-heat boiler.
Presenting author email: vverma@vub.ac.be

Emissions and efficiency of a multi-fuel pellet boiler (40 kW) at nominal load were compared with emissions and efficiency at reduced load, while fired with six biomass pellets. The pellets include reed canary grass (*Phalaris arundinacea*), pectin waste from citrus shells (*Citrus reticulata*), sunflower husk (*Helianthus annuus*), peat, wheat straw (*Triticum aestivum*) and wood pellets. The measurements of emissions comprised of carbon monoxide (CO), nitrogen oxides (NO_x), sulphur oxides (SO_x) and fine particle mass concentrations (using DINplus and isokinetic sampling techniques).

Emissions varied as a function of operational loads, for each type of pellets. The CO emissions were insignificant with reed canary grass (RCG), citrus pectin waste (CPW) and straw pellets at nominal load, however, at reduced load same pellets emitted 1.9, 4.0 and 7.4 times higher CO than wood pellets, respectively. Peat pellets emitted maximum CO at nominal load (4221.1 $mgNm^{-3}$, 12.6 times higher than wood pellets) however; at reduced load CO emission was insignificant. The highest NO_x emissions were reported with CPW, which were 3.4 and 4.6 times higher than wood pellets at nominal load and reduced load, respectively.

Fine particle emissions were measured employing DINplus and isokinetic sampling techniques and the results were compared. During isokinetic sampling, time constancy (15 minutes) was maintained instead of sampling gas volume constancy, as was done for DINplus sampling (270 litres). Eventually, a higher volume of flue gas was sampled during isokinetic sampling, leading to higher fine particle mass concentration than DINplus technique.

Comparison of the fine particle emission from the combustion of agro-forestry pellets at two different operational loads is shown in Fig.1. Fine particle emissions were highest with sunflower husk and lowest with reed canary grass pellets, at both operational modes. The best performance of the concerned boiler was reported with wood pellets, followed by reed canary grass and citrus pectin waste pellets, however, wood pellets combustion emitted 1.7 and 2.0 times higher $dust_{DINplus}$ than reed canary grass pellets at nominal and reduced loads, respectively. Emissions of $dust_{Isokinetic}$ were 1.1 and 1.4 times higher with wood pellets than reed canary grass pellets at nominal and reduced load, respectively.

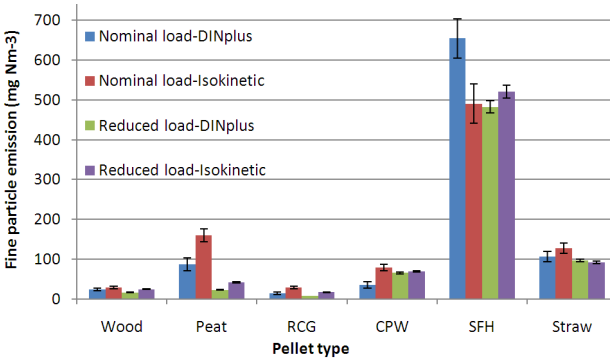

Fig.1: Fine particle emissions from the combustion of agro-forestry pellets at different operational load, measured with DINplus and isokinetic sampling technique. [RCG = reed canary grass; CPW = citrus pectin waste; SFH = sun flower husk pellets; NL = nominal load; RL = reduced load].

As fine particle emission is one of the major issues with small scale biomass combustion systems, reed canary grass pellets may be considered as a good alternative fuel for residential boilers. Furthermore, not only fuel specific combustion optimization but also operational loads specific optimization is essential for efficient use of agro-forestry pellets in this type of boilers

The basic performance of Jatropha curcas seed stove and its indoor air pollution over traditional wood stoves

Haryono S Huboyo[1], Puji Lestari[2], Susumu Tohno[1]

[1] Graduate School of Energy Science, Kyoto University Yoshida-Honmachi, Sakyo-ku, Kyoto 606-8501, Japan
[2] Department of Environmental Engineering, ITB Jl.Ganesha 10 Bandung, Indonesia
Keywords: Biomass burning, Black carbon, Indoor aerosols, Mass size distribution.
Presenting author email: huboyo.h@ax2.ecs.kyoto-u.ac.jp

The use of clean fuel such as LPG in remote rural areas in Indonesia is facing difficulty in popularizing it due to geographical aspects and poor recognition of safety in using a LPG stove among the people. Jatropha curcas seed stove (JCS) could become an alternative, however the level of emissions need to be further analyzed. We have focused on basic evaluation of the stove performance by means of the Water Boiling Test (WBT) in a field simulated kitchen, analysis of indoor air pollutants ($PM_{2.5}$ and CO) due to utilization of this stove and its comparison with traditional wood stove (WS) using three measurement points (near ventilation, cooker's site and far from ventilation) in the field simulated kitchen. Several studies have used the simple WBT to analyze the basic performance of the stoves either traditional or improved (Berrueta et al., 2008; Jetter and Kariher, 2009; Wagutu et al., 2010).

In order to analyze indoor air pollutants, we used inexpensive photoelectric monitors (UCB monitors), Sioutas cascade impactor and CO monitor. Furthermore mass size distribution of black carbon (BC) was also measured to emphasize on the health impacts that may arise in using the JCS.

WBT results indicated that thermal efficiency of JCS was more than 60% compared to around 17% of WS. During water boiling process (with lid), the aerodynamic size range less than 0.25μm was predominant in the $PM_{2.5}$ mass distribution of BC, and ventilation (natural ventilation) use in the room increased the proportion of BC in $PM_{2.5}$ (Fig. 1). In general, the percentages of BC in $PM_{2.5}$ of JCS were 3.7 times and 5.4 times of those of WS without ventilation and with ventilation, respectively.

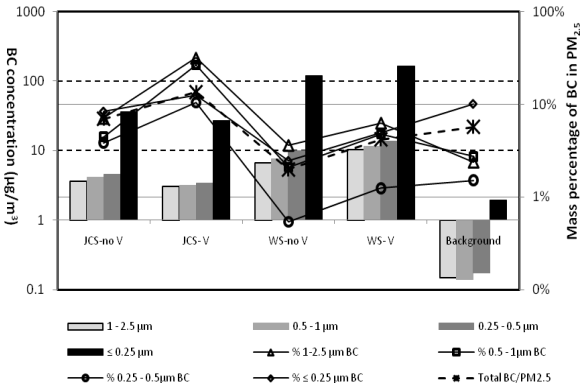

Figure 1 Mass size distribution of black carbon during water boiling process on different stoves

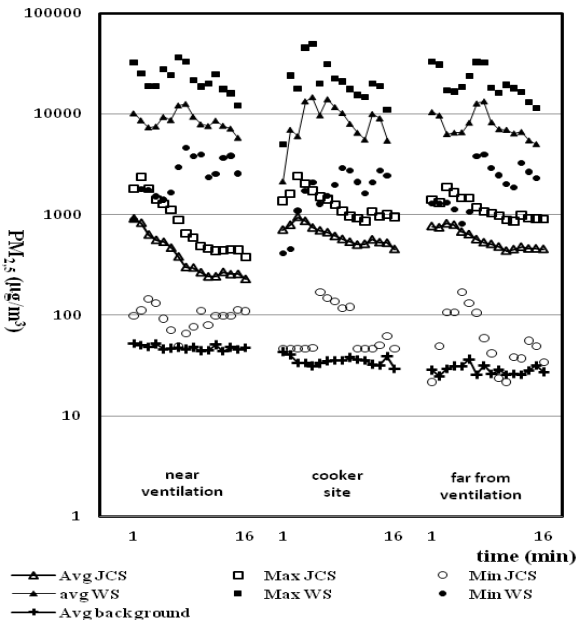

Figure 2 Temporal variation of $PM_{2.5}$ during water boiling process on different stoves (unventilated)

The indoor $PM_{2.5}$ concentrations generated by the JCS was high enough reaching more than 650 μg/m^3 (without ventilation) and 190 μg/m^3 (with ventilation) on average at the position of cookers.

The mass concentrations were approximately 7% and 3.6% of those in WS without ventilation and with ventilation respectively. In addition, the distribution of pollutants is relatively uniformly distributed in the unventilated room (Fig. 2).

Nonetheless, in fact the highest $PM_{2.5}$ concentrations were found during ignition and end-fire phases of stoves either JCS or WS due to tremendous smoke emission.

This work was financially supported by Global Centre of Excellence (GCOE) Program of Graduate School of Energy Science, Kyoto University and Environmental Management Leader Program of Kyoto University.

Keywords: biomass combustion, $PM_{2.5}$, chemical composition, emission factor
Presenting author email: celia.alves@ua.pt

In Portugal, the use of biomass for residential heating is a common practice and, although it can reduce the consumption of fossil fuels at the domestic level, it constitutes an important source of atmospheric pollutants (Schmidl et al., 2008). In addition to gases, biomass burning releases large amounts of particulate matter, mainly $PM_{2.5}$, which has relatively long residence time in the atmosphere. This fraction is the most dangerous to the human health (Dai et al., 2006) and has an important impact on regional and global air quality (Monks et al., 2009) and climate (Randles and Ramaswamy, 2010). Emission factors from biomass burning are rather inexistent in Europe; the available emission factors were obtained for US biofuels (Fine et al., 2004), uncommon in Europe. The type of stove used and the species of wood and their characteristics are factors that can have an important influence on particle emissions (McDonald et al., 2000). Therefore, in order to establish smoke profiles for the biofuel types commonly used in Europe, wood-burning stoves typical of those found for residential heating in the country of study have to be used (Schmidl et al., 2008). In this way, it will be possible to use more specific locally available data in order to accurately assess the contribution of biomass burning and evaluate its impacts.

A set of tests was carried out to determine the gas and chemical composition of $PM_{2.5}$ emitted from the combustion of shrub biomass in a stove. The shrub selected for this study was *Ulex sp.* which is common in the North-West Portuguese forest. The shrub biomass constitute an important source of energy because they have an important calorific value (20 MJ kg^{-1} and 8.4 MJ kg^{-1} for higher and lower heating values, respectively) (Regueira et al., 2005).

The biomass fuel was prepared in order to have two fractions: green parts (twigs with leaves less than 5 mm in diameter) and brown parts (stems more than 5 mm in diameter). The aim was to determine the characteristic of the emissions from the combustion of these two different parts of the shrub. The biomass was arranged in bundles of similar length and with a mass between 0.6 and 1 kg to be combusted after air drying.

A stove commonly used in Portugal for domestic heating was used for combustion experiments. It is operated in the batch mode and produces hot air by a combination of natural and forced convection, and radiation. The stove has a combustion chamber 0.44 m height x 0.59 m width x 0.36 m depth. Exhaustion of combustion was done by a vertical chimney with 0.2 m internal diameter and 3.3 m height. Combustion cycles lasted 20-30 minutes.

The flue gas composition was monitored continuously at the exit of the chimney: i) total volatile hydrocarbons were determined using an automatic analyser with flame-ionisation detector and ii) CO_2 and CO were determined using a non-dispersive infrared analyser.

Fine particles ($PM_{2.5}$) were collected on quartz filters using a low volume sampler in the dilution tunnel that was directly coupled to the chimney. Filters were analyzed in order to determine the carbonaceous content (elemental and organic carbon) and water-soluble inorganic ions using a thermal-optical transmission technique and ion chromatography, respectively.

This study will represent a step towards a better characterisation of emission from combustion of different parts (green and brown) of the shrub biomass. At the same time, it will contribute to improve the characterization of emission profiles of species growing in the Mediterranean region in order to contribute to source apportionment and to improve emission inventories.

anavicente@ua.pt

In summer 2009, gas and particulate fractions were measured from several wildfires occurring in central Portugal. The total volatile hydrocarbons and carbon oxides (CO_2 and CO) collected in Tedlar bags were measured using automatic analysers with flame ionisation and non-dispersive infrared detectors, respectively. Carbonyls (formaldehyde and acetaldehyde) were sampled from the Tedlar bags in DNHP cartridges and analysed by high-performance liquid chromatography. Fine ($PM_{2.5}$) and coarse ($PM_{2.5-10}$) smoke particles were collected sequentially, on pre-fired quartz fibre filters, with a portable high-volume sampler. The organic and elemental carbon content of particulate matter was analysed by a thermal-optical transmission technique (Alves et al., 2011a). The detailed speciation of organic compounds in smoke samples was carried out by gas chromatography-mass spectrometry. The levels of almost 50 elements were quantified by inductively coupled plasma-mass spectrometry. The water-soluble ions were obtained by ion chromatography.

Emission factors (EF) for some gaseous compounds and particulate matter were calculated taking into account that EF is a parameter that relates the emission of a particular species of interest to the amount of fuel burned. Usually it is defined as the amount of a compound released per amount of dry fuel consumed, expressed in units of g kg^{-1} (Alves et al., 2011a; Reid et al., 2005). The modified combustion efficiency (MCE) was calculated and used for each sampling event to define the relative amount of flaming and smouldering combustion for biomass burning (Alves et al., 2011b; Yokelson et al., 2009). MCE values higher than or less than 0.9 indicate dominance of flaming or smouldering combustion, respectively (Reid et al., 2005). The emission factors obtained in Portugal were as follows (in g kg^{-1} biomass, dry basis): 131-488 for CO, 822-1523 for CO_2, 0.97-104 for total hydrocarbons, 2.0-21 for $PM_{2.5}$, 2.4-24 for PM_{10}, and 0.5-39 for OC (in PM_{10}). MCE values ranged from 0.52 to 0.88, corresponding to a greater predominance of smouldering than flaming combustions. Average emission factors of 1.46±0.53, 0.46±0.34 and 0.12±0.07 g kg^{-1} (dry basis) were obtained for acetaldehyde, formaldehyde and propionaldehyde, respectively.

The dominant elements were B, Ti, Mn, Cu, Zn, Zr and Ba; rare earth elements (e.g. La, Ce, Nd, Pr, Sm, Tb, Tm, Yb) were also detected in smoke aerosols as minor constituents. The water-soluble ions contributed, on average, to 3.4% and 2.2% of the fine and coarse particle mass, respectively.

The chromatographically resolved organics included *n*-alkanes, *n*-alkenes, *n*-alkanoic acids, *n*-di-acids, unsaturated fatty acids, phenolic compounds, ketones, steroids, di- and triterpenoids, PAH, with retene as the major compound, and anhydrosugars. The anhydrosugar levoglucosan, and its stereoisomers mannosan and galactosan, constituted the main thermal alteration products and, therefore, are specific markers for wood combustion in ambient particulate matter (Medeiros and Simoneit, 2008; Simoneit et al., 1999). As expected, levoglucosan was the most abundant anhydrosugar, followed by mannosan and galactosan. These compounds were detected in fine particles at levels in the ranges 1.7-37, 0.7-13 and 0.5-7.7 mg g^{-1} OC, while in coarse particles the values were 2.9-40, 0.7-10 and 0.4-7.4 mg g^{-1} OC, respectively.

Incense burning is an important kind of air pollution in Taiwan, especially in the ceremonial worshiping of gods in Budhism, Taoism and folk religions. Studies to date have mainly focused on emissions of metals and particle-bound polycyclic aromatic hydrocarbons (PAHs), size distributions, and toxicities (Yang et al., 2007). Studies of size distributions show that incense smoke particles are typically in the submicrometer size range (Chang et al., 2007; Yang et al., 2007). Such an analysis is necessary if informed strategies and policies related to incense burning and air pollution are to be developed. Furthermore, this study identified the chemical species contained in incense smoke and identified potential marker compounds.

The four most popular types of incense in Taiwan are marketed under the names *Lao Shan*, *Hsing Shan*, *Liao* and *Chen*. Three lab-made sticks of the same type were burned simultaneously during each run. Total particulate matter was collected on a quartz filter (102 mmφ, Pall) at 30.0 L min^{-1} using a modified mid-volume air sampler fastened to the top of the tube. A total of 24 samples of particulate matter, 6 for each type of incense, were collected. Twenty-five chemical compounds were characterized in all: ten carboxylic acids, nine water-soluble inorganic species, three anhydrosugars, and three sugar alcohols using a Dionex DX-600 ion chromatograph (IC), a Dionex ICS-1000 IC and a Dionex ICS-2500 IC equipped with pulsed amperometric detection (PAD).

The total particulate matter (PM) mass emission factors were 43.7±1.08 mg g^{-1} of *Lao Shan*, 46.3±2.68 mg g^{-1} of *Hsing Shan*, 37.8±0.83 mg g^{-1} of *Liao* and 45.9±0.60 mg g^{-1} of *Chen*. Chemical analysis of emissions from the four types of incense, shown in Table 1, revealed that of the 25 components in four groups characterized, anhydrosugars formed the major group, at 43-53 % w/w of identified particulate and 858.6-1586 μg g^{-1} of incense, followed by inorganic salts at 30-33 % w/w of identified particulate and 662.6-956.9 μg g^{-1} of incense, carboxylic acids at 10-17% w/w of the identified particulate and 268.6-392.8 μg g^{-1} of incense, and sugar alcohols at 4.4-7.1% w/w of the identified particulate and 102.3-142.5 μg g^{-1} of incense.

The anhydrosugar levoglucosan (1,6-anhydro-β-D-glucose, Levo), used as a marker of biomass burning, was always the most abundant species in emitted PM for four incenses, accounting for 80.3-91.0% w/w of total identified anhydrosugars (shown in Fig. 1).

Table 1. Emission factors of PM and components in four groups per gram of incense from four types of incense.

	Emission factor (μg g^{-1} incense)											
	Lao Shan			Hsing Shan			Liao			Chen		
	Mean	SD	%	Mean	SD		Mean	SD	%	Mean	SD	%
PM mass (mg g^{-1})	43.72	1.08		46.28	2.68		37.78	0.83		45.94	0.60	
Inorganic salts	681.6	55.1	30.4	734.0	55.1	31.8	956.9	141.9	32.0	662.6	67.6	33.2
Carboxylic acids	268.6	22. 8	12.0	392.8	34.2	17.0	306.6	59.9	10.3	329.7	95.2	16.5
Anhydrosugars	1169.8	47.2	52.2	1078.3	171.1	46.7	1586.4	24.5	53.0	858.6	127.0	43.1
Sugar alcohols	120.6	8.1	5.4	102.3	7.2	4.5	140.8	13.0	4.7	142.5	23.7	7.2

K^+ and Cl^- were the second most abundant components (K^+ and Cl^- were summed), accounting for 63.1-75.5% w/w of total identified inorganic salts. The most abundant carboxylic acids in the emissions were formic and acetic acid, accounting for 37.9-64.4% w/w of total identified carboxylic acids. Xylitol was the dominant sugar alcohol at 18.2-36.6% w/w of total identified sugar alcohols. In addition to Levo, xylitol and formic acid are not found in four unburnt incenses, indicating these abundant species are potential markers for incense burning.

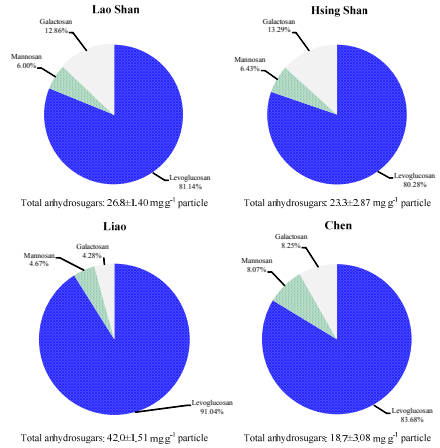

Fig. 1. Contribution of individual species to total amount of anhydrosugars in PM emitted from incense burning.

Keywords: dry deposition, deposition velocity, urban area
Presenting author email: pierre.roupsard@irsn.fr

Introduction

In the case of an accidental or chronic atmospheric pollution by a nuclear plant, aerosols deposition transfer coefficients must be known. A major issue is to determine the impact of aerosols contained in the radioactive plume on urban areas. In dry atmospheric conditions, transfer coefficients are defined by the dry deposition velocities Vd ($m.s^{-1}$), the ratio between the aerosol vertical dry deposition flux ($particles.m^{-2}.s^{-1}$) and the concentration of aerosols ($particles.m^{-3}$; Seinfeld and Pandis, 1998). Dry deposition velocities are dependent on atmospheric turbulent conditions and surface roughness. Actually, for urban surfaces, only a few dry deposition velocities were measured, in field or in laboratory environments. Moreover, existing data are not linked with atmospheric conditions (Fowler *et al*, 2009). Therefore, it is important to improve the knowledge and the models on urban areas.

The aim of this wind tunnel study was to quantify, experimentally, dry deposition velocities for a submicron aerosol on three different urban surfaces, for three different wind speeds (U_{ref}). We measured also air turbulence intensities and friction velocities U_* in the wind tunnel.

Test equipment and methods

Experiments were conducted in April 2010 in the IRPHE closed-circuit wind tunnel (8.7 m x 0.7 m x 0.3 m). Dry deposition has been studied successively on glass, cement facing and synthetic grass with U_{ref} equals to 1.3, 5.0 and 10 $m.s^{-1}$. The bottom of the tunnel was totally recovered with each type of studied surface to develop the characteristic boundary layers. Deposition velocities were measured at three distances from the tunnel entrance (1, 5 and 7 m). A monomodal polydisperse submicron fluorescein aerosol, representing the accumulation mode of the atmospheric aerosol, was generated and injected in the wind tunnel (Maro *et al*, 2010). Spectrofluorimetric measurements of deposited aerosols on squares of each urban-type surface gave deposition fluxes. Spectrofluorimetric measurements of aerosols taken on filters gave aerosol concentrations in the wind tunnel.

Turbulence intensity, friction velocity and air velocity measurements were made by hot wire anemometry at three distances (1, 5 and 7 m) for each type of surface and at the three flow velocities U_{ref}.

Results and discussions

Friction velocity increased with wind speed and surface roughness. This study showed a significant increase of the deposition velocity with the surface roughness and with the wind speed (figure 1). But the increase due to surface roughness was much more important than the increase due to wind speed.

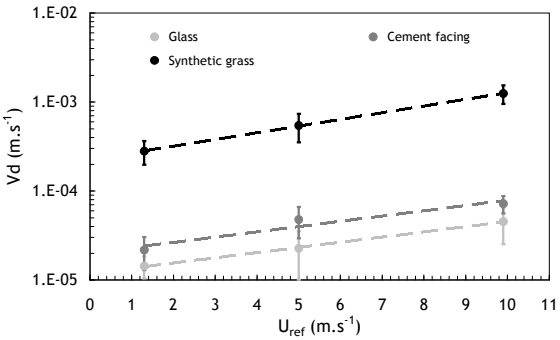

Figure 1. Dry deposition velocity Vd function of air flow velocity U_{ref}.

We found also that the ratio between deposition velocity and friction velocity on each surface was not constant (Table 1).

Table 1. Mean Vd/U_* ratio function of substrate

Substrates	Vd/U_* ($.10^{-3}$)
Glass	0.05 ± 0.05
Cement facing	0.11 ± 0.05
Synthetic grass	1.2 ± 0.3

These experiments in wind tunnel are the first step of a future study on the dry deposition in urban areas. The next step will be *in situ* experiments to take into account all the atmospheric parameters existing in urban environments.

Particle fluxes over arctic sea ice during COBRA

J.D. Whitehead[1], J.R. Dorsey[1], M.W. Gallagher[1], M.J. Flynn[1] and G. McFiggans[1]

[1]Centre for Atmospheric Science, School of Earth, Atmospheric and Environmental Sciences, The University of Manchester, Oxford Road, Manchester, M13 9PL, UK
Keywords: aerosols, fluxes, arctic.
Presenting author email: James.Whitehead@manchester.ac.uk

Particle fluxes were measured over Arctic sea ice during the COBRA (Impact of combined iodine and bromine release on the Arctic atmosphere) experiment at Hudson Bay, Canada, during February and March, 2008. Eddy covariance fluxes of fine and ultrafine particles were measured using Condensation Particle Counters (CPCs; TSI, models 3776 and 3010) in conjunction with an ultrasonic anemometer (Metek) mounted at a height of 2.5 m on a mast positioned out on the sea ice. Deposition velocities (v_d) were calculated from the ratio of the particle number flux and concentration. After filtering the data for stationarity and fetch, and applying appropriate corrections, a mean v_d of 0.119 ± 0.115 mm s^{-1} (standard error; n = 230) was found for particles measured with the CPC3776 (i.e. with a lower size threshold of 2.5 nm). With the CPC3010 (D_p > 10 nm), a mean v_d of 0.066 ± 0.106 mm s^{-1} (standard error; n = 236) was found. These values are smaller than those measured in previous experiments over ice floes in the Arctic Ocean (0.3 mm s^{-1}; Nilsson and Rannik, 2001), and over a snow covered ice sheet in Antarctica (0.47 mm s^{-1}; Contini *et al.*, 2010). Ultrafine particle concentrations (as determined by the difference in concentrations between the two CPCs) were low, suggesting that no nucleation events occurred during the measurement period. Optical Particle Counters (OPCs; Grimm, model 1.108) were placed at heights of 0.19 and 1.34 m on the mast, allowing size segregated fluxes of particles in the size range 0.3 – 20 μm to be derived using the aerodynamic flux gradient method. Strong emission fluxes were observed shortly after midday, 3rd March, when winds from over Hudson Bay increased to more than 10 m s^{-1}, suggesting ice particle resuspension. Number fluxes of these particles were largest in the smallest size channels (lower cut 0.3 μm), while the largest sizes (around 20 μm) dominated the mass flux. Number fluxes also increased with friction velocity u_*, particularly in the smaller sizes, and the relationship between flux and u_* will be investigated. Measurements with a Differential Mobility Particle Sizer (DMPS) showed an enhanced mode in the mass size distribution between 400 – 500 nm during these resuspension events. The aerosol size distribution measurements were also classified according to air mass and sea-ice versus land fetch.

The COBRA project was funded by the UK Natural Environmental Research Council (NERC) (NE/D006015/1). Logistical support at the measurement site was provided by Environment Canada.

Rain scavenging of below-cloud aerosol particles: field measurements using Electrical Low Pressure Impactor and Scanning Mobility Particle Sizer coupled with Aerodynamic Particle Sizer

P. Laguionie, D. Maro, B. Letellier and S. Le Cavelier

IRSN (Institute of Radioprotection and Nuclear Safety), Cherbourg-Octeville, 50130, France
Keywords: atmospheric aerosols, wet deposition, scavenging coefficient, urban environment, ELPI, SMPS, APS
Presenting author email: philippe.Laguionie@irsn.fr

Introduction

In case of punctual or chronic atmospheric pollution by a nuclear plant, aerosol deposition transfer processes at work must be known. A major issue is to determine the rain scavenging of below-cloud aerosol particles, which is by far the most efficient atmospheric aerosol sink (Andronache, 2003). As distribution of radioactive chemical species is aerosol-size dependent, the scavenging sensitivity with respect to aerosol particle size has to be determined.

Removal process mechanism involves microphysical interactions between aerosol particles and hydrometeors. Practically, wet scavenging is typically modelled by coefficients and is usually parameterised by $dc/dt = -\Lambda c$ with c being aerosol concentration (number.cm^{-3}) and Λ the scavenging coefficient (s^{-1}). Λ parameterisation is, however, highly uncertain (Sportisse, 2007) and several orders of magnitude difference in Λ are still found between modelled values and estimates obtained from scarce *in situ* data.

The aim of the present study was to make a comparison of Λ obtained by Electrical Low Pressure Impactor (ELPI) and Scanning Mobility Particle Sizer (SMPS) coupled with Aerodynamic Particle Sizer (APS) under different rainfall intensity conditions. Data were acquired *in situ* in urban context (Cherbourg-Octeville, France) and are part of the INOGEV research program supported by the French National Research Agency.

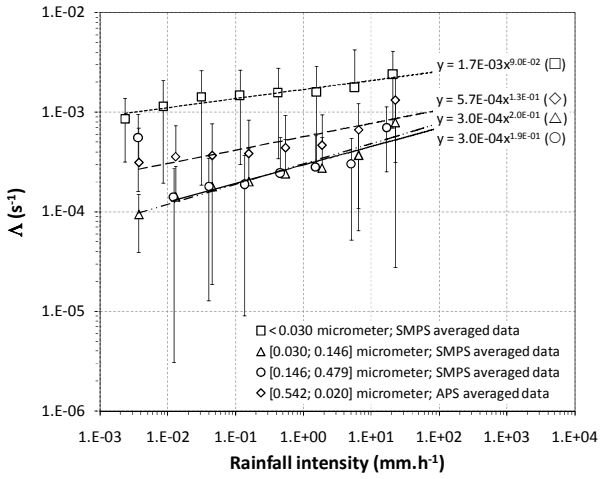

Figure 1. Scavenging coefficient versus rainfall intensity for 4 SMPS-APS granulometric classes.

First results

Firstly, SMPS and APS produced 1800 data that showed a power relationship between Λ and rainfall intensity over the full granulometric classes (Figure 1). A similar relationship was found with the 50 data from ELPI (Figure 2) (Vendel, 2007). So, different gears gave consistent results: parameters used to fit the power law are aerosol-size dependent.

Secondly, for a given granulometric class, no significant discrepancy was found between the two measurement methods.

Thirdly, compared to theoretical Λ values given in literature, Λ experimental parameter appeared one to several orders of magnitude higher.

The consequences of these results will be further discussed at the conference.

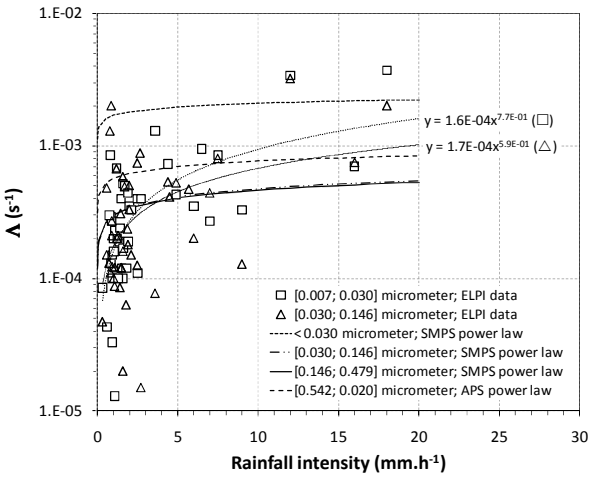

Figure 2. Scavenging coefficient versus rainfall intensity for 2 ELPI granulometric classes compared with SMPS-APS power law models presented in Figure 1.

Open burning of agriculture and garden residues is an important source of toxic air pollutants into the atmosphere with significant impacts on human health, air quality and global climate change. On a global scale, the estimated annual total dry matter combusted due to agriculture burning is around 540 Tg yr^{-1} (Andreae & Merlet, 2001), but the impact of emissions on the atmosphere is somewhat uncertain, because consistent data on agriculture burning are much sparser than data on other anthropogenic sources.

To assess the particulate matter (PM) composition, the smoke from three different agriculture and garden residues, commonly subjected to open field burning in Northern Portugal (potato haulm (A), arable weed vegetation (B) and collard greens stalks/pruned green leafy-twigs (C)) have been sampled into 3 different size fractions ($PM_{2.5}$, $PM_{2.5-10}$ and $PM_{>10}$). To replicate another frequent practice of reducing or dispose agriculture/garden debris, residue C was complementarily burned in a metal container with addition of used lubricant oil. The size-segregated aerosol samples were analysed for elementar (EC) and organic (OC) carbon by a thermal-optical transmission technique. The organosoluble OC was fractionated by vacuum flash chromatography and analysed by gas chromatography-mass spectrometry (Alves *et al*., 2011).

Burning of residue C produced the highest PM emissions. OC was the dominant carbonaceous component in all aerosol samples, contributing to about 98% of total carbon (TC). The detailed chemical profiles of particulate emissions, including organic tracer compounds, have been assessed. The contribution of phenolics (0.2-39% OC, w/w) and organic acids (1.5-13% OC, w/w) to OC was always predominant over other organic compounds, whose distribution patterns were found to vary from one residue to another. The polyphenols, as the guaiacyl derivatives, were particularly abundant in PM from the residue C burning, but anthropogenic constituents completely superimposed the emission profiles after addition of used lubricant oil. Since it was shown that the relative contribution of different carbon forms and organic compounds may strongly depend on the size of the particulate matter (Fig. 1), the barely analysis of one size fraction cannot be reliable enough to assess neither global emission tendencies nor the profiles of individual chemical components in smoke.

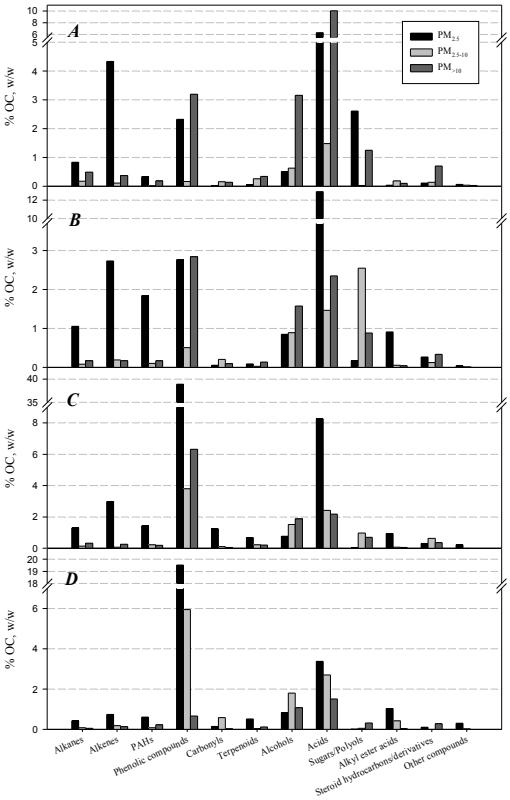

Figure 1. Contribution of chromatographically resolved organic compounds to OC in size-segregated particulate matter emissions.

Abstract: In order to study the Physical and chemical characteristics of aerosols, samples of Total Suspended Particulates (TSP) were collected using a high volume sampler at Pune, a semi-urban location in SW India during Mar 2009 to Feb 2010. TSP samples were analyzed for water soluble components like F, Cl, NO3, SO4, NH4, Na, K, Ca and Mg and acid soluble components like Al, Zn, Fe and Cu using Ion-Chromatograph and Atomic Absorption Spectrometer. Analysis of the data revealed that the monthly mean TSP concentrations varied between 471.3 microgram per cubic meter and 30.5 microgram per cubic meter with an annual mean value of 159.8 microgram per cubic meter. TSP concentrations were found to be less during post-monsoon and winter (October through February), compared to those in summer and monsoon (March through September). Anthropogenic activities like vehicular emissions and dust particles originated from urban activities were the major sources for TSP. TSP showed good correlation with all the major ionic components, especially with SO4 (R = 0.62) and NO3 (R= 0.67) indicating the impact of anthropogenic sources over the aerosols at Pune. However, the overall aerosol nature was alkaline (Ave pH = 6.17) mainly due to the neutralizing effects of Ca and NH4. SO4 contributed more (58.8%) to the total acidity as compared to NO3 (41.1%) whereas; Ca contributed more (66.5%) to the total alkalinity than NH4 (33.5%). Seasonality of acid soluble component Al, Fe and Cu showed remarkable increase, indicating the dominance of soil source over the man-made activities. Overall study on TSP indicated that aerosols at Pune were mainly affected by the local sources.

Cluster analysis of single particle data acquired with a Light Scattering Probe AMS during the MEGAPOLI campaigns in Paris, France

F. Freutel[1], T. Klimach[1], J. Schneider[1], F. Drewnick[1], and S. Borrmann[1,2]

[1]Particle Chemistry Department, Max Planck Institute for Chemistry, Mainz, 55128, Germany

Presenting author email: fr.freutel@mpic.de

Recently, the Light Scattering Probe (LSP) has been introduced as an add-on to the Aerodyne Aerosol Mass Spectrometer (AMS) (Cross *et al.*, 2007), enabling efficient single particle measurements with the AMS for particles with diameters of about 300 – 1000 nm. In contrast to typically deployed single particle instruments which use laser desorption and ionization (LDI) to analyze individual particles, here thermal desorption and electron impact ionization are used to analyze submicron particles after optical detection. These quantitative single particle data not only give further information on the ensemble data routinely measured with the AMS, but also complementary information to the data acquired with LDI instruments (e.g., non-refractory vs. refractory particles).

We deployed an LSP-AMS during two one-month campaigns at a suburban site in Paris, France: MEGAPOLI summer in July 2009, and MEGAPOLI winter in January/February 2010. Several ten thousands of spectra were acquired during these two campaigns, giving an extensive, representative dataset of typical LSP-AMS single particle spectra at a suburban measurement site. The LSP-AMS was alternated within every minute between single particle mode and ensemble mode, making comparisons between AMS ensemble and single particle data possible. Also, side by side to the LSP-AMS, an LDI single particle instrument was deployed, providing complementary information to the single particle data acquired with the LSP-AMS.

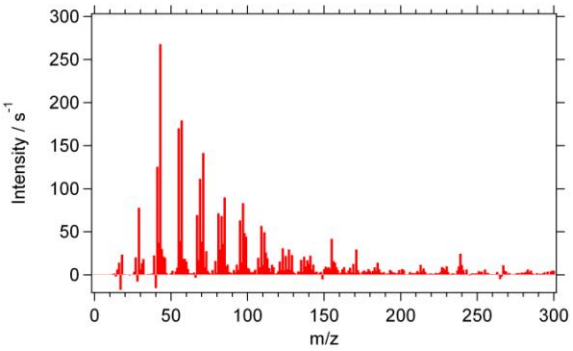

Figure 1. Single particle spectrum of a hydrocarbon-like, freshly emitted organic aerosol particle.

Here, clustering algorithms (k-means, fuzzy c-means) which are typically used to analyze LDI single particle data are applied to single particle data acquired with the LSP-AMS. Examples of typical single particle mass spectra found are shown in Figure 1 and Figure 2 (top). Figure 1 shows an exemplary mass spectrum of a so-called hydrocarbon-like organic aerosol (HOA) particle, featuring typical fragmentation patterns (e.g., m/z 57) of freshly emitted particles, possibly from traffic exhaust. In contrast, Figure 2 (top) shows the mass spectrum of an internally mixed particle containing ammonium sulfate (e.g., typical m/z's 16 for NH_4, 48 and 64 for SO_4) and aged organic material (e.g., m/z 44). The assumption that these signals at marker m/z's correspond to material in a single particle is supported by corresponding particle time-of-flight traces of the markers, shown in Figure 2 (bottom). The marker signals for ammonium, sulfate and aged organic material peak at the same time, indicating the simultaneous arrival and evaporation at the ionization region.

Here we show results of clustering the LSP-AMS single particle data, giving further insight into the mixing state of the non-refractory, submicron aerosol particle mass measured with the AMS during the MEGAPOLI field campaigns.

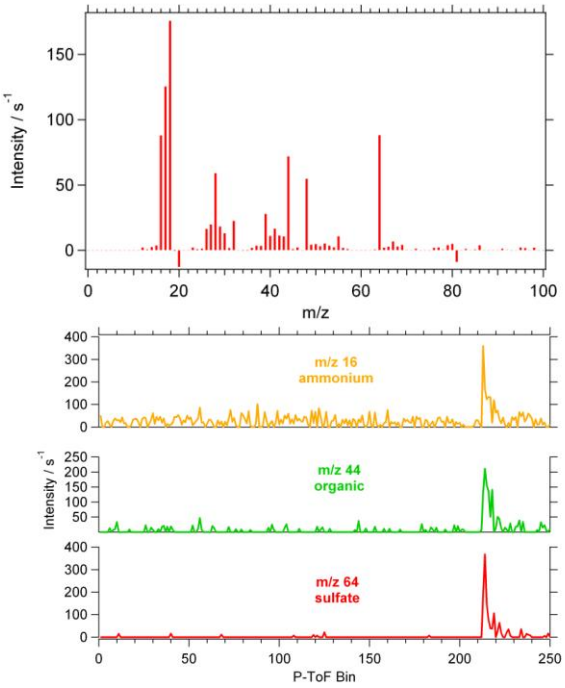

Figure 2. Top: Single particle spectrum of an internal mixture of ammonium, sulfate and aged organic material. Bottom: Time traces of the individual marker m/z's, showing strong indication for an internally mixed particle.

Presenting author email: c.pohlker@mpic.de

We applied Scanning Transmission X-ray Microscopy - Near Edge X-ray Absorption Fine Structure (STXM-NEXAFS) analysis to investigate the morphology and chemical composition of aerosol samples from a pristine tropical environment, the Amazon Basin. The samples were collected in the Amazonian rainforest during the rainy season and can be regarded as a natural background aerosol. The samples were found to be dominated by Secondary Organic Aerosols (SOA) in the fine and Primary Biological Aerosol Particles (PBAP) in the coarse mode (Martin et al., 2010; Pöschl et al., 2010). Lab-generated SOA-samples (produced by the (photo)oxidation of isoprene, α-pinene and *β*-caryophyllene) and microtome slices of fungal spores were measured as reference samples. The aim of this study was to investigate the microphysical and chemical properties of a tropical background aerosol and its internal mixing state (Russell et al., 2002; Kilcoyne et al., 2003; Takahama et al., 2007; Tivanski et al., 2007; Moffet et al., 2010).

The STXM-NEXAFS results of the lab-generated SOA have been analyzed and compared to SOA from the Amazonian region. In the Amazon samples, SOA occurred as spherical droplet-like particles or as coatings on PBAP. In the lab samples, SOA occurred as droplets of different sizes, sometimes exhibiting internal structures (‘raisin-like’ structure). Concerning chemical composition, the NEXAFS spectra have been utilized to estimate the elemental ratios of C, N and O. Unexpectedly, all ambient SOA samples show a high content of N (around 20% or even more). Furthermore, the spectra exhibit characteristic signal patterns for different functional groups. In most cases the spectrum near the C-edge is dominated by the carboxylate signal, but prominent peaks for hydroxyl-, keton carbonyl- and alkene-peaks have also been observed. The spectral characteristics of the lab samples depend on the precursors applied for their generation.

For PBAP, the C-, N- and O-specific NEXAFS maps allow insights into the intracellular structure and chemical composition of fungal spores, which clearly dominate the coarse mode of the Amazonian samples. Furthermore, clusters of bioparticles could be identified. PBAP show a complex NEXAFS spectrum due to a wide variety of differently functionalized biomolecules, with different spectra and element abundances for individual cell components.

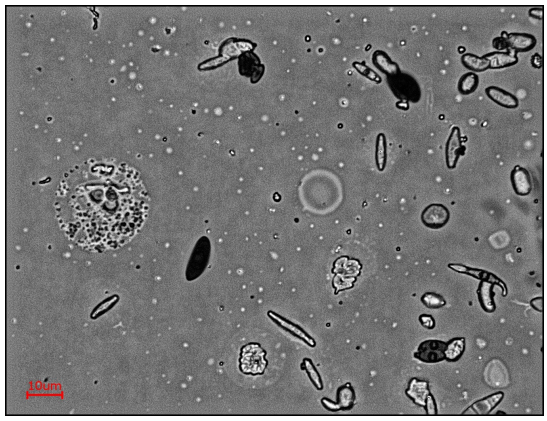

Figure 1. Light microscopy picture of PBAP and SOA particles from Amazonian rainforest.

Physico-chemical property measurements for aerosols at Manchester

A.M. Booth[1], D.O. Topping[1], G. McFiggans[1], C.J. Percival[1]

[1]School of Earth, Atmospheric and Environment Science, University of Manchester, Manchester, M13 9PL, UK

Here we present an overview of different lab measurements at Manchester designed to test various estimation methods of physical properties important for aerosol modelling: Vapour pressures, enthalpies of fusion, melting points, surface tensions, water activity, solubility and freezing point enhancement.

Vapour pressure

The direct and indirect impacts of atmospheric aerosols are one of the greatest uncertainties in our understanding of radiative forcing. Organic compounds in aerosols are ubiquitous and incredibly varied, with possibly hundreds of thousands of compounds. Gas (to particle partitioning is responsible for a considerable fraction of organic aerosols (OA), and is frequently described by an equilibrium based absorptive partitioning model. The vapour pressures of the components making up the OA are an important parameter in absorptive partitioning. Accurate vapour pressure estimation methods and experimental data to test them against are important in improving our understanding of the OA fraction in atmospheric aerosols. KEMS (Knudsen Effusion Mass Spectrometry) is a technique which allows the measurement of very low volatility compounds without the need to extrapolate from high temperatures or make any assumption with regard to activity coefficients. We have measured several sets of compounds (substituted diacids, cyclic diacids, substituted benzoic acids and nitro compounds) and have evaluated vapour pressure estimates against them. The impact of using different estimation methods has then been quantified by partitioning calculations.

Enthalpies of fusion, Melting points

The compounds measured using KEMS are solids at room temperature and pressure; however, current gas/particle partitioning models use the sub-cooled liquid reference state, as do activity models. The sub-cooled liquid is the metastable liquid which exists if solidification does not occur at temperatures below that of the triple point. By using the solid state vapour pressures measured with KEMS in combination with enthalpies of fusion and melting points measure using DSC (Differential Scanning Calourimetry) we can derive sub-cooled liquid vapour pressures for the classes of compounds we have measured (substituted diacids, cyclic diacids, substituted benzoic acids and nitro compounds).

Surface tension

An aerosol particle's equilibrium composition and the vapour pressure of each component above the particle are governed by two effects, the Raoult and Kelvin effects. These two effects are represented in the Kohler equation describing the equilibrium conditions for water over a solution droplet, an important parameter for CCN activation predictions. The Kelvin effect accounts for the enhancement of vapour pressure as a result of curvature by reference to the surface tension. We have measured surface tensions of several mixed organic and inorganic systems. We have then evaluated the accuracy of surface tension predictions and determined the impact on cloud droplet activation predictions.

Activity and solubility

The other component of the Kohler equation, the Raoult effect, considers the influence of interactions taking place in solution on the bulk equilibrium composition and equilibrium partial pressure of components above a solution. Prediction of the equilibrium composition of multicomponent particles requires calculations of component 'activity' which is a thermodynamic quantity representing an 'effective' concentration; be it of water or any solute. We have measured the water activity and solution solubility of several multi-component systems in order to provide data to help develop thermodynamic models such as AIOMFAC. We are also developing an ion attachment source to allow the KEMS system to be used in activity coefficient determination.

Instrumental improvements and applications of the compact laser mass spectrometer LAMPAS 3 for on-line single particle characterization

K.-P. Hinz[1], E. Gelhausen[1], K.-C. Schäfer[1], Z. Takats[1] and B. Spengler[1]

[1]Institute of Inorganic and Analytical Chemistry, Justus Liebig University Giessen, Giessen, D-35392, Germany

Keywords: Aerosol mass spectrometry, Atmospheric aerosols, Chemical composition, Single particle analysis

Presenting author email: klaus-peter.hinz@uni-giessen.de

Mass spectrometric instrumentation is an important analytical tool for the investigation of aerosols. With such instruments a fast and detailed physical and chemical characterization of aerosol particles is possible. Aerosol particles play a central role in various areas such as indoor and outdoor environments and influence the earth climate and human health. Furthermore, on-line particle analysis with transportable mass spectrometric systems enables in-situ investigations of aerosols for real-time identification in fields such as homeland security and medicine. Applications of these devices include e.g. in situ identification of tissue types in electro-surgery or indoor and outdoor pollutants.

Currently, various transportable on-line mass spectrometers are used for single particle characterization. Size-resolved chemical analysis of particles at sites of interest is possible with high temporal resolution for investigation of particle populations under highly variable measurement conditions. Most of these particle mass spectrometers are large and bulky and therefore the measurement sites can not be reached directly with the instrument.

Miniaturization is therefore necessary to use such systems in e.g. private homes or hospitals, in airplanes or small cabins, in ships or research stations on mountains. As a consequence, the compact mobile laser mass spectrometer LAMPAS 3 (19" rack on wheels, 150 cm in height) was developed with improved instrumental parameters and options. Particles are introduced into the instrument through a differentially pumped inlet system. Inside the mass spectrometer particles are optically detected by two continuous laser beams. Particle size is determined using their size-dependent velocity. Afterwards, an actively triggered UV laser evaporates and ionizes the detected particles. The generated ions are analyzed with a bipolar time-of-flight mass spectrometer. Optionally, delayed ion extraction and ion analysis with a reflectron time-of-flight analyzer can be used for improved determination of ion masses. Using these instrumental features a significant enhancement of mass accuracy and mass resolving power is possible. An improved quality of results is also observed, using enhanced statistical classification and interpretation of data.

Several measurements were performed with particles of various origins. Spectra from a single particle are shown in Figure 1. This particle was produced during cutting porcine liver with an electro-scalpel under laboratory test conditions.

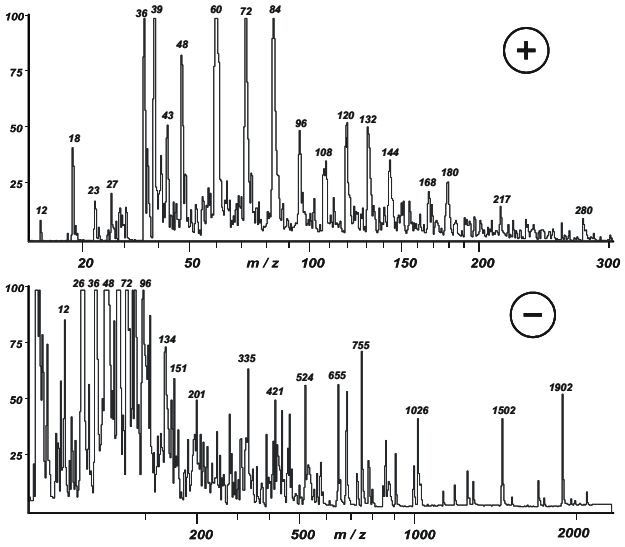

Figure 1. Positive and negative ion mass spectrum of a single particle generated with an electro-scalpel from porcine liver (aerodynamic particle 0.5 μm).

Spectra in Figure 1 show ion signals in a broad mass range with good mass resolution. Further investigations will be performed to characterize different types of tissues with the goal of in situ tissue identification in combination with simultaneous analysis of gaseous components.

Instrumental improvements of the LAMPAS 3 system and results from the analysis of various aerosols will be shown. In the future, the compact laser mass spectrometer LAMPAS 3 will offer the possibility of advanced in situ particle identification in various applicational fields.

Chemical characterization of fine aerosols over eastern central India

D.K. Deshmukh and M.K. Deb*

School of Studies in Chemistry, Pt. Ravishankar Shukla University, Raipur, Chhattisgarh, India 492 010

Keywords: $PM_{2.5}$, Dicarboxylic acids, Ion Chromatography

Email:dhananjaychem@yahoo.in

The concentrations of low molecular weight dicarboxylic acids in fine ($PM_{2.5}$) particles collected during July 2009 to November 2009 in Raipur ($21^o14'N$ & $81^o38'E$), India were analyzed. Low molecular weight dicarboxylic acids constitute a significant fraction of water soluble organic aerosols in the atmosphere. Twenty five sets of weekly $PM_{2.5}$ samples were obtained using eight stage cascade impactor type aerosol sampler at a flow rate of 28.3 ALPM. Collected PM_1 samples were analyzed for 10 low molecular weight dicarboxylic acids using ion chromatography. The influence of meteorological factors on the concentrations of dicarboxylic acids was also studies.

Table 1
The mean mass concentration of fine particles ($PM_{2.5}$) during July 2009 to November 2009

Months	$PM_{2.5}$ mass concentration ($\mu g\ m^{-3}$)			
	Mean	SD	Min.	Max.
Jul. 2009	81.6	12.4	62.1	94.2
Aug. 2009	39.4	14.2	22.3	51.1
Sep. 2009	68.3	18.3	56.1	76.2
Oct. 2009	161.6	32.1	122.1	168.9
Nov. 2009	129.1	24.6	96.6	142.1
Fall	68.1	21.6	39.4	81.6
Winter	145.3	23.0	129.1	161.6

Table 2
Concentrations (ng/m^3)of dicarboxylic acids in $PM_{2.5}$ aerosols in Raipur, India

Species	Concentration of dicarboxylic acids (ng/m^3)			
	Mean	SD	Min.	Max.
Oxalic	731.9	181.2	534.2	1020.6
Malonic	10.2	8.0	3.4	22.3
Succinic	7.7	1.8	5.5	10.2
Glutaric	5.8	4.4	2.3	12.4
Maleic	16.4	4.8	11.1	24.0
Fumaric	11.0	2.8	8.1	14.8
Phthalic	18.9	11.9	7.0	35.4
Malic	8.7	4.6	3.2	14.7
Tartaric	14.5	4.6	10.5	21.2

The ratio of malonate to succinate was used to distinguish primary sources from secondary sources of these acids. The mean concentrations and associated standard deviation of $PM_{2.5}$ aerosols was $96.0\pm48.9\ \mu g/m^3$. Oxalic (C_2) acid was found as the most abundant species followed by phthalic and maleic acid in $PM_{2.5}$ aerosols. $PM_{2.5}$ aerosols contained, on average, 731.9 ng/m^3 oxalic acid, 18.9 ng/m^3 pthalic acid, 14.7 ng/m^3 tartaric acid, 16.4 ng/m^3 maleic acid, 11.0 ng/m^3 fumaric acid, 10.2 ng/m^3 malonic acid, 8.7 ng/m^3 malic acid, 7.7 ng/m^3 succinic acid, and 5.8 ng/m^3 glutaric acids.

Size Distribution and Source Analysis of Polycyclic Aromatic Hydrocarbons (PAHs) contained in PM_{10} in Waliguan and Xining of China

L.L Tang[1,2], S.J. Niu[1], D.T. Liu[2], X.W. Li[3], X.Z. Zhang[3], S.X. Fan[1],H. Nie[4] and H. Coe[2]

author email: lili.tang@nuist.edu.cn; lili.tang@manchester.ac.uk

Abstract:

To explore the properties and sources of polycyclic aromatic hydrocarbons (PAHs) contained in PM10 in Waliguan and Xining of Qinhai Province, China during summer, 10-group aerosol samples were installed at the Waliguan Atmospheric Background Observatory and Qinghai Station of Meteorology. Waliguan station (36° 17'N, 100° 54'E) is the highest GAW (Global Atmospheric Watch) station, and is located in a remote region on the northeastern boundary of the Qinghai-Tibetan plateau at a height of 3810 meters. Qinghai Station（36° 34'N, 101° 45'E）is located in the center of Xining city at a height of 2275 meters. Size-segregated particles were sampled using cascade impactors (Thermo) from May 24 to June 4, 2007. Size resolved chemical compositions of aerosol were investigated in order to characterize regional aerosol pollution. The meteorological conditions during the measurements maintained high temperatures and high RH. The mass concentration and size distribution of PM_{10}, and the spectral distributions of PAHs were analyzed. The daily mean concentration of PM_{10} was 24.85μg·m^{-3} and the particle size distribution exhibited three-modes in Waliguan; whereas the daily mean concentration of PM_{10} was 65.25μg·m^{-3} in Xining where the particle size distribution showed dual-modes.

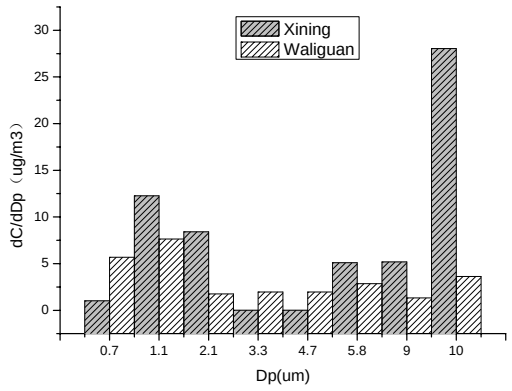

Figure 1. Mass size distribution of average PM_{10} mass concentration in sampling periods.

The percentage of accumulated particle mass in Waliguan was greater than in Xining. The concentration of PAHs in PM_{10} was 8.38ng·m-3 in Waliguan, much lower than Xining .

Due to the different photochemical pathways, the properties of PAHs and long-range transport of particles, PAHs with high molecular weight were mainly distributed in the fine particles and PAHs with lower molecular weight are relatively richer in the coarse particles at Waliguan. High molecular weight polycyclic aromatic hydrocarbons in the two sample sites were monodispersed in size. It is concluded that the PAHs pollution in Waliguan was associated with the seasonal transitions with the Asian monsoon system and transport from eastern/central China industrial emissions.

Modelling atmospheric OH-reactivity over boreal forest

D. Mogensen[1], S. Smolander[1], A. Nölscher[2], J. Williams[2], V. Sinha[2,3], T. Nieminen[1], M. Kulmala[1], L. Zhou[1], A. Sogachev[4], A. Guenther[5], and M. Boy[1].

Presenting author email: ditte.mogensen@helsinki.fi

Currently, researchers believe that H_2SO_4 is taking part in both aerosol formation and growth. It is therefore highly essential to predict correct OH concentrations by models, since it is from OH-oxidation of SO_2 that H_2SO_4 eventually is produced. Wrong H_2SO_4 concentrations in models lead to wrong modelled aerosol parameters, which among other effects, increase uncertainties on climate predictions from aerosols.

We have modelled the total atmospheric OH-reactivity in a boreal forest and investigated the individual contributions from gas phase inorganic species, isoprene, monoterpenes, and methane along with other important VOCs. Daily and seasonal variation in OH-reactivity, as well as the vertical OH-reactivity profile until the boundary layer, was examined.

We present modelled and measured data from the two campaigns; HUMPPA-COPEC-10 (Hyytiälä United Measurements of Photochemistry and Particles in Air -- Comprehensive Organic Precursor Emission Concentration 2010) July-August, 2010 and BFORM (Boreal Forest OH Reactivity Measurements) August 2008. Both campaigns took place in Hyytiälä, SMEAR II station, Southern Finland. For model results we have used SOSA; a one-dimensional vertical chemistry-transport model (Boy et al. 2011) which includes detailed chemistry.

Model simulations only account for ~ 50% of the total measured OH sink, and we believe the reason for missing OH-reactivity (modelled OH-reactivity subtracted from measured OH-reactivity) is unmeasured unknown BVOCs, and limitations in our knowledge of atmospheric chemistry including uncertainties in rate constants.

The vertical OH-reactivity has been modelled and compared with directly measured vertical OH-reactivity at two different heights - one in canopy and one above canopy. In Figure 1, the modelled vertical OH-reactivity until 23 meters (above canopy) is visualized. A night time peak in the OH-reactivity corresponding to the monoterpene concentration trend is observed.

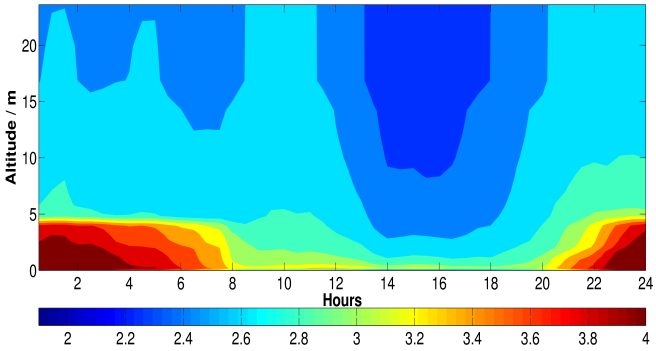

Figure 1: Daily averaged modelled OH-reactivity from the 13th to the 27th of August 2008, as a function of altitude.

During daytime the OH-reactivity decreases due to a more well mixed atmosphere. However, the accumulated OH-reactivity until the boundary layer peaks in the middle of the day, which correlates with VOC emissions. In winter time, the canopy OH-reactivity peaks during day. However, our investigations show that the main contribution to the OH-reactivity during winter is of inorganic origin.

We have also investigated correlations between aerosol condensation sink, different aerosol modes and missing OH-reactivity. A correlation between missing OH-reactivity and growth of nucleation mode particles (3-10nm) was found, suggesting that OH oxidised products condense on the smaller particles. No correlation between missing OH-reactivity and larger mode particles was found.

Characterization chemical and microbiological of atmospheric particulate matter during an intense African Dust Event on Sourth Spain

A.M. Sánchez de la Campa[1], A. Gracía[1], J.L. Ramos[1] and J. de la Rosa[2]

[1]Estación Experimental del Zaidín, CSIC, C/ Profesor Albareda 1, E18008 Granada, Spain

Keywords: chemistry, TSP, microbial transport, African Dust
Presenting author email: ana.sanchez@pi.uhu.es

A rural monitoring station situated in this region has been used in the sampling of TSP during a strong Saharan dust event (18-20 march 2010). The study area is situated in the Doñana National Park, Gulf of Cadiz (SW Spain), which is located in the south-western corner of the autonomous region of Andalusia, Spain.

This region serves as a transitional zone between the African and European continents from a climatic perspective, with very dry summers (35 mm of rainfall as a mean for the June-September period) and annual rainfall of 520 mm/yr. The predominant wind directions are SW, NWN and NE, which are heavily influenced by synoptical conditions and breeze circulation.

The Sahara desert is one of the major sources of windblown dust in the Northern Hemisphere. Duce (1995) estimated that 20% of the dust generated in the Sahara desert is suitable of long-range transport. The annual emissions from the Sahara-Sahel region to the atmosphere are approximately 1 billion tons (Moulin *et al.*, 1997).

Multidisciplinary studies of aerosol physics and chemistry have shown the impact of long-range transport pollutants in this region of the SW Iberian Peninsula (Rodríguez *et al.*, 2001; Pey *et al.*, 2008). However, the distribution of microorganisms in difference particles size has being ignored. Recently, dust events have been shown to introduce a significant pulse of microorganisms (Griffin, 2007) and other microbiological materials into the atmosphere (Jaenicke, 2005). Temporal and spatial variability of microbes within the dust clouds is important. Griffin et al. 2001 shown that around 25% are plant pathogens and 10% are opportunistic human pathogens in air samples during dust events in United States Virgin Islands.

Given the proximity to North-African continent, Andalucia region register a significant impact of APM from the Sahara and Sahel. The aim of the study was to characterization mineralogical and the airborne microorganisms of atmospheric particle obtained during the impact of one of these air masses by using a high-volume equipped with TSP inlets. The composition of the airborne microorganisms was determined by sequencing and cloning the 16S rRNA genes. Contrary to culture techniques, the rRNA sequence approach for microbial identification does not depend on viability under laboratory conditions.

Mineralogical and chemical composition of North African aerosol has been studied by numerous researchers. Calcite ($CaCO_3$), dolomite ($CaMgCO_3$), quartz (SiO_2), clay minerals (Kaolinite, illite, smectite, palygorskite, and chlorite) and feldspars (Guerzoni *et al.*, 1997; Caquineau *et al.*, 1998) are characteristic of African aerosol. Iron oxides and calcium sulphate also has been identified (Glaccumm and Prospero, 1980; Schütz and Siebert, 1987). During the episode of Saharan dust outbreak (18-20 march 2010), the atmospheric particulate material is composed essentially by quartz, feldspars, clay minerals, carbonate and radiolarites.

[3]Group of atmospheric optics, University of Valladolid, 470741, Valladolid, Spain

Keywords: Geochemistry, Sedimentable Particle, Doñana Natural Park.

In this work, we evaluate the levels and chemical composition of atmospheric particulate matter deposited around the Doñana Natural Park, SW of Spain.
Specially, we are interesting in the flux of particulate matter originated from anthropogenic activities, and as they can contribute in the change of the geochemistry of soils. Near the area of Doñana, an important Industrial State is placed, composed by a petroleum refinery, Cu-smelter and several factories of phosphorite transformation.
In this study, we have selected the monitoring station of Matalascañas, belonging to Air Quality Control Network of Andalusia. In order to compare with other urban and industrial sites, simultaneously we have sampled sedimentable particles at University Campus monitoring station (city of Huelva) and La Rábida, respectively.
Samples were collecting from June 2008 to June 2009 at a rate of 1 sample/15 days of bulk deposition. Upon sampling, pH, conductivity and alkalinity were measured in unfiltered samples. At laboratory, samples were filtered through quartz microfibre filters. The soluble fraction was extracted with MQ H_2O at 80ºC. Major ions were analyzed in filtered samples to determine the deposition of soluble material.
After gravimetric study, the filters were digested following the methodology of Querol et al (1999), which use a strong acid digestion (HF + HNO_3 + $HClO_4$) of ½ of filter.
Anions were determined by Ion Chromatography. Filter samples were analyzed by the procedure developed by Querol et al. (2001) to determine the composition of the insoluble fraction by means of an ICP-OES and ICP-MS.
Images of Secondary Electron and Back Scattered (SEI and BSEI) were studied with a Scaning Electron Microscopy (SEM-EDS) in order to recognize the size, shape and composition of single particles.
The annual levels of bulk deposition (soluble and insoluble fractions) registered in this area were up to 16 g/m^2/yr. These depositions levels were low in comparison with other sites of the industrial and urba sites of Huelva (26 and 28 g/m^2/yr in University Campus and La Rábida, respectively), and others representative monitoring stations of Spain (20 to 30 g/m^2, Castillo, 2006). Peak concentrations were obtained during June to October (Fig. 1).

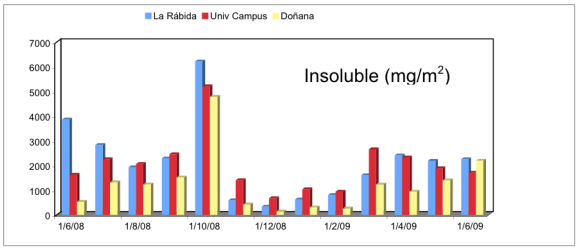

Figure 1.- Montly concentrations of deposited particles (units: g/m^2/yr).

From the soluble ions, the major contributors to the total mass were the marine aerosol (3.5 g/m^2/yr), higher than the concentrations obtained in University Campus (1.8 g/m^2/yr) and La Rábida (2.5 g/m^2/yr), Anthropogenic species concentration (SO_4^{2-}, NO_3^- and NH_4^+, 2.5 g/m^2/yr) is similar to University Campus (2.3 g/m^2/yr), and lower than La Rábida (6.8 g/m^2/yr),
Also, in the insoluble fraction, crustal species concentration (Ca^{2+}, Mg^{2+}, K^+, 0,49 g/m^2/yr) is lower than the concentrations of University Campus (0,66 g/m^2/yr) and La Rábida (0,73 g/m^2/yr)
The levels of trace elements were low also comparared with urban and industrial environments.
These results are comparable with abandoned mining areas of the Iberian Pyrite Belt.

Presenting author email: milagros.santacatalina@ua.es

This work presents the comparison between aerosol and rain composition in an area located in Southeast Spain in the period 1999-2008. The study area is a semi-arid region with annual precipitation less than 300 mm and important influence of urban-industrial activity (cement, ceramic and related industries). Data of PM_{10} levels, rainfall and particle water soluble compounds from both type of samples are compared. In case of rain composition, several stations (rural and urban) are also compared. Results show the evolution of NO_3^-/SO_4^{2-} ratio in rain in the study area compared with that of coastal and background nearby stations. The comparison between PM_{10} composition and rain composition series shows a good agreement. In both cases, levels of sulphate are higher in summer months due to the oxidation reactions in the atmosphere at high temperatures and the levels of nitrate are higher in winter months.

From 2004 to 2010 PM_{10} daily samples were collected with a high volume Digitel DL77 sampler. Munktell filters of micro-quartz fibre with 15 cm of diameter were used for the sampling. Rainfall was collected every 15 days at the same station from 2008 and from 1999 in Agost station (a rural station located in the same area). Zarra and Guardamar are background and coastal stations respectively, outside the area of study with rainfall chemistry available used for comparative purposes. SO_4^{2-} and NO_3^-, and main soluble ions in both PM_{10} extracts and rainfall samples, were analysed by ion chromatography (DIONEX DX-120).

Figure 1 shows the evolution of $NO_3/nssSO_4$ ratio in rain in the study area compared with that of coastal and background nearby stations. The ratios in Agost station (in the study area) and Zarra are higher than the ratio in the coastal station nearby the study area. This would be consistent with an increasing degree of nitrate oxidation with increasing distances from the coast were fresh emissions of NO_X occur. This was pointed out by Sanz et al (2002).

Figure 2 shows the comparison between ratio NO_3^-/SO_4^{2-} in aerosol and ratio NO_3^-/SO_4^{2-} in rainfall. There are not significant differences between these average ratios. Concerning seasonal variation of ratios, winter months ratios are higher than summer months. This could be related with the increase of nitrate levels, respect sulphate levels, in winter months due to traffic emissions. In contrast, in summer months levels of nitrate decrease in concordance with the decline of traffic and the ammonium nitrate decomposition. But on the other hand levels of sulphate increase due to oxidation reactions in the atmosphere at high temperatures. Then, ratios in summer months are lower than in winter ones.

Crustal related ions, very relevant in the composition of PM_{10} and rainfall in the area, are also addressed in terms of efficiency of deposition from aerosols. The deposition rates have been compared with data from a three years study conducted in the area from 1989-1991 (Carratalá and Bellot, 1997) showing a decrease in the levels of sulphates and crustal material and an increase in nitrates.

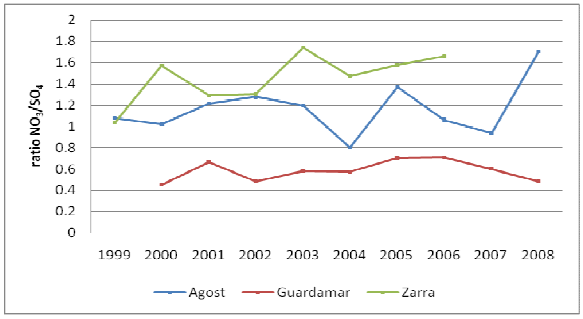

Figure 1. Evolution of annual $NO_3/nssSO_4$ ratio in rain at different stations.

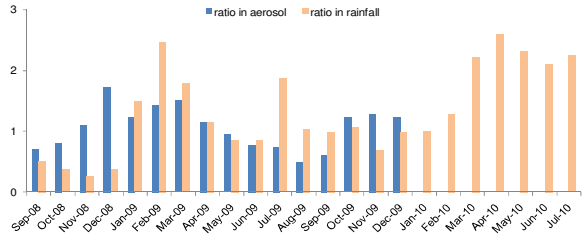

Figure 2. Comparison between ratio NO_3^-/SO_4^{2-} in aerosol and ratio NO_3^-/SO_4^{2-} in rainfall.

Spark generators for nanoparticle generation

Scaling up the production rate of Ge nanoparticles by spark discharge

S. Kala, F.E. Kruis, M. Rouenhoff and C. Blumberg
Institute for Nanostructures and Technology, Faculty of Engineering Science and Center for Nanointegration Duisburg-Essen (CeNIDE), University of Duisburg-Essen, Duisburg, 47057, Germany
Keywords: Aerosol generation
Presenting author email: shubkala@gmail.com

Nanoparticles of pure Si and Ge are important due to the potential of obtaining visible photoluminescence, which is useful for many applications including photovoltaics, lasers and infrared dyes. In most of the cases, solution-based methods have been utilized to produce nanoparticles of Si and Ge, which causes difficulties in interpretation of properties due to presence of reaction residues and lack of monodispersity. In the present study, the suitability of spark discharge technique to prepare pure semiconductor nanoparticles has been investigated. Since Bulk Ge has smaller electron and hole effective masses and a larger dielectric constant than bulk Si (Taylor et al., 2004) the quantum effect is expected to be more pronounced in Ge than in Si, and was thus selected for this study.

Initially, a conventional spark discharge between two Ge electrodes of diameters of ~6 mm was created by means of a high-voltage supply and set of capacitors (Schwyn et al., 1988). Sintering and size-selection steps leads to production of high-quality monodisperse Ge nanoparticles. However, the resulting number concentration is found to be too low for efficient deposition.

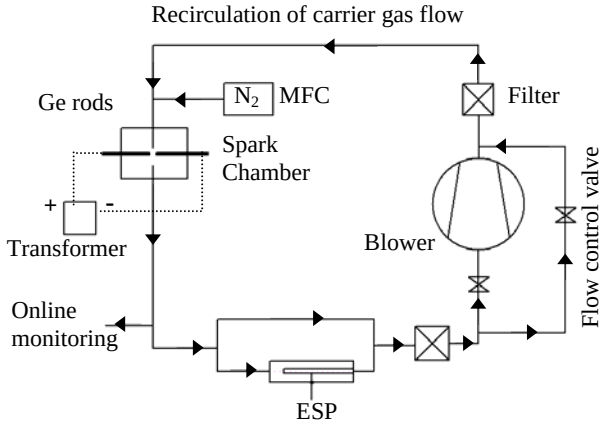

Figure 1. Schematic diagram of Ge nanoparticles synthesis setup under high-flow conditions. ESP means electrostatic precipitator, which is for the deposition of the generated Ge nanoparticles.

In order to increase the production rate of Ge nanoparticles, the high-voltage supply and set of capacitors are replaced by a low-cost transformer based on an induction coil delivering 2×7.5 kV (AC), 40 mA. The Ge electrodes are separated by distance of 0.5-2 mm and are connected to the transformer, as shown in Figure 1. In order to be able to use higher carrier gas flow rates, the facility contains a powerful blower and filters allowing to recirculate the carrier gas. A small flow ~ 1 slm (standard liter per minute) is introduced via mass flow controller (MFC) so that the outlet flow can be monitored.

On increasing the carrier gas flow rate from 5-60 slm, mobility diameter of the generated particle corresponding to maximum concentration (D_{max}) is observed to decrease from 58 to 13 nm. Particle production rate and D_{max} as a function of carrier gas flow rate are shown in Figure 2. Typically, production rate of 20-25 nm size nanoparticles is found to be ~2.6 mg/hr with a flow rate of 40 slm. A small amount of larger particles due to splashing is also observed during scanning electron microscopy investigations. As an increase in flow rate leads to reduction of the production rate, the use of several parallel reactors was found to be the best way to increase the production rate.

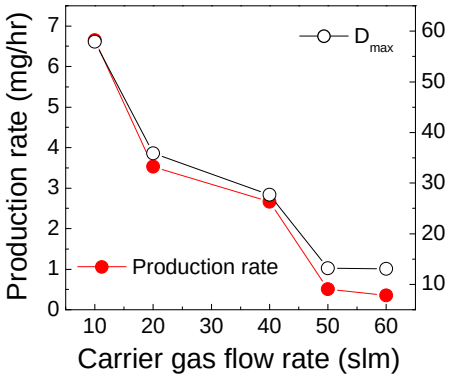

Figure 3. Variation in production rate and mobility diameter corresponding to maximum concentration (D_{max}) as a function of carrier gas flow rate.

Aerosol Modelling

Multi-scale modeling of aerosol formation in pipe flow

C. Winkelmann[1], A.K. Kuczaj[1], S. Stolz[1,2] and B.J. Geurts[2,3]
[1]Philip Morris International R&D, Philip Morris Products SA, 2000 Neuchâtel, Switzerland

[3]Department of Applied Physics, Eindhoven University of Technology, 5300 MB Eindhoven, The Netherlands
Keywords: CFD, modelling, nucleation, growth, coagulation, numerical simulation.
Presenting author email: christoph.winkelmann@pmi.com

Many applied problems in fluid mechanics have a multi-scale character due to physical processes evolving at many different time and/or length scales. Examples range from turbulent flows with different length scales to chemically reacting and multi-phase flows with various time scales. In most applied flow problems, resolving all scales in space and time present in a flow is not computationally feasible. For the non-resolved time-scales, e.g., time scales on which nucleation of over-saturated vapors is occuring, suitable models can be developed.

In general, the nucleation time-scale can be some orders of magnitude smaller than the timestep of the fluid simulations. To demonstrate this, we focus on aerosol flows in a rather simple geometry, but with an abrupt phase change caused by an immediate cooling of hot vapors that triggers creation of the aerosol droplets. The flow cooling is introduced by a rapid change of wall temperature in the considered pipe geometry as seen in Fig. 1(a). Consequently, an aerosol is formed from the hot vapors which are initially in the gas phase (Fig. 1(b,c)).

In our model, the aerosol is simulated in an Eulerian frame exploiting the computational efficiency of such approach. The formation of aerosol droplets is described by classical nucleation theory. Models for coagulation of, condensation to and evaporation from the droplets are included. In addition to the flow equations for mass, momentum and energy conservation, equations for the aerosol mass and number load are solved. In this method of moments approach, the diameter of average mass of the evolving aerosol can be easily determined. In order to account for the omitted time scales in the nucleation process, a sub-timestep model has been developed and included in our simulation to allow for computations at reduced computational effort. The accuracy of the obtained flow solution with this coarse-graining of the aerosol creation process is one of the key objectives for investigations presented in this work.

Our aim is to provide a simple computational framework for testing and analyzing aerosol models. In the literature only a modest number of detailed numerical experiments are available for aerosol generation processes by nucleation in flows of condensable vapors. Here, we consider the generation of an aerosol by a rapid cooling of hot vapors in laminar flow (Nguyen *et al.*, 1987).

We use the setup and flow parameters described by Nguyen *et al.* (1987) and consider a pipe flow with prescribed axial wall temperature profile starting from the temperature of hot saturated vapors of dibutyl phthalate and changing rapidly to room temperature within a short downstream distance (Nguyen *et al.*, 1987; Pyykönen and Jokiniemi, 2000). The aerosol model is implemented as an extension to the open-source software OpenFOAM®, which provides sufficient flexibility for consideration of geometrically more complex flow domains.

Our focus lies on two important aspects. First, the analysis of the time resolution at which the simulations need to be performed in order to obtain accurate results at minimal computational cost. For this, a set of simulations is carried out with different time-step sizes in order to investigate the accuracy and necessity of sub-time step modeling. Second, the validation of the method with experimental data available in the literature.

The extension of this work to multi-component aerosol formation and turbulent flow is ongoing.

Distribution of stripped droplets by sizes at drop shattering in a uniform flow

A.G. Girin[1]

[1] Odessa National Maritime University, Odessa, 65029, Ukraine
Keywords: dispersion, droplets, size distribution, aerosol evolution.
Presenting author email: club21@ukr.net

Distribution function $f_n(r)$ of quantity of torn daughter droplets by sizes is obtained at arbitrary ratio $h = A/3H$ of rate of mass efflux $A = 0.46(1+\alpha^{\xi})^{-1}(\mu^2/\alpha)^{1/6}$ to rate H of relaxational decreasing of relative velocity of parent drop and gas flow. The result is based on investigation of local surface instability with due regard to changing of velocity profile across the boundary layers, as well as to changing of velocity and boundary layer thicknesses along drop surface (Aslanov, Girin, 1981). It revealed for weak-viscosity liquids a new type of hydrodynamic instability – "gradient instability". Mechanism of this type differs from that of Kelvine – Helmholtz type and is caused by large enough velocity gradient inside liquid boundary layer. The theory explains the "stripping" mode of breakup as quasi-continuous dispersing from unstable part $\varphi_{cr} < \varphi < \pi/2$ of drop surface (φ is polar angle of surface ground).

Approximately spherical shape of drop and speedy stream (i.e. large values of gradient instability criterion GI>>0.3) were assumed. At approximation of experimental data for drop velocity versus time in the form $W = 1-\exp(-H\tau)$, the drop mass history $M = \left(1-h+h\exp(-H\tau)\right)^3$ was obtained by integrating the differential equation of drop mass efflux (Girin, 2011). To obtain distribution function we need to integrate the differential equation for torn droplets quantity (Girin, 2011) in a strip Δr along lines $r(\varphi,\tau) = const$. It was carried out due to approximation of these lines by straights with effective slopes $a_{ef}(r,h)$, which yields:

$$\frac{\Delta n(\tilde{r})}{\Delta \tilde{r}} = f_n(\tilde{r}) = \frac{B_1^3 B_2}{(h-1)\tilde{r}^4}\frac{a_{ef}(\tilde{r})}{H^2}\sum_{i=1}^{4} A_i\left(\Phi_{i*}(\tilde{r}) - \Phi_i^*(\tilde{r})\right),$$

where $\Phi_i(\tilde{r}) = C^i(\tilde{r})\left(\sin^2\varphi(\tilde{r}) + \sin^2(\varphi(\tilde{r}) + \theta_i(\tilde{r}))\right)$ and $C(\tilde{r}) = (h-1)/\left(h - (\tilde{r}/(B_1\Psi(\varphi)))^2\right)$ must be calculated on lower $\varphi = \varphi_*$ and upper $\varphi = \varphi^*$ limits of integration; $\tilde{r} = r/R_0$, $A_i = 0.25C_4^i h^{i-1}(1-h)^{4-i}$, $\theta_i = \pi - \gamma_i$ at $h < 1$ and $\theta_i = \gamma_i$ at $h > 1$, $\gamma_i = \arcsin((iH/2a_{ef})^2 + 1)^{-0.5}$. Formula allows to calculate intermediate distribution of droplets torn to any moment before breakup terminates. Values $\varphi_*(\tilde{r})$ and $\varphi^*(\tilde{r})$ are to be found from equations of left and right boundaries of dispersion region and set of lines $\tilde{r}(\varphi,\tau) = const$. Analysis of behavior of these lines permitted to find expression for a_{ef}, which is valid in wide diapason of h. It was fitted with account for most influence of its initial values and less influence of mean values. Besides, it was necessary to set up natural demand to get in the limit $h \to 1$ the expression obtained in case $h = 1$ exactly.

The calculated distributions $\Delta n(\tilde{r})$ are shown on fig. 1. Their shapes depend on values of h, while the sizes of totality of torn droplets are defined by parameter $B_1 = 1.60\alpha^{1-2\xi}\,\mathrm{Re}_d^{-0.5}$, which plays the role of sizes scale. As well, $B_2 = 0.15\mathrm{Re}_d^{1.5}\,\alpha^{7\xi-3.5}(1+\alpha^{\xi})^{-1}$ is responsible for quantity scale (here $3\xi = \log_{\alpha}(\alpha\mu)$ is parameter of mutual viscous engagement of media in boundary layers, $\alpha = \rho_g/\rho_l$ and $\mu = \mu_g/\mu_l$ are their density and viscosity ratios, $\mathrm{Re}_d = 2R_0\rho_g V_g/\mu_g$ – Reynolds number of parent drop). At $h > 1$ function $\Delta n(\tilde{r})$ has ascending and descending branches, which make maximum at $\tilde{r}_{mod}$. As h increases, the part of fine fractions widens, and at $h \approx 2$ it becomes comparable with that of the base one. The analysis shows, that values of h slightly higher than $h = 1$ are inherent to flows behind shock and detonation waves, the values $h > 4$ correspond to ablation of liquid meteoroids and the case $h < 1$ – to incomplete shattering, inherent to viscous drops.

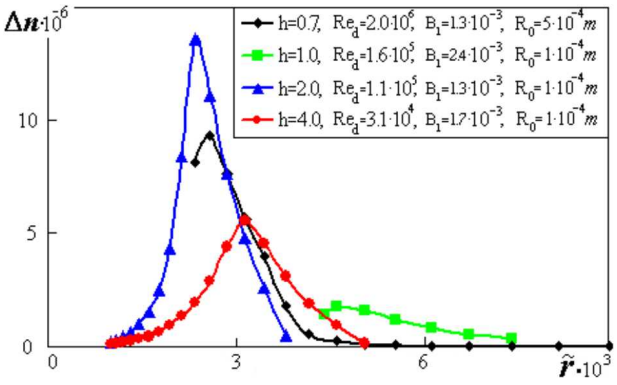

Figure 1. Distributions $\Delta n(\tilde{r})$ at various h.

Model of shattering which is based on mechanism of gradient instability provides approximate analytical relations for main regularities of the process. Obtained distribution function will be the ground for model of subsequent processes of rapid acceleration, evaporation of spray of torn droplets and formation of inflammable mixture in wake of a shattering drop.

In their fourth assessment report, the Intergovernmental Panel for Climate Change (2007) states that the aerosols have a potentially significant cooling effect in global warming. Additionally, there is an increasing public concern e.g. about the health effects of fine particles. To investigate these and many other unknowns related to both primary and secondary particle formation and growth, aerosol dynamical models are often applied.

The original UHMA (University of Helsinki Multicomponent Aerosol) model was developed for studies of tropospheric new particle formation in clear sky conditions (Korhonen *et al*., 2004). The size-segregated, sectional box model included all basic aerosol dynamical processes: nucleation, condensation, coagulation and dry deposition, and has been used quite extensively and successfully to study new particle formation characteristics especially in the boreal forest environment of Hyytiälä, Finland.

Since the first UHMA description paper (Korhonen *et al.*, 2004), the program code has evolved due to e.g. addition of new minor processes, such as organic nucleation (Vuollekoski et al., 2010) and snow scavenging (Kyrö *et al*., 2009), which both have proven reasonable.

Science aside, the program code has gone through significant changes. For example, the coagulation coefficients are now recalculated only after significant changes in the sizes of particle bins have occurred, which typically causes a drastic reduction in computing time.

The new version is capable of directly using measurement and other input data to e.g. continuously set the vapor concentrations or initialize the particle distribution.

The condensation routine has been partially rewritten in an effort to describe the discrete general dynamic equation governing particle dynamics more accurately. As a result, all model dynamics are now described by differential equations, which makes the adaptation of differential equation solvers easier. In addition to the original Euler forward, the current version also includes the algorithms known as Euler—Cauchy and the 4th order Runge—Kutta. The improved condensation routine also includes a safety check: the time step of the model is also dynamically lowered, if too high growth rates threaten the numerical stability of the model.

The most significant difference between the original UHMA and the new version, aptly dubbed UHMAEMO, is, however, in structure: the code has been divided in more, shorter source files, and is now completely modularized. There are no global variables that would be visible outside of the scope of each function. Instead, all important variables are input and output via *ad hoc* data types. This means that UHMAEMO can be coupled with the majority of e.g. meteorological and chemical models with little effort.

Currently, UHMAEMO is being coupled with a chemistry module in an effort to create a detailed box model, as well as with chemical, emission and meteorological modules aiming for regional models.

Natural and anthropogenic aerosols may have a great impact on climate as they can directly interact with solar radiation and indirectly affect the Earth's radiation balance and precipitation by modifying clouds. In order to quantify the direct and indirect effect, we must understand the complex processes that connect an aerosol particle to a cloud droplet. However, while modern measurement techniques are able to detect particle sizes down to nanometer all the way from ground up to the stratosphere, the data does not serve for all of our needs for understanding the processes. Hence we will demonstrate a modelling approach to investigate the complex processes of aerosols in the atmospheric boundary layer (ABL).

SOSAA (model to **S**imulate the concentration of **O**rganic vapours, **S**ulphuric **A**cid, and **A**erosol) is the first column model existing in the world with detailed chemistry and aerosol dynamics parallelized. It can be used to study aerosol processes in the ABL for long period. The model (Figure 1) includes the aerosol dynamics module UHMAEMO (Vuollekoski et al., 2010) coupled with the chemistry-transport column model SOSA (Boy et al., 2011).

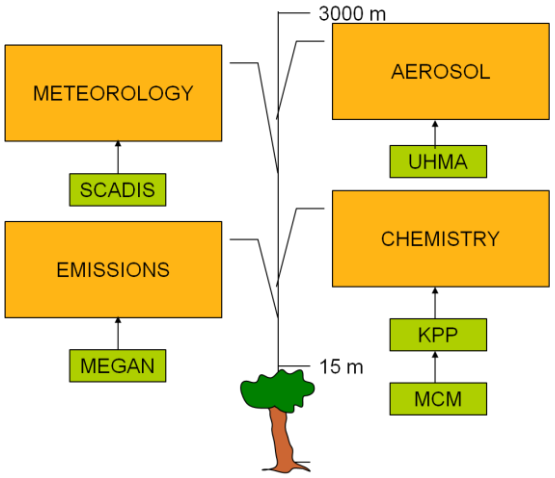

Figure1. SOSAA model structure

SOSA attempts to reconstruct the emissions, transport, and chemistry in the ABL in and above a vegetation canopy using meteorological measurements. UHMAEMO (**U**niversity of **H**elsinki **M**ulticomponent **A**erosol Module) simulates tropospheric new particle formation in clear sky conditions. It is developed from the UHMA model which includes all basic aerosol dynamical processes: nucleation, condensation, coagulation and dry deposition (Korhonen et al., 2004).

As a first application of the model, we present nucleation studies for the year 2010 with different nucleation theories including homogeneous nucleation of sulphuric acid and water, kinetic nucleation, and activation nucleation. Aerosol particle growth has also been studied with different growth rates.

Most of the input measurement data are from the SMEAR II station in Hyytiälä, Finland. Sounding data for upper boundary condition are from neighbouring meteorological stations.

Africa is one of the least studied continents in respect to atmospheric aerosols (Laakso *et al.*, 2006). In this study we simulated observed new particle formation and growth in a relatively clean savannah environment in South Africa.

MALTE (Model to predict new Aerosol formation in the Lower TropospherE) is a one-dimensional model, which includes modules for boundary layer meteorology as well as aerosol dynamical and chemical processes (Boy *et al.,* 2006). The model used in this study is a further developed version, where the original turbulence scheme is replaced with that of SCADIS to get more reliable results considering vertical turbulent fluxes (Lauros *et al.*, 2010). The aerosol dynamic processes are simulated with UHMA (University of Helsinki Multicomponent Aerosol model). UHMA focuses on new particle formation and growth (Korhonen *et al.*, 2004), and thereby MALTE is well suited to study these phenomena. The emissions of monoterpenes and other organic vapours from the canopy are calculated with MEGAN (Model of Emissions of Gases and Aerosols from Nature), described by Guenther *et al.* (2006). The chemistry is calculated using the Kinetic PreProcessor (KPP) (Damian *et al.*, 2002), and chemical reaction equations are from the Master Chemical Mechanism (http://mcm.leeds.ac.uk/MCM/). Previous studies indicate, that this model is able to predict new particle formation events at the surface (Lauros *et al.*, 2010, Boy *et al.*, 2006) and in the boundary layer (Siebert *et al.*, 2007) with good agreement compared with measurements.

The measurements utilized in this study were done at a relatively clean background savannah site in central South-Africa. The location is characterized with relatively low pollutant concentrations with occasional polluted air masses from the industrial areas 100-300 km to the east. New particle formation at the site has been found to take place during most of the sunny days, 69% of the days showing clear nucleation with additional 14 % of the days with non-growing nucleation mode (Laakso *et al.*, 2008; Vakkari *et al.*, 2010). The measurements utilized in this study include meteorological variables (temperature, relative humidity, wind speed and direction, precipitation, and radiation), trace gas concentrations (SO_2, NO_x, CO, and O_3) and aerosols (number size distribution, particulate mass, and ion number size distribution) and concentration of volatile organic compounds.

The observational data was used for input and comparisons with the simulations. We selected a couple of days of continuous data and varying conditions of clean and polluted background air. The frequent new particle formation events and particle growth during this period was evaluated in detail. This work will present new model results to explain the high observed nucleation event frequency and discuss the reasons for high frequency of nucleation episodes observed.

Simulation of binary aerosol droplet formation

X. Z. Zhen, H.-J. Schmid

Particle Technology Group, University of Paderborn, Paderborn, 33098, Germany

Keywords: Monte Carlo simulation, binary aerosol formation, nucleation, growth, coagulation.
Presenting author email: xinze.zhen@upb.de

A theoretical analysis of binary droplet formation from a water/glycerol vapour mixture has been performed using a “1.5”-dimensional population balance model to simulate the evolution of the aerosol drop size distribution as well as the mean droplet concentration. The simulation includes the relevant mechanisms nucleation, condensation, evaporation and coagulation.

The simulation model was developed and implemented in the commercial solver PARSIVAL. The self-adaptive numerical algorithms in PARSIVAL are based on the Galerkin h-p (h-p: Variable grid - variable order) method and a temporal discretization of Roth’s type (Wulkow et al., 2001).

As expected, from these simulation results it can be seen that nucleation and condensation are strongly affected by the supersaturation. The properties of the droplets are investigated at different vapor compositions. At a higher glycerol concentration in the vapor despite higher nucleation rates larger droplet sizes evolve compared to low glycerol vapor pressure. The evolution of the mean droplets composition starts from almost pure glycerol, is then reduced quickly, passes a minimum before, finally increasing again towards equilibrium composition. Furthermore, the final mean droplet size depends on the mass of vapor at a constant vapor composition of water/glycerol.

The influence of the mechanisms in determining the droplet size is an important focus. As shown in figure 1, at the beginning of the process, aerosol nucleation is playing a dominant role, with rather small droplet growth rates. Later on, the condensation process becomes more and more important and due to the increasing number of droplets and growing particle surface the condensing mass increases rapidly and the mean droplet size significantly increases. The coagulation process is becoming significant even later than the condensation. With severe reduction of the number of droplets coagulation leads to an even faster growth of droplet sizes.

One of our main goals in this work is to study the evolution of the aerosol drop size distribution and the droplet concentration distribution from the water/glycerol vapour mixture. However traditional dynamic simulation methods are at a disadvantage when modeling more than one internal variable, whereas. Monte Carlo methods easily can be extended to a multidimensional case. Monte Carlo simulation is based on the use of a particle ensemble representative for the whole system in order to calculate the properties of the system. Here we use event-driven Monte Carlo algorithm with a stepwise constant-volume method formulated for simultaneous nucleation, condensation and coagulation (Maisels et al., 2004). By using event driven time evolution, the problem of choosing a correct time step is removed. The accuracy of the Monte Carlo solver depends on the number of simulation particles. The droplet number changes according to the chosen mechanism. At each step of the simulation a mechanism is selected with a probability that is directly calculated with the rate of the three processes. The nucleation and coagulation processes result in increases or decreases of the drop concentration, respectively. However, condensation results in surface growth but does not effect the total drop number concentration. When the droplet number in the simulation volume increases or decreases by a factor of two of its initial value, the simulation volume is halved or doubled, respectively.

A systematic validation of the Monte Carlo algorithm with respect to simulation parameters (ensemble size, integration step size etc.) will be presented. Subsequently, a comparison of droplet size distributions and droplet composition resulting from Monte-Carlo and 1.5D-population balance, respectively, will be given. Furthermore, a parameter study using the Monte Carlo technique shows impressively the advantage of this new algorithm.

In future studies the simulation results will be verified by laboratory experiments.

New particle formation has been observed to take place in various conditions in the atmosphere. The actual mechanisms of particle formation are still unknown, but they can be divided into two groups: electrically neutral and ion-induced mechanisms. One way of estimating the fraction of particles formed via ion-induced nucleation is to determine the fraction of charged particles at the size where particles are formed (Laakso *et al.* 2007). However, this fraction cannot usually be measured at such a small sizes due to instrumental limitations.

Kerminen *et al.* (2007) derived an equation describing the behaviour of the charging state, S, (i.e. the quotient of the charged fraction and the charged fraction in the bipolar equilibrium) as a function of diameter using several simplifying assumptions. With the use of the equation, a curve can be fitted to the measured values of S to extrapolate the value of S at the size of particle formation, which can then be used to estimate the fraction of ion-induced nucleation. Iida et al. (2007) derived a method to determine also the diameter growth rate of particles based on the behaviour of the charged fraction.

Both Kerminen *et al.* and Iida *et al.* assumed symmetric concentrations of negatively and positively charged small ions (diameter < ~2.0 nm) as well as negatively and positively charged particles. In this study we have derived an equation describing the behaviour of charging state and developed a method to determine the particle growth rate from the charged fraction in a charge asymmetric framework.

The initial charging state of freshly formed particles, whether undercharged or overcharged, evolves towards the charge equilibrium with a rate that depends on the concentrations of small ions and the growth rate of particle diameter. In the symmetric case the charged fraction evolves towards the charged fraction in bipolar equilibrium and thus the charging state evolves towards unity (Figure 1). In the asymmetric case, the charged fraction evolves towards an equilibrium, $f_{as}^{\pm}$, that can be estimated by scaling the bipolar equilibrium, $f_{eq}^{\pm}$, with the concentrations of small ions, $f_{as}^{\pm}=N^{\pm}/N^{\mp}\times f_{eq}^{\pm}$. Example behaviours of charging states as a function of diameter are shown in Figure 1.

Similarly to many other environments, the average concentrations of negatively and positively charged small ions were observed to be substantially different in urban environment in Helsinki, Finland where charging states were measured using an Ion-DMPS instrument between December 2008 and February 2010 (Gagné *et al.* 2011). The fraction of ion-induced nucleation and particle diameter growth rates were analyzed both assuming equal concentrations of small ions and without this assumption. The fractions of ion-induced nucleation did not depend much on this assumption. However, the growth rates determined from the charged fraction and particle size distribution agreed better in the charge asymmetric framework.

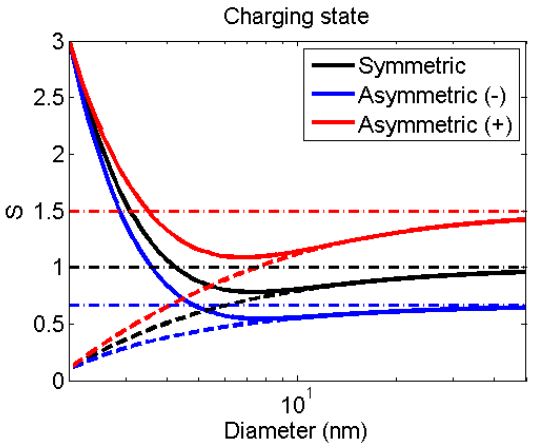

Figure 1. The charging state as a function of diameter. The particle growth rate was 6 nm h^{-1} and the initial charging state at 2 nm was 3 (solid lines) or 0.1 (dashed lines). The small ion concentrations were 500 cm^{-3} in symmetric case and 400 and 600 cm^{-3} for negative and positive ions, respectively, in the asymmetric case. The dashed-dotted lines correspond to values in equilibrium.

Can dimethyl sulphide cause new particle formation over the central Arctic Ocean?

M. Karl[1], A. Gross[2], C. Leck[3] and L. Pirjola[4]

Keywords: dimethyl sulphide chemistry, aerosol model, climate effects, nucleation
mka@nilu.no

In summer, the central Arctic Ocean is an oceanic region nearly free from influences of continental or anthropogenic sources of sulphur gases. The formation of sulphate particles is known to take place in environments where the available aerosol surface area is low and the condensational loss of nucleating vapours is not favoured. Thus the Arctic environment seems to be ideal to test the climate feedback mechanism postulated by Charlson et al. (1987) (CLAW hypothesis).

According to the CLAW hypothesis, dimethyl sulphide (DMS) produced by marine phytoplankton and ventilated into the marine boundary layer (MBL) can be oxidized to sulphuric acid (H_2SO_4) which nucleates to form new particles and subsequently new cloud condensation nuclei (CCN). However, the nucleation ability of DMS-derived H_2SO_4 in the MBL is controversial and has been much discussed. Representations of DMS gas phase chemistry and of sulphuric acid nucleation are highly uncertain (Karl et al., 2007), limiting our understanding of fundamental processes in the study of the CLAW hypothesis.

A sectional aerosol dynamics model, MAFOR (Marine Aerosol FORmation), has been developed in the frame of this study to predict nucleation in the MBL and examine the CLAW hypothesis. MAFOR includes detailed gas phase and heterogeneous chemistry and aerosol dynamics with different nucleation schemes: classical binary, ternary, ion-induced and kinetic nucleation parameterizations.

MAFOR is used to model the aerosol evolution and gas phase constituents observed during the Arctic Ocean Expedition (AOE-96) to the central Arctic Ocean from beginning of July until end-August of 1996 (Leck et al., 2001). Model output was compared to results from two well-documented aerosol models: MONO32 (Pirjola and Kulmala, 2000) and AEROFOR (Pirjola, 1999).

An unexpected result was that classical homogeneous binary and ternary nucleation theories failed to predict new particle formation in the Arctic. Three nucleation mechanisms were able to predict new particle formation in the Arctic: ion-mediated, kinetic sulphuric acid and cluster activation. Interestingly, nearly linear relationships between DMS concentrations and total number concentrations of nucleated particles were found by the model when applying a combined ion-mediated/cluster activation nucleation mechanism (Figure 1).

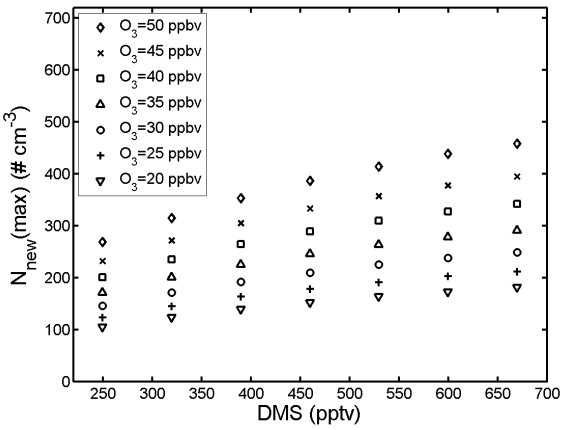

Figure 1. Modelled daily maximum number concentrations of nucleated particles using different DMS and O_3 concentrations.

Model simulations indicate that growth of nucleation mode particles (3-25 nm diameter) to CCN sizes under Arctic conditions can only occur in the presence of condensing organic vapours with sufficiently high concentrations in the gas phase (>7 pptv). Freshly nucleated stable clusters of 1-2 nm diameter sizes did not grow to detectable sizes during the simulations since the Kelvin effect prevents condensation of the organic vapour to the very small particles.

Main conclusion from the study is that to fully understand the role of DMS in the formation of new particles, uncertainties associated with several key reaction rate constants in the atmospheric oxidation chain of DMS need to be reduced.

Adsorption in biogenic SOA formation

E. Laukkanen[1], H. Korhonen[1], L. Hao[2], J. Joutsensaari[2], J. Smith[1,2], K. Lehtinen[1,2] and H. Kokkola[1]

Presenting author email: emmi.laukkanen@fmi.fi

Secondary organic aerosol (SOA) particles in the atmosphere affect the Earth's energy balance directly by scattering solar radiation and indirectly by acting as cloud condensation nuclei. Majority of SOA particles formed in the atmosphere originate from volatile organic compounds (VOC) emitted the biogenic sources. (Hao *et al* 2009 and the references therein) Despite their importance for climate and abundance in the atmosphere, the factors affecting their radiative forcing such as their formation in atmosphere, are poorly known.

In a recent study biogenic SOA formation was observed in plant chamber experiments with living Scots pine seedlings (Virtanen *et al* 2010). Conclusion of those experiments was that the formed aerosol particles were in solid, most likely in amorphous state. The state of the particles is important to know because it affects the way the particles behave chemically and how they are treated in models.

So far it has been assumed in models that all formed particles are mainly in liquid phase and that the growth of the particles is dominated by absorption instead of adsorption of oxidation products of VOCs. Rounds and Pankow (1990) formulated a theory of SOA formation by adsorption. However, it has not been included in many of the aerosol models.

In this study, SOA formation in a plant chamber was modelled with a zero dimensional SALSA aerosol microphysics model (Kokkola *et al* 2008). The measurement set up presented by Hao *et al* (2010) was simulated. In the chamber the VOCs emitted by Scots pine seedlings were oxidized by ozone leading to new particle formation. The emisions included mainly α-pinene, β-pinene, Δ^3-carene, limonene, myrcene and β-phellarndrene.

The saturation vapor concentrations were determined by fitting calculated SOA yields to measurements. The saturation vapor concentrations used in the calculations were varied to represent the conditions in a case of solid and liquid particles. The solid phase particle has lower equilibrium vapor pressure than a similar sized in liquid phase. New particles formation rate was determined from the measurements.

Our simulation show that modelled particle size distribution resemble the measured one much more closely when gas-to-particle conversion is assumed to occur via adsorption. This result supports the observations by Virtanen *et al* (2010). It is very likely that under ambient conditions the gas-to-particle partitioning of SOA occurs from organic gases to solid state particles.

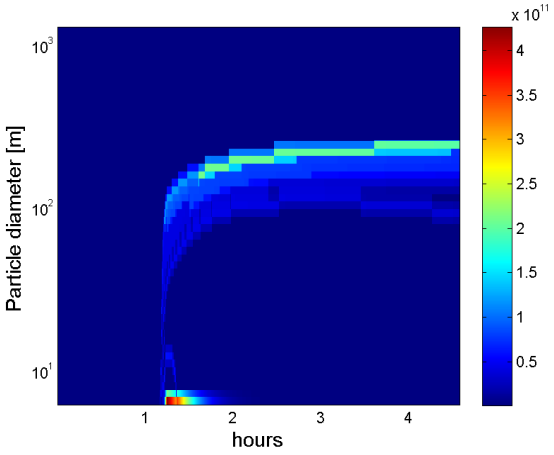

Figure 1: Particle formation event and growth through adsorption of SOA precursor gases on particles. The colorbar describes the number concentration of particle in molecules per cubic meter.

Atmospheric aerosols - Specific Aerosol Types

Relationship between water soluble calcium and anions in a kosa (Asian dust) aerosol

I. Mori[1] and M. Nishikawa[1]

[1]National Institute for Environmental Studies, Tsukuba, Japan
Keywords: Ca, nitrate, sulfate, mineral aerosol.
Presenting author email: mori.ikuko@nies.go.jp

Water soluble calcium (Ca) is typically the main ion fraction in the aerosol collected during an Asian dust event (e.g., Shen et al., 2009). The increased concentration of soluble Ca in an aerosol registered as a spike when a kosa event was observed (Suzuki et al., 2008). Therefore, it was proposed that soluble Ca in aerosols is a good marker of a kosa event (Suzuki et al., 2008). The solubility of Ca in the Certified Reference Material (CRM) of Simulated Asian Mineral Dust (CJ-2) varied with the solvent and with the mass ratio of CRM to solvent (Mori and Nishikawa, 2009). Many groups have reported that nitrate and sulfate ions are attached to kosa aerosol particles (e.g., Suzuki et al., 2008). The solubility of Ca in a kosa aerosol can be changed by the presence of those anions. In this presentation, we demonstrate a relationship between soluble Ca and anion concentrations using data obtained during the research campaign entitled " A Study on Dust and Sand Storms" conducted by the Ministry of the Environment, Japan.

Total suspended particulates (TSP) were collected at nine locations throughout Japan using high volume samplers with quartz fibre filters, when kosa events were observed in China. The aerosol mass concentration and the concentrations of the chemical components of the aerosols were determined by procedures described by Mori et al. (2002). Four kosa events (8-9 and 18-19 April 2006, 1-2 April 2007, and 26-27 May 2007) were selected for this study. Details of the research campaign and the selected heavy dust events are described in MOE (2009).

The solubility of non sea salt Ca (nssCa) in the aerosols collected during the kosa events ranged from 50-90%, and was much higher than the solubility of Ca in Chinese loess (18.1%) (Duvall et al., 2008). The equivalent concentration of water soluble nssCa (ws-nssCa) in the aerosol collected during the kosa events increased as those of exA (excess anion: NO_3^- + $nssSO_4^{2-}$ - NH_4^+) increased (Figure 1). A 1:1 correlation was, however, not found. The equivalent concentration of ws-nssCa was lower than that of exA in most of the samples, but was higher in some samples.

When the equivalent concentration of ws-nssCa was lower than that of exA, the nssCa solubility was in the range 60-80%; much higher than that for Chinese loess (18.1%). An estimation using the data presented in Nishikawa et al, (2000) indicated that 60-75% Ca in the CRMs of Chinese loess and/or Simulated Asian Mineral Dust would be present as $CaCO_3$. The nssCa solubility data obtained from authentic kosa aerosol samples implied that CO_3-Ca in a kosa aerosol was fully dissolved when the exA concentration was higher than that of the ws-nssCa. It also implied that Ca other than CO_3-C was dissolved also.

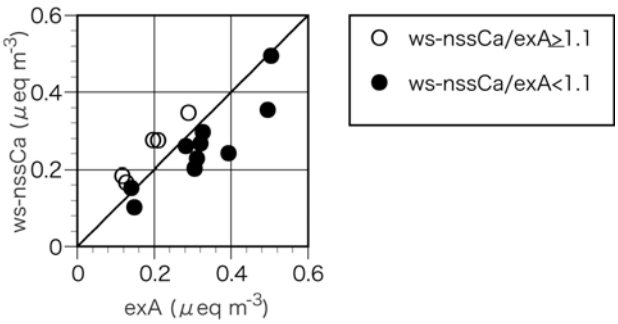

Figure 1. The relationship between ws-nssCa (water soluble - non sea salt Ca) and exA (excess anion: NO_3^- + $nssSO_4^{2-}$ - NH_4^+) for the aerosol collected during kosa (Asian dust) events in Japan. The solid line corresponds to the 1:1 correlation.

When the equivalent concentration of ws-nssCa was higher than that of exA, the nssCa solubility was 50-60%. It was higher than that for Chinese loess (18.1%), but lower than the Ca solubility (60-75%) estimated assuming that the $CaCO_3$ in kosa is fully dissolved. The ratio of the concentration of excess ws-nssCa (ws-nssCa - exA) to total nssCa was 0.1-0.2, and was comparable to the solubility of Ca in Chinese loess.

These results indicated that 10-20% Ca in a kosa aerosol was naturally dissolved, and additional CO_3-Ca dissolved according to the concentration of exA.

The authors thank the members of A Study on Dust and Sand Storms for collecting the aerosol samples and for various datasets. Part of this research was supported by the Environment Research and Technology Development Fund (B-0901) of the Ministry of the Environment, Japan.

A large field experiment of the Saharan Mineral Dust Experiment (SAMUM) was performed in Praia, Cape Verde, in January and February 2008 (Ansmann et al., 2011). This work reports on the chemical composition, shape and mixing state as well as derived refractive indices of individual particles determined by electron microscopy. In addition, aerosol mass concentrations and bulk mineralogical composition are addressed.

Three dust periods were recorded during the measurements, divided by transitional periods and embedded in maritime-influenced situations. Determined by filter gravimetry, the total suspended particle mass/PM_{10}/$PM_{2.5}$ in average was 250/180/74 µg/m³, respectively, for the first dust period (17 to 21 January) and 250/230/83 µg/m³ for the second (24 to 26 January). The third period (28 January to 2 February) was the most intensive with 410/340/130 µg/m³ (Kandler et al., 2011b).

Approximately 48,000 individual particles collected by cascade impactors were analyzed by automated scanning electron microscopy for their shape, chemical composition and mixing state (Kandler et al., 2011a). The aerosol at Praia is a superposition of mineral dust, sea-salt, sulfates, and soot aerosol. Particles smaller than 500 nm are mainly sulfates, mineral dust, mineral dust-sulfate-mixtures, and soot-sulfate-mixtures. Particles larger than 2.5 µm consist of mineral dust, sea-salt, and few mineral dust-sulfate-mixtures. A transition range exists in between.

The major internal mixtures are mineral dust-sulfate (sub- and super-micron) and soot-sulfate (sub-micron only). Mineral dust-sea-salt mixtures occur occasionally, mineral dust-soot mixtures were not observed. However, in the super-micron range by means of the dust-sulfate-sea-salt model applied in this approach, most of the particles are not internally mixed.

The shape of the particles in terms of aspect ratio was 1.3 to 1.4 for dry particles smaller than 500 nm and 1.6 to 1.7 for larger ones. A non-significant dependence of the aspect ratio on the particle composition was determined. A model calculation showed that at high relative humidities during dust conditions 13 % to 40 % of the particles are most probably spherical, while during maritime-influenced conditions this was the case for 39 % to 90 %.

The complex refractive index was derived from the measured chemical composition for each individual particle, using a mineralogy mixing model (Kandler et al., 2011a). While the real part of the refractive index showed low variation (1.55 to 1.58 at 532nm), a multi-modal imaginary part was detected as function of particle size, reflecting the complex aerosol composition. Soot mainly influences the light absorption for wavelengths longer than the hematite absorption edge (500 to 550 nm), while for shorter wavelengths the iron oxide in the mineral dust is dominating. The refractive index distribution of the aerosol is depending on the source region of the mineral dust and on the presence/absence of a marine component.

By X-ray diffraction of filter samples it was determined that the total suspended dust (bulk) consisted of kaolinite, K-feldspar, quartz, plagioclase, illite/mica, chlorite, gypsum, halite, and calcite. Kaolinite dominated the clay minerals, and K-feldspar was the most abundant feldspar component. Even during maritime periods, mineral dust contributed significantly to the aerosol mass at Cape Verde, usually dominating over the sea-salt.

By means of single particle analysis, a change in mineralogical composition with particle size was observed through chemical fingerprints. As it was to be expected, at increasing abundance of feldspars was observed with increasing particle size. However, the majority of the particles shows a chemical fingerprint which cannot be attributed to a (common) mineral phase, and in addition a high variation exists. We conclude that most of the silicate particles are aggregates of clay minerals or clay minerals covering other silicates and non-silicates.

Keywords: Sahara dust event indicators, trace metal concentration
Presented author email: vassiliki@ipta.demokritos.gr

Long-range transport of Sahara dust is often observed in the Mediterranean region. These events greatly influence the atmospheric aerosol concentrations leading to significant increase of the measured levels. Sampling of Total Suspended Particles (TSP) from a research aircraft was performed at different heights during a Sahara dust long-range transport event over central Europe, (Eleftheriadis et al., 1999). The trace elements content of TSP was examined by XRF analysis The results have shown that the concentration ratios of Ca/Fe, Ti/Fe and Mn/Fe were found to have characteristic values within the Sahara dust layers compared to those closer to the surface. The aim of the present study was to investigate the connection between Sahara dust phenomena and the atmospheric concentration of trace metals found is suspended particulate matter seasonally collected in Athens, Greece over a long-term period (approximately two decades) by utilizing the aforementioned ratios.

All samples were collected at the Demokritos GAW site (GAW-DEM, 2007) throughout the period 1980-1996 and specifically during the months January – February for the winter season and June – July for the summer one. The filters were analyzed by Electrothermal Atomic Absorption Spectroscopy (ETAAS), for the metals Pb, V, Ni, Mn, Cu, Fe, Al (graphite Furnace) and Mg, Ca and Zn (flame).

The Ca/Fe and Mn/Fe concentration ratios were calculated for each sample. The mean values of the ratios calculated by Eleftheriadis et al. (1999) for three different heights were in the range: Mn/Fe: 0.009-0.017 and Ca/Fe: 0.574-0.698. Based on the average and standard deviation of these three values, a range for each ratio was calculated (Mn/Fe:0.007-0.019, Ca/Fe: 0.490-0.755) and it was assumed that this range can be considered as a criterion for the occurrence of a Sahara dust transport event. The origin of air mass arriving at the sampling site during the sampling periods was identified by means of the HYSPLIT4 Model of ARL (Air Resources Laboratory). Back-trajectory analysis was conducted with a total transport time of 160-220h and with a start altitude of 200m AGL and 1500m AGL for two starting times 8:00a.m. and 5:00p.m. If there was an indication of long-range transport of African dust, control runs would be conducted for other times on the same day well.

In a total of 260 samples 110 displayed Ca/Fe and Mn/Fe concentrations ratios in the range of the proposed criterion. However, only for 7 samples both ratios (Mn/Fe and Ca/Fe) satisfied both criteria. HYSPLIT back-trajectory analysis revealed that 5 of these samples corresponded to Sahara dust events. Given that 5 out of 7 samples complying with both criteria corresponded to Sahara dust events, it is suggested that Mn/Fe and Ca/Fe concentration ratios may be combined and used as indicator of long range transport of African dust in this region

Reference value criterion	Number of values	Sahara dust events	Sahara dust events (%)
Mn/Fe 0.007-0.019	92	15	16.4
Ca/Fe 0.490-0.755	11	6	54.6
Both criteria satisfied	7	5	71.4
No criterion satisfied	150	10	6.7

Dust and its associated iron pools can regulate primary productivity and nitrogen fixation rates, resulting in altered carbon uptake and biogenic air-sea gas fluxes, which have feedback effects on climate and dust production (Jickells et al., 2005). While the importance of atmospheric dust in the iron supply to the oceans is now recognized, the actual quantification of the flux of dissolved iron from mineral dust remains one of the major uncertainties of the global iron connections in the Earth's System. The uncertainty in the flux is mainly due to large variation of the fractional iron solubility (dissolved to total Fe in %) of the dust. It is reported that this solubility ranges from ~0.1 to 80%, with higher values observed in more remote parts of the oceans where aerosol mass concentration is lowest (e.g., Hand et al., 2004; Baker and Jickells, 2006).

Several hypotheses have been proposed to explain such systematic trends in iron solubility during dust transport. One of the hypotheses is the physical processing proposed by Baker and Jickells (2006), who suggested that size sorting of dust during trans-Atlantic transport lead to the observed inverse relationship between the fractional iron solubility in dust aerosol and the atmospheric dust mass concentration. Baker and Jickells (2006) proposed that the greater solubility at lower dust concentrations was due to a larger surface area to volume ratio of the finer dust. However, it may not be possible to unambiguously confirm that particle size effects are solely responsible for the relationship based on atmospheric measurements because the aerosols collected in the field may have been subjected to other processes which alter their iron solubility (Baker and Croots, 2010).

In this study, we combined laboratory experiments with global aerosol modeling to evaluate this "physical hypothesis". We re-suspended two soil samples from known dust source regions (the Western Sahara (WS) and the Tibesti Mountains (Tibesti)) in pre-cleaned air and collected the particles using an 8-stage cascade impactor. This process does not involve any liquids. Shi et al. (2011) showed that the geochemical properties of the samples are representative of the atmospheric Saharan dust. We then measured the fractional iron solubility of each size fraction.

The results showed that iron fractional solubility ranged from ~0.1% in coarse dust particles (e.g., >1 μm) to ~0.3-0.7% (<1 μm) (Fig. 1). The measured iron solubility data were then applied to a global aerosol model, GLOMAP, to evaluate how the variations in fractional iron solubility with sizes affect the fractional solubility in total dust aerosols during trans-Atlantic transport. GLOMAP considers the gravitational settling of the dust particles and traces the evolution of dust size distribution during transport (Manktelow et al., 2010). The modeling results show a decrease in the mean size of dust during trans-Atlantic transport. However, this decrease in size only led to a small increase in dust fractional iron solubility from ~0.1% in areas close to the source region to ~0.2% in more remote part of the Atlantic Ocean. Therefore, the simulated dust fractional Fe solubility due to physical sorting is one to two orders of magnitude lower than the measured ones by Baker and Jickells (2006).

These results indicate that the physical sorting of dust particles is probably not the only process that causes the systematic increase in fractional iron solubility in the dust aerosols during transport.

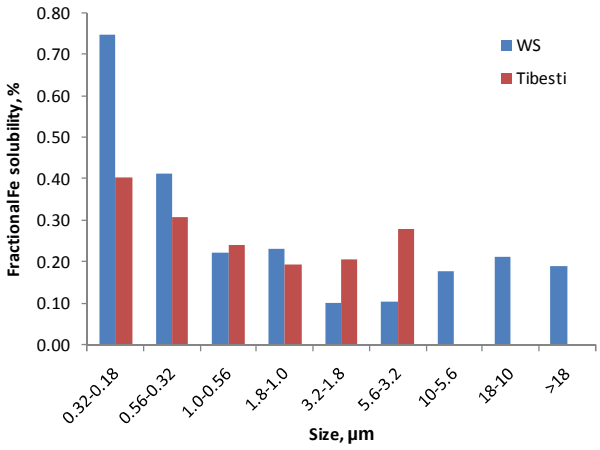

Figure 1. Size dependence of fractional dust iron solubility in the WS and Tibesti samples

The Nature Park of El Hondo (SE Spain, 8 km from the Mediterranean coast, 2387 ha) suffers from desiccation-flooding annual cycles with partially anthropic regulation. This area was chosen to study relationships between wind erosion and suspended particulate matter levels, as a small-scale instance of the ephemeral lake regions (like the Chotts in Tunisia and Algeria) which have been identified as intermittent dust sources.

In the frame of the EroHondo project, we have characterized several intense erosion events that led to high suspended particulate matter concentrations inside the Nature Park and at a coastal village, La Marina, 11 km downwind.

Two main measurement points were chosen inside El Hondo, 6 km apart from each other and aligned in a NW-SE direction. Prevailing winds blow either from NW or SE. Two aerosol spectrometers (Grimm 365), 2 low-volume samplers with PM10 inlet head (Derenda LVS3.1), 1 portable meteorological station (Casella Nomad) and 1 meteorological tower with anemometers at four heights were used. In addition, 2 DustTrak II with PM10 inlets were utilized as portable instruments in different locations. Saltation was registered by passive collectors in a number of points in the erosion areas.

The Nature Park became flooded after the strong rainfalls occurred beginning autumn 2009. The second campaign was conducted from August to December 2010, when the water sheet was reduced. As the soil was getting drier, the concentration of Na and Cl strongly increased in the first 1.5 cm of the soil and white saline crusts were formed over a great portion of the soil surface.

The severe erosion events were concentrated in autumn. These events were produced mostly under westerly winds associated with the passage of Atlantic frontal systems and no rainfall. Levanter, an easterly wind, was conducive to moderate particulate entrainment episodes into the atmosphere. Wind speeds larger than 9 m s^{-1} (measured at 5-min intervals at 2 m height) triggered the events.

Soil surface experienced a significant decrease in top soil rich elements: Na levels decreased 4.3 times after the episodes in the main erosion area, while its concentration was reduced 2.5 times at the SE location. The suspended particle concentration reflected this change with very high Na levels.

The horizontal flux of saltating particles, i.e. the total mass of material transported streamwise in saltation movement, was obtained from the passive sand catchers. These collectors feature omnidirectional openings at 5 heights. The vertical profile of the mass collected in the traps fits quite well to an exponential. Fluxes of 85.5 kg through 1 m of field width and 32.5 cm height have been registered in a single erosion event.

In the areas with sparse vegetation cover, sand shadows were formed to the lee of the tussocks. Their lengths and widths are proportional to the lengths and widths of the plants. While lengths are larger than the plant heights, their widths are smaller than the corresponding tussock widths.

Registered daily PM10 levels inside the Nature Park ranged from 6.7 to 342.2 μg/m^3, depending on the precise wind direction of the large plumes. The major elements in this fraction were Ca, Na and Mg. Number concentrations for each particle size larger than 1.3 μm were up to ten times higher the concentrations registered when the dust plume impacted on other areas.

Punctual measurements with the DustTrak equipments showed four times lower PM10 values at La Marina than at the SE site. In turn, levels due to local entrainment around the SE site were four times higher than the values registered at the SE site due to deflation in the main erosion area.

We gratefully acknowledge financial support from the Spanish Ministry of Science and Innovation (project EroHondo, CGL2008-05160). We thank also the staff of the Nature Park of El Hondo for their assistance whenever it was needed.

Wind Erosion and Suspended Particle Concentration in an area of Ephemeral Lakes

We present results of the second year of measurements conducted at the Nature Park of El Hondo (SE Spain, 8 km from the Mediterranean coast, 2387 ha). The objective of the research, in the frame of the EroHondo project, is to better understand the relationships between wind erosion and suspended particulate matter levels. This area suffers from desiccation-flooding annual cycles with partially anthropic regulation. When the water sheet decreases, the sediments lying on the dry surface are susceptible to wind erosion. The study area is therefore an intermittent dust source.

Two main measurement points were chosen inside of El Hondo. They are 6 km apart from each other, aligned in a NW-SE direction (PON and SE sites). Prevailing winds blow either from NW or SE. Two aerosol spectrometers (Grimm 365), 2 low-volume samplers with PM10 inlet head (Derenda LVS3.1), 1 portable meteorological station (Casella Nomad) and 1 meteorological tower with anemometers at four heights were used. In addition, 2 DustTrak II with PM10 inlets were utilized as portable instruments in different locations. Saltation was registered by passive collectors in a number of points in the erosion areas.

The Nature Park became flooded after the strong rainfalls occurred beginning autumn 2009. The second campaign was conducted from August to December 2010, when the water sheet was reduced. Thanks to this reduction, severe erosion events were registered in autumn 2010. A detailed description of these events is presented in another contribution to this conference. Here the focus is on general results regarding dependences on wind speed, and on events leading to suspended particulate matter concentrations of a few $\mu g/m^3$, typical of low to moderate winds.

As found during the first year campaign, 24-h average PM10 concentrations as well as the chemical elements in that fraction, showed a decrease with increasing wind speeds, although around 9 m s^{-1} (daily means from wind speeds measured at 2 m above the ground) there is some evidence of a small increase in concentrations. Dilution would appear as the leading mechanism; however, we found that the proportion of crustal elements with respect to PM10 does show a clear increase with wind speed. This implies an enrichment of the suspended crustal fraction though concentrations are decreasing due to dilution.

Continuous (5-min) measurements of particle number concentrations in 31 size channels from 0.25 to 32 µm show (Fig. 1):

(1) A net decrease in concentration for all particulate sizes smaller than 15 µm with increasing wind speeds. The reduction is stronger for particles in the 4 – 12.5 µm range and it occurs just for winds larger than 1 m s^{-1}. This is due to the dilution of accumulated aerosols. (2) Particles larger than 15 µm show a net concentration increase with increasing winds. (3) On intense erosion events, at the largest wind speed the concentrations of particles of 0.58 µm and larger are increased. Moreover, particles of 1.3 µm and larger present concentrations ten times higher than those under light wind situations. Number concentration roses show this increase associated to the directions of the dust source areas for particles of 1.3 µm (and larger) at the SE site. At the PON location, where the dust plume is less frequently found, the association to the direction of the dust drift is only observed for particles larger than 20 µm and corresponds to local erosion.

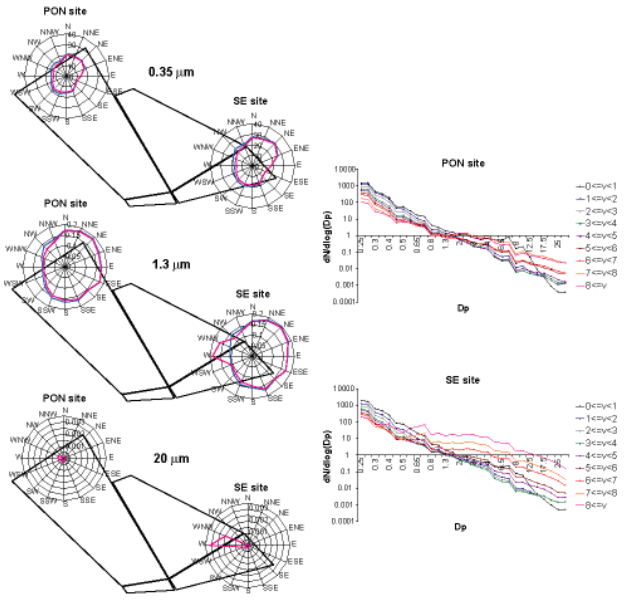

Figure 1. (Left) Concentration number roses for the two study sites; roses in red include also erosion events. (Right) Aerosol size distributions according to different wind speed intervals.

We gratefully acknowledge financial support from the Spanish Ministry of Science and Innovation (project EroHondo, CGL2008-05160). We thank also the staff of the Nature Park of El Hondo for their assistance whenever it was needed.

Atmospheric aerosols - Aerosol Processes and Properties

Futures of atmospheric radioactive aerosol monitoring by β- and γ-radiation

V.S. Yakovleva[1], A.V. Vukolov[1], I.I. Ippolitov[2], V.D. Karataev[1], P.M. Nagorsky[2] and S.V. Smirnov[2]

[1]Department of Applied Physics, Tomsk Polytechnic University, Tomsk, 634050, Russian Federation

Keywords: radioactivity, atmosphere, ionising radiation, monitoring.
Presenting author email: vsyakovleva@tpu.ru

Natural background radiation is one of the most important elements of atmosphere, and its variations are closely connected with the change of weather parameters of atmosphere, its chemical and aerosol composition. Registration and further analysis of ionizing radiation fields in the atmosphere is carried out by one radiation type – γ-radiation. Monitoring of β-radiation in the atmosphere is practically absent. β- and γ-background in the surface atmosphere is caused by one and the same sources: soil radionuclides and atmosphere decay products of radon and thoron. Taking this fact into account, one should expect similar behavior of β- и γ-radiation fields in the surface atmosphere. However, due to large differences in their penetrating power, a legal question arose: how agreed the variations of different types of natural ionizing radiation are.

Thus, the problem arose to perform the comparative evaluation of spectrum-time parameters of β- and γ-radiation fields and to examine their interactions with atmosphere-electrical values of the surface layer.

At Tomsk observatory of radioactivity and ionizing radiation (TORIR) the monitoring is performed via automated information measuring system of metheorologycal, electrical parameters of atmosphere, β- and γ-field characteristics at different height and depth. The measurements are continuous with 1 minute time step. At the height of 25 m in a standard weather booth there are two gas counters of β+γ-radiation (type STS-6), one of which is worn in aluminum casing for beta-radiation delay. Thus, one counter registers β+γ-radiation and the other one – only γ-radiation. Pure β-background is obtained by registration of a difference.

Preliminary results of monitoring data analysis allow to make a conclusion that contributions of β- and γ-radiation into the total level of background atmosphere radiation depend on different meteorological factors and one type of radiation correlates with other weakly. It could be seen in Fig. 1, 2. Data arrays (Fig.2) were infiltrated through a band filter F=(2 days)$^{-1}$ - (2 hours)$^{-1}$, red spots indicate summer, blue – winter.

It was found, however, that within some periods of the synoptic scale the correlation between β- and γ-radiations can be rather high (***d*** in Fig.1). Beta-background variations appeared to be comparatively weakly connected with variations of synoptic scale pressure and closely connected with diurnal variations of atmosphere temperature and humidity. Air pressure fall can result in suppression of this relation (***a*** in Fig.1) as well as in appearance of synchronous spikes of β- and γ-data series (***b***, ***c*** in Fig.1). γ-background variations with diurnal cycle are expressed weakly, however, there are periods when they are expressed clearly (***d*** in Fig.1).

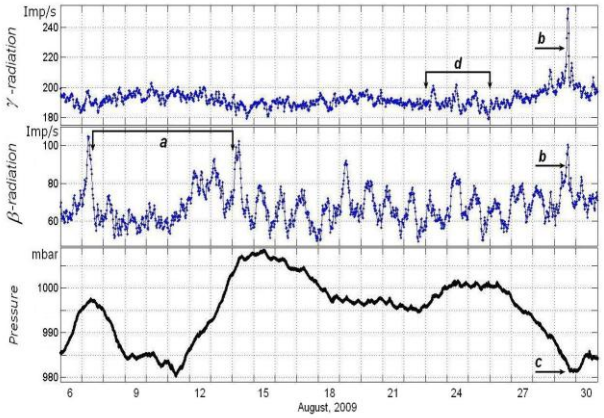

Figure 1. Variations of β-, γ-radiation components and atmosphere pressure at synoptic scale.

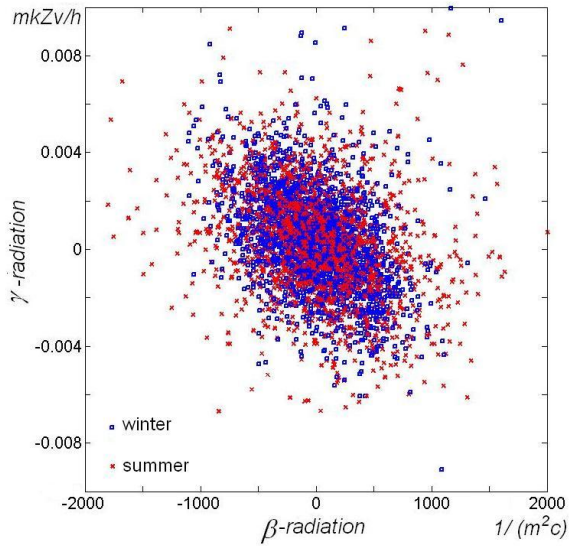

Figure 2. Correlation between variations of γ- and β-radiation fields for 2009-2010.

Aerosol contributions to speleothem chemistry

Jonathan Dredge[1] and Ian Fairchild[1]

[1] Department of Geography, Earth and Environmental Sciences, University of Birmingham, Birmingham, West Midlands, B15 2TT, UK
Keywords: Speleothem, Cave, Forest fire, Palaeoclimate
Presenting author email: jad099@bham.ac.uk

Speleothem are cave formations formed of mineral deposits (e.g. Stalagmites). They offer a multiproxy palaeoclimate resource; many proxies have been investigated and utilised for palaeoclimatic reconstruction. Traditional investigatory geochemical studies often combine stable isotope analysis and, increasingly, trace element analysis with disequilibrium dating. The contribution of aerosols to speleothem chemistry and their applicability for reconstructions remains untested and the extent to their value as an addition to palaeoclimate sciences unknown.

Aerosols become suspended into the earth's atmosphere through a multitude of processes both natural (e.g. volcanic eruptions, wind-blown sands, forest fires) and anthropogenic (e.g. biomass burning, vehicle emissions, constructions etc). Aerosols enter the cave network as a result of cave ventilation processes and are either deposited or cycled and removed from the system. Consequently, through aerosol incorporation, speleothem have the ability to preserve a record representing a multitude of processes not yet constrained by previously investigated proxies. Aerosols used in combination with more traditional speleothem proxies will add an extra dimension to palaeoclimate reconstructions.

For speleological studies, the aerosol component of interest is that which deposits within the cave network and is available for incorporation into precipitated calcite. The deposition of aerosols is collected using surrogate surface techniques that are currently being investigated and tested through controlled experiments and active sampling. Aerosols will be detected, identified, characterised and ultimately quantified to determine their prominence in the karst system.

Aerosols will be investigated on a case study basis, searching for suitable proxies from emissions of environmentally significant processes. One key focus of the investigation it to determine the ability of speleothem to record forest fires through aerosol incorporation, Yarrangobilly caves in Australia will be used as a primary case study for this. Ultimately a record of forest fire through time will be produced. Coupling this with data obtained from more traditional climate proxies the results will significantly improve the understanding of forest fire occurrence through the region.

Monitoring will allow for the temporal and spatial determination of aerosols in the karst network. Speleothem samples will be analysed in combination with in-situ monitoring to determine incorporation factors and record preservation. By understanding how aerosols are transmitted within the cave and ultimately incorporated into speleothems, a record of aerosol event frequency, intensity and timing can be produced and directly correlated with changing palaeoclimate.

Investigations of the vertical distribution of tropospheric aerosol layers using the data of multi-wavelength lidar sensing

S.V. Samoilova, Yu.S. Balin, G.P. Kokhanenko, and I.E. Penner

Zuev Institute of Atmospheric Optics Siberian Branch of Russian Academy of Science, 1, Academicheskii Avenue, 634055 Tomsk, Russia
Keywords: multi-wavelength Raman lidar, aerosol optical coefficients, Ångström exponent.
Presenting author email: ssv@seversk.tomsknet.ru

From March 2006 to October 2007 regular lidar observations of vertical aerosol distribution at Tomsk (56^0N, 85^0E), West Siberia, have been performed within the framework of CISLINET, the lidar network in the CIS territories (Chaikovskii *et al*, 2006). Multi-wavelength Raman lidar measurements (355/387nm and 532/607nm and 1064nm) were carried out twice a week in the daylight time (07:00 – 08:00 UTC) and once a week in the nighttime, 2-3 hours after the sunset. To reconstruct the optical coefficients, 84 realizations were selected, including 38 measurements in the nighttime.

Vertical distribution of the optical coefficients of the aerosol layers

The two-year-long observations show that the mean values of the heights of the mixing layer and PBL are 0.80 ± 0.19 and 1.22 ± 0.33 km in the cold season (from October to March) and 1.39 ± 0.39 and 2.26 ± 0.85 km in the warm season of observations, from April to September, respectively. The mean values of the optical coefficients in the boundary layer (without internal mixing layer, starting from 0.45km) and in the free troposphere (FT) are presented in Table1 for all nighttime measurements.

Table 1. Mean (STD) values of aerosol backscatter coefficient (ABC), aerosol extinction coefficient (AEC), and lidar ratio (LR)

Planetary boundary layer

Wavelength (nm)	ABC $*10^5$ ($km^{-1}sr^{-1}$)	AEC $*10^3$ (km^{-1})	LR (sr)
355	194(128)	116(61)	59(16)
532	128(102)	66(43)	51(9)
1064	56(32)	25(14)	44(16)

Free troposphere

Wavelength (nm)	ABC $*10^5$ ($km^{-1}sr^{-1}$)	AEC $*10^3$ (km^{-1})	LR (sr)
355	19(4.5)	9.5(1.9)	49(9)
532	14(3.5)	7(1.4)	48(6)
1064	6.5(1.5)	3.5(0.9)	54(10)

The mean value of the total particle optical depth calculated from AERONET data is 0.152 ± 0.04 at 500nm (Sakerin *et al*, 2008). The contribution of the free troposphere into the total aerosol optical thickness increases with decrease of the height of the boundary layer. According to our measurements, the value of this contribution is, in average, $21 \pm 11\%$ at 355 nm, $27 \pm 13\%$ at 532 nm и $34 \pm 16\%$ at 1064 nm.

Spectral behavior of optical coefficients and microphysical characteristics of aerosol particles

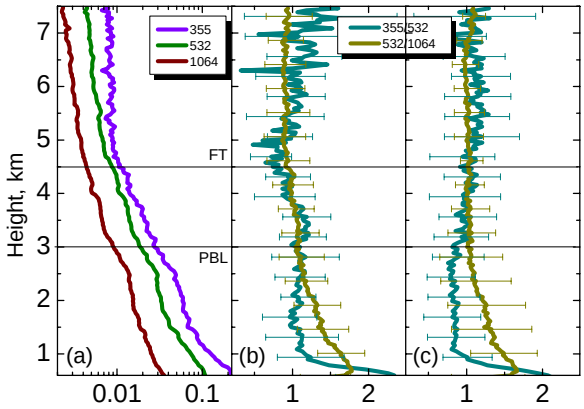

Figure 1. Mean vertical distribution of extinction (a), km^{-1}, and Ångström exponent for extinction (b) and backscatter (c) coefficients.

Ångström exponent for the extinction coefficients is sensitive to fine mode volume fraction of aerosols but not fine mode geometric radius, while Ångström exponent for the backscatter coefficients is sensitive to the fine mode radius but not the fine mode volume fraction (Samoilova, 2011). The lidar ratio and Ångström exponent for the backscatter coefficient depend strongly on the real, m_R, and imaginary, m_I, parts of the refractive index. Limited range of variation of the lidar ratio leads to the corresponding limited range of variations m_I (for fixed m_R), which is displaced toward greater values m_I with increasing m_R.

Quantifying the concentration of volcanic ash aerosol in ground-based lidar returns

F. Marenco[1], B. Johnson[1] and R. Hogan[2]
[1]Observational Based Research, Met Office, Exeter EX1 2NF, United Kingdom
[2]Department of Meteorology, University of Reading, Reading RG6 6BB, United Kingdom
Keywords: volcanic particles, remote sensing, optical properties.
Presenting author email: franco.marenco@metoffice.gov.uk

Long-range transport of volcanic ash from Iceland to the united Kingdom occurred in April-May 2010, following the eruption of the Eyjafjallajökull (Mona *et al*, 2010; Ansmann *et al*, 2010; Flentje *et al*, 2010; Pietruczuk *et al*, 2010; Hogan *et al*, 2010).

Ground-based observations were made at Exeter, United Kingdom, on 16 and 18 April 2010 using a Leosphere ALS450 backscatter lidar featuring a depolarisation channel.

At 14:00 (UTC+1) on 16 April a strongly depolarising volcanic ash layer was observed high above the Boundary Layer (BL) aerosol, at an altitude of about 2800 m. The ash layer altitude slowly decreased, and reached 1400 m at around 20:00 (UTC+1), just above the top of the BL aerosol. The ash layer depth was estimated to vary between 100 and 400 m.

On the morning of 18 April, a depolarising double ash layer at 1000-1500 m was detected, above the top of the BL aerosol at 900 m. In the afternoon, the top of the BL aerosol increased up to 1700-1800 m; after that time, the depolarisation of the BL increased, indicating that ash and BL aerosol were both entrained in turbulent mixing.

The lidar equation has been solved using the scheme described in Marenco and Hogan (2010), which uses depolarisation to distinguish aerosol types and involves three atmospheric components rather than the two traditionally assumed in lidar retrievals. The assumed atmospheric components are: Rayleigh scattering, volcanic ash (depolarisation ratio 0.34), and BL aerosol (non-depolarising). The assumptions on depolarisation ratio were based on the analysis of the lidar signals themselves at times where the two aerosols where spatially separated. This has allowed determining the contribution of volcanic ash and BL aerosol separately, even at the times where they were mixed.

Mie scattering computations have been performed to estimate ash optical properties, based on the aerosol size distribution retrieved from an AERONET sunphotometer at the Chilbolton observatory, United Kingdom. A refractive index of $1.52 - i0.00155$ and a density of 2.3 g cm^{-3} were assumed. The computations gave a specific extinction $K_{\text{ext}} = 0.6$ m^2/g for the coarse-mode of the retrieved size distribution.

The above estimate of specific extinction has been combined with the lidar retrievals to estimate mass concentration of volcanic ash, resolved in both height and time. Peak concentrations of 1500 and 1000 μg/m^3, respectively, were observed on 16 and 18 April, and column loads were estimated to range between 0.15 and 0.45 g/m^2.

A good description of the atmospheric aerosols is needed in order to address its role in the Earth radiative balance and consequently its effect on global warming. A great deal of uncertainties on aerosol effect is due to the spatial and temporal inhomogeneities of the aerosols properties.

With the purpose of reducing these uncertainties, several network of sun-sky radiometers have been established worldwide providing a well tracked calibration procedure, good quality standards and homogeneity on the retrievals. They are AERONET: http://aeronet.gsfc.nasa.gov;PHOTONS:http://loaphotons.univ-lille1.fr/;RIMA:ww.rima.uva.es/; and SKYNET: atmos.cr.chiba-u.ac.jp/.

However intercomparison studies among products provided by different networks (Che et al., 2008, Campanelli et al., 2004, Estelles et al., 2010) showed that most of the differences are due both to calibration procedures and to the inversion schemes used for processing the sun-sky radiometers dataset.

The Skyrad code (T. Nakajima et al., 1996) is the official algorithm processing data from SKYNET network. It consists of an efficient multiple scattering radiative transfer scheme and an inversion scheme which is able to retrieve the columnar aerosol volume distribution, the extinction aerosol optical thickness at several wavelengths in the visible region, the phase function and the single scattering albedo from measurements of direct and diffuse solar irradiance.

In this work the performance of the new version of the Skyrad code (Skyrad5) will be analysed. This version improves the calculation of the single scattering albedo, often overestimating the values provided by AERONET, and the behaviour of the coarse mode of the volume size distribution.

Products will be compared with the retrievals provided by the previous version 4.2. in order to evaluate the improvements. This comparison will be performed using data from ESR (European SkyRad users' network).

ESR is a network of sun-sky radiometers not included in any federated networks. Aim of ESR is giving a standard of quality to the database and a protocol of calibration, as required by the World Meteorological Organization (WMO) guidelines. One of the objectives of ESR is pursuing the improvement of current inversion techniques and improving studies of overlapping among already existing federated network.

ESR is composed of 13 sites located in Italy, Spain, Poland and United Kingdom. The measurements performed in each site cover a wide range of aerosol types: urban (Rome, London, Barcelona, Valencia), maritime (Plymouth), rural (Bologna, Cambridge, Cardington), background (Belsk) and low mountain (Potenza) .

Some ESR site are co-located with AERONET sites, providing the possibility of performing an intercomparison with retrievals from the Dubovik code (Dubovik et al., 2000), that is the standard algorithm for processing AERONET database.

For the above reasons the ESR database resulted to be particularly suitable to perform the evaluation of the new Skyrad5.

Modelling of aerosol scattering and absorption parameters in the troposphere of West Siberia

S.A. Terpugova, M.V. Panchenko, V.V. Polkin, V.S. Kozlov

V.E. Zuev Institute of Atmospheric Optics, Tomsk, 634021, Russia
Keywords: aerosol, scattering, absorption, optical depth
Presenting author email: swet@iao.ru

Atmospheric aerosol is one of the factors driving the climatic system. Aerosol radiative and climatic effects are determined mostly by the aerosol optical depth, single scattering albedo and asymmetry parameter of the aerosol phase function.

One of the approaches to the improvement of the reliability of the aerosol models is correct setting the input parameters taking into account regional peculiarities and seasonal variability of the aerosol optical characteristics.

This paper presents the results of simulation of the climate relevant aerosol characteristics in West Siberia. Calculations are based on the empirical model of the optical characteristics of the atmosphere developed on the basis of the data of airborne sensing of the vertical profiles of the scattering coefficient and microstructure of the atmospheric aerosol (Panchenko et al, 2001). The model was supplemented by the data of airborne measurements of the vertical profiles of the BC mass concentration (Kozlov et al, 2009) that enabled us to estimate the imaginary part of the complex refractive index.

Aerosol was represented as a sum of three log-normal non-absorbing fractions with the refractive index n = 1.5, according to the empirical microstructure model (Panchenko et al, 2001). Parameters of the fractions (the median radius, variance of the radius logarithm, and the volume concentration) were chosen so that the total scattering coefficient at the wavelength of 0.51 μm calculated using the Mie theory was equal to the seasonal mean value at the corresponding height (Panchenko et al, 1996). Then soot was added to the non-absorbing aerosol in order to estimate the complex refractive index. Three hypotheses of the presence of soot in aerosol were considered.

1. Soot with the refractive index $n = 1.8–0.74i$ was added as an independent narrow fraction. The optical parameters of the mixture were determined as their sum with the weight, corresponding to the seasonal mean soot fraction.

2. It was assumed that soot is homogeneously included into aerosol particles. The optical constants of such medium were determined by the well-known mixture rule.

3. Soot also was assumed to be homogeneously included into particles, but its content depended on the aerosol particle size according to the results of Hitzenberger and Tohno (2001).

Then the values of real and imaginary part of the complex refractive index were recalculated to the real values of relative humidity using the well-known Hanel's relationships.

At the last stage, angular scattering characteristics, single scattering albedo and the aerosol optical depth were retrieved.

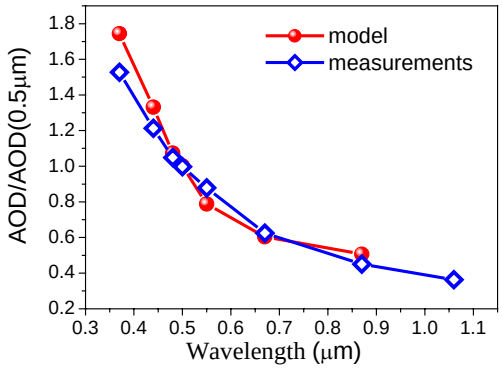

Figure 1. Comparison of measured and calculated aerosol optical depth

In the Figure 1, the normalized spectral behavior of the aerosol optical depth obtained from calculations is compared with the mean summer value obtained in 1995-2005 from measurements with CIMEL CE-318 sun-photometer. As it is seen, the results of measurements and calculations are in good agreement in the wavelength range 0.44 to 0.87 μm. some discrepancy is observed at longer wavelengths that could be explained by the errors in extrapolation of the microphysical characteristics to the range of largest and smallest particles.

Influence of wind field patterns on aerosol optical depth over Athens and the Aegean sea

V. Kotroni[1], S. Kazadzis[1], K. Lagouvardos[1], V. Amiridis[2], E. Gerasopoulos[1]
[1]IERSD, National Observatory of Athens, GR-15236, Athens, Greece
[2]ISARS, National Observatory of Athens, GR-15236, Athens, Greece
Presenting author email: kazadzis@meteo.noa.gr

One of the most important meteorological events occurring over the Aegean Sea during summer is the Etesian winds. The Etesians result from a combination of the monsoon effect that leads to the formation of a thermal low pressure trough over Turkey, with higher pressures over Southern Balkans (Weather in the Mediterranean, 1962; Prezerakos, 1984).They are northern sector winds blowing over the Aegean Sea during summer and early fall. More precisely, the etesians are mainly north-easterly in the northern Aegean, northerly in the central and southern Aegean and tend to become north-westerly near the southwestern Turkish coasts. The air masses regularly originate from the region of southern Russia and the Caspian Sea and they are dry and relatively cool, contributing to the decrease of surface temperature and the moderation of summer heat and discomfort (Weather in the Mediterranean, 1962; Kotroni et al. 2001). The sustained wind speed associated with the Etesians often attains surface values exceeding 15 ms^{-1}, (with gusts over 20-25 ms^{-1}). The etesians are also affecting the Athens greater area during summer and when they prevail they contribute to the ventilation of the city, decreasing thus the pollution levels and the aerosol load over the area.

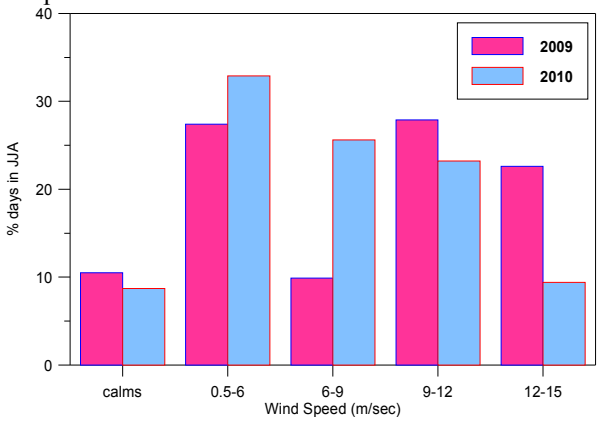

Figure 1. Percentage of wind occurrence in the period JJA from a surface station in Central Aegean.

This study investigates the role of the wind flow during summer on the optical depth of aerosols over Athens. The study focuses in the period June-July-August (JJA) of the years 2009 and 2010. As it can be seen in Figure 1 the occurrence of high wind speed regimes and thus of etesian winds during 2010 was much lower than in 2009. For determining the effect of the wind flow on the optical depth of aerosols we have used the following sources:

(a) The Imaging Spectro-radiometer (MODIS) Terra and Aqua Collection 5. (Aerosol optical depth (AOD) daily measurements at 550nm over Athens area and over Myconos island),

(b) Sun-photometric aerosol optical properties measurements from the ground-based Atmospheric Remote Sensing Station (ARSS) (Amirids et al., 2009) over the city of Athens (37.^{90} N, 23.^{80}E, 130 m a.s.l., Amiridis et al., 2009). ARSS is equipped with a CIMEL CE318-NEDPS9 sunphotometer for the retrieval of AOD at 8 wavelengths from 340 to 1640 nm, The CIMEL instrument is a part of NASA's AERONET (**http://aeronet.gsfc.nasa.gov**).

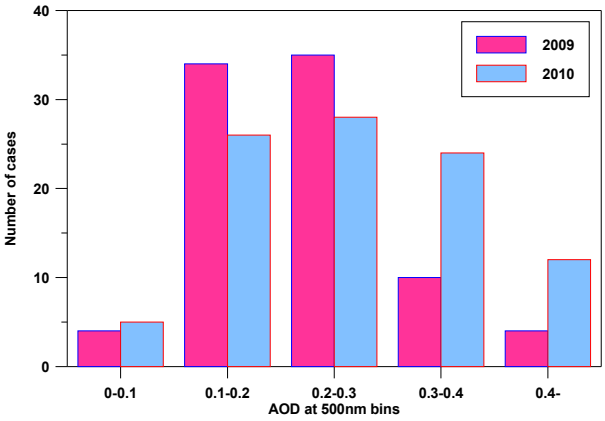

Figure 2. Daily mean Aerosol Optical depth measured at Athens area with the CIMEL sun-photometer divided in 0.1 range AOD bins, for the summer of 2009 and 2010

Sun-photometric measurements showed a 16% AOD increase during summertime comparing 2009 and 2010. For more thorough analysis we have excluded Saharan dust transport cases that affect the aerosol statistics and they are not related with the etesian occurences. MODIS satellite retrievals showed that in both Athens and Myconos area aerosol optical depth is lower in 2010 compared to the one for 2009. More specific both sites show a decrease of 25% and 22% during June and a 5% and 13% respectively during August, while for July AOD values are similar.

Aerosol Optical Depth in East Mediterranean using MODIS and CALIPSO satellite retrievals

E. Marinou[1,3], V. Amiridis[1], S. Kazadzis[2], D. Kopania[2], A. Papayannis[3]
[1]ISARS, National Observatory of Athens, GR-15236, Athens, Greece
[2]IERSD, National Observatory of Athens, GR-15236, Athens, Greece
[3]National Technical University of Athens, GR-15773, Athens, Greece
Presenting author email:elmarinou@noa.gr

Aerosols play a very important role in the Earth-atmosphere energy system as they modify the radiative forcing through various atmospheric processes. In this study we focus on the Mediterranean aerosols which originate from various sources, such as the superimposition of a marine component, a mineral dust component (Saharan dust outbreaks and local dust suspension) and the local and anthropogenic components through long-range transport (Lelieveld, 2002).

The focus of this work was the synergistic use of MODIS and CALIPSO satellite products, together with ground-based sun-photometric aerosol related measurements, for the East Mediterranean region, in order to:

- Establish a 10 year (2000-2010) aerosol optical depth (AOD) climatology based on MODIS measurements over various locations in Greece
- Investigate the best MODIS satellite pixel resolution for the representation of AOD using ground based sun-photometric validation measurements at Athens area.
- Explore the possible continuation (for the years after 2007) of the previous reported (Koukouli et al., 2010) negative AOD trends for the area.
- To investigate the ability of the satellite sensor to detect local AOD sources, by comparing AOD and aerosol vertical profile (CALIPSO) satellite retrievals at neighboring sites with different aerosol types (urban-rural).

The tools that have been used were:

a. The Imaging Spectro-radiometer (MODIS) Terra and Aqua Collection 5, products, using various MODIS spatial resolutions (10x10, 30x30, 50x50Km and 1X1 degrees).

b. CALIPSO's lidar (CALIOP) Level 2, version 3.01, aerosol backscatter coefficient profile products.

c. Sun-photometric aerosol optical properties measurements from the ground-based Atmospheric Remote Sensing Station (ARSS) over the city of Athens (37.9^0 N, 23.8^0E, 130 m a.s.l., Amiridis et al., 2009). ARSS is equipped with a CIMEL CE318-NEDPS9 sunphotometer for the retrieval of aerosol optical depth (AOD) at 8 wavelengths from 340 to 1640 nm, The CIMEL instrument is a part of NASA's AERONET (**http://aeronet.gsfc.nasa.gov**).

Concerning the MODIS pixel resolution sensitivity study, we have compared various MODIS spatial windows sizes around the ARSS station. We found good correlations for the window sizes of 50x50km (R=0.747) and 30x30km (R=0.687) and very bad correlation for the 10x10km resolution (R=0.286).

The seasonal variability of the AOD over the 2000-2010 years over Greece have shown maximum AOD levels during July- August for all Greek sites with more distinct maxima for the Northern part of Greece, associated with transported aerosol load from the North-NorthEast directions. In addition, April-May AOD maxima have been found especially in ths Southern part of Greece associated with transported Saharan dust events.

Concerning the AOD trends, negative values have been found for most of the areas that have been investigated. More specific, for Athens area we have found for the period March 2000 to July 2004 a decreasing trend in aerosol load of 2.8 ±2.5% per year and it's stabilization for the time period 8/2004-9/2010 with decreasing trend of 0.96 ±1.20% per year.

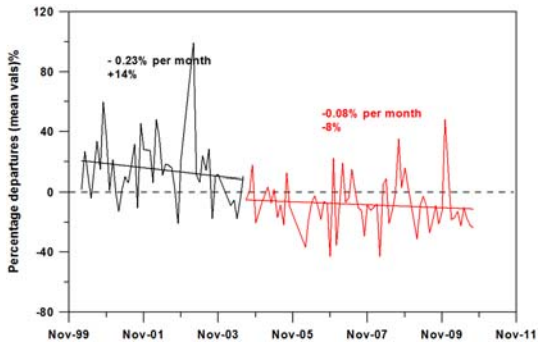

Figure 1.Percentage departures of monthly mean AOD values at 550nm without annuality from MODIS/Terra data, for 10 years, for the area of Athens, for the time period before and after summer 2004.

Finally, we have used mean monthly AOD values retreved from MODIS and CALIPSO mean aerosol vertical profiles over various sites around Athens area. This, in order to try to investigate the sensitivity of the satellite retrievals on a complex aerosol urban area compared with neighboring rural sites.

A general work focused on the study of Saharan dust intrusions is presented as a case study of air masses advected from the Saharan region to the Canary Islands and the Iberian Peninsula (IP). This work is divided in two parts in order to examine two relevant and different aspects of this study. Each one is separately submitted. This second one (Part 2) presents the evaluation of potential dust impact on surface once the Saharan dust intrusion arrives at the Southern IP. In this case, ground-level in-situ measurements together with AERONET columnar-integrated data and closest-to-surface backtrajectory analysis, as well, are used for that purpose. The dust detection, identification and vertical structure analysis were described in the Part 1. Observations were performed on 14 March 2008 (1-day dusty episode) in two of those three Spanish stations, where the dust intrusion coming from the Saharan region was monitored (see Part 1). Both of them are located in the Southern IP within the dust-influenced area: the Atmospheric Sounding Station 'El Arenosillo' (ARN) at the SE and the Granada station (GRA) at the SW of the IP.

Backtrajectory analysis reveals that the closest-to-surface air masses are coming directly from Northern Africa, whereas those ending at 3-km carrying the dust plume are coming from the considered Sahara-Tenerife-IP pathway (see Part 1). Rather low particle sedimentation is expected to occur directly from the dust 3-km height plume. Therefore, dust particles registered at ground level are not related to deposition processes for particles of that dust plume with low potential impact on surface. However, dust incidence exists, being more significant in the SE region (GRA) respect to the SW area (ARN).

Differences on particle deposition processes are observed in both sites by using the temporal evolution of the total volume particle concentration for discrete size ranges. They are due to the particular dust transport pattern occurred over each station: particles detected in ARN would be the result of a gravitational deposition process, while those in GRA would be mostly influenced by their horizontal movement.

AERONET volume size distributions ($VSD^{AERONET}$) were compared to those calculated from the most coincident in time ground-level in-situ measurements (VSD^{GL}) (see Figure 1). The effective radius was calculated for each VSD datasets. The obtained results ($r_{eff}^{AERONET} > r_{eff}^{GL}$) are opposite to those reported by Müller et al. (2010) ($r_{eff}^{AERONET} < r_{eff}^{GL}$), where AERONET and airborne (at 2-3 km height) in-situ measurements were performed. Differences between AERONET and in-situ measurements show a clear dependence on height of the dust particle VSD. That is reflected by the different in-situ measurements platform used, either ground-level or airborne. Further vertical size-resolved observations are needed for evaluation of the impact on surface of Saharan dust arrivals to the IP.

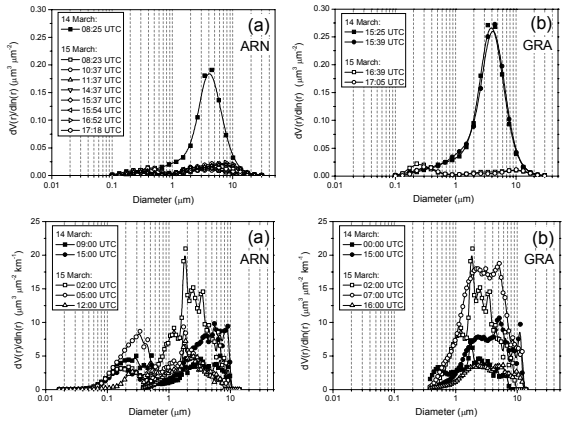

Figure 1. Volume size distributions (VSD) from AERONET data (top) and ground-level in-situ measurements (bottom) in ARN (a) and GRA (b) sites.

Aerosol particles affect the radiative energy budget of the Earth-atmosphere system, although current estimates remain highly uncertain. One reason for this uncertainty is the lack of long-term observations of vertical distributions of several aerosol properties, including size distributions. LIDAR (Light Detection and Ranging) systems, coordinated as networks, are a powerful tool in closing this observational gap.

One of those networks, EARLINET (European Aerosol Research Lidar NETwork, Bösenberg et al., 2003) has been studying tropospheric aerosols on continental scale since 2000. The network activity is based on scheduled measurements, a rigorous quality assurance program both at algorithm and instrument level, and a standardized data exchange format. As part of the quality assurance program, intercomparison campaigns among several co-located instruments from different network stations and a reference system are performed (Pappalardo, 2004). One of those campaigns, SPALI10 (SPAin Lidar Intercomparison 2010), took place in Madrid (Spain, 40.45ºN, 3.73ºW, 663 m asl) from 18 October to 5 November 2010 in the frame of the EARLINET-ASOS project (Advanced Sustainable Observation System) [www.earlinetasos.org]. It involved four lidar systems (Madrid, Granada, Barcelona and Evora) and the reference system from Potenza. The main objective of the campaign was checking the performance of multiwavelength Raman lidars, used for vertically resolved measurements of the particle optical properties.

Anyhow, during the campaign, a large suite of instruments complemented the study of the atmosphere. At ground level, aerosol size distribution and chemical composition were continuously monitored. Particle number size distributions were determined with a combination of a Scanning Mobility Particle Sizer (TSI SMPS 3936) and an Optical Particle Counter (GRIMM 1108), covering the radius range from 15 nm to 20 μm.

Additionally, airborne in-situ measurements were performed to characterize vertical profiles of aerosols. Size distribution data between 0.10 and 3.0 μm in diameter were provided by a PCASP 100-X (Passive Cavity Aerosol Spectrometer Probe) installed onboard the INTA-C212 aircraft. The column integrated characterization of the atmospheric aerosol was provided by a sun tracking photometer (Cimel CE-318-4). The sky radiance measurements, performed at the almucantar and principal planes in conjunction with solar direct irradiance measurements at several wavelengths, were used to retrieve the volume size distribution. The extensive dataset obtained during SPALI10 field campaign enables to compare ground-level and airborne in situ measurements and remote sensing techniques to characterize the vertically-resolved size distribution of aerosols. Several relevant features shown in the comparison of the results obtained by the different instruments are discussed.

Keywords: aerosol, lidar, CALIPSO, EARLINET.

Tropospheric aerosols, and in particular anthropogenic aerosols, are one of the most uncertain elements in the estimation of radiation budget. In fact, the uncertainties in aerosol direct and indirect anthropogenic forcing are of the same magnitude of the effects themselves (Forster et al., 2007). The assessment of their impact on the Earth radiative budget requires an increasing knowledge of the aerosol properties and their temporal and spatial distribution.

A multiwavelength Raman lidar is operated at the Andalusian Centre for Enviromental Research in Granada (Spain, 37.16ºN, 3.6ºW, 680 m asl). This system is based on a Nd:YAG laser source operating at 1064, 532 and 355 nm. Detection is carried out in seven channels corresponding to elastic wavelengths at 1064, 532p (parallel-polarized), 532s (perpendicular-polarized) and 355 nm, and Raman shifted wavelengths from nitrogen (387 and 607 nm) and water vapour (408 nm). The system is described in detail by Guerrero-Rascado et al. (2008). Since 2004, the Raman lidar is operated at the Granada station, and in April 2005, the instrument was incorporated to the EARLINET network (Bösenberg et al., 2001).

Since middle 2006, scheduled measurements have been performed at Granada in temporal coincidence with CALIPSO overpasses. CALIPSO (Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations), the first satellite-borne lidar specifically designed for aerosol and cloud studies, provides high vertical resolution profiling of aerosol and clouds on global scales (Winker et al., 2007).

Three years of measurements have been analyzed in order to obtain a characterization of the atmospheric aerosol in the urban environment of Granada. A set of 150 aerosol extinction and 507 aerosol backscatter profiles has been used in this study. Mean values and variances of the aerosol extinction and backscatter in the boundary layer have been calculated. Aerosol properties like extinction-to backscatter ratios (lidar ratio, LR) and Ångström exponents have allowed for characterizing the different aerosol types (Giannakaki,et al., 2010)..
Validations of CALIPSO attenuated backscatter coefficient profiles have been carried out using our lidar system for different atmospheric conditions. Figure 1 shows the attenuated backscatter profiles at 532 for CALIPSO and Granada Raman lidar during a Saharan dust event on 5 July 2008. A good agreement is observed from 3 km up to the tropopause. However, there are differences in the vertical distribution of the aerosol in the lowest layers. These discrepancies are due to the distance between our station and the closest position in the satellite path (around 70 km far away). It is important to show that this area has a complex topography.

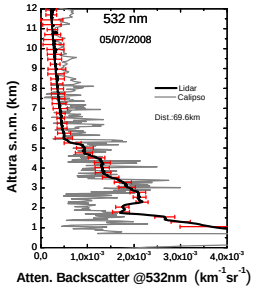

Figure 1. Attenuated backscatter profile at 532 nm for CALIPSO and Granada Raman lidar.

This paper presents one-year dataset of Raman lidar measurements conducted at the South African EUCAARI (The European Project on clouds, aerosols and climate) site Elandsfontein (Laakso *et al.*, 2010). Previous lidar measurements have been sparse on the African continent, especially in the Southern areas.

The measurement site is located on the eastern part of Highveld, approximately 200 km east of Johannesburg at a hilltop about 1750 meter asl. Additional instrumentation provided aerosol absorption and scattering, chemical composition, number size distribution (10 nm – 10 µm), aerosol optical depth (AOD), trace gases (SO_2, O_3, NO_x, H_2S) and basic meteorology. The region has significant anthropogenic emissions especially from coal-based power production, petrochemical industry and further away, the megacity of Johannesburg. Other important sources are frequent savannah fires, especially during the dry season (June-October) and some local biofuel burning.

The lidar measurements were started on the 13th December 2009 and were stopped at the end of January 2011. The instrument in use was a seven-channel Raman lidar called "POLLY^{XT}–POrtabLe Lidar sYstem eXTended" (Althausen *et al.*, 2009). The output of the instrument includes vertical profiles of the particle backscattering coefficient at three wavelengths (355, 532 & 1064 nm) and of the particle extinction coefficient at two wavelengths (355 & 532 nm) for the whole troposphere. The vertically integrated extinction coefficient gives the AOD. In addition, such size/composition-dependent, intensive particle quantities as the Ångstrom exponents, the lidar ratio and depolarisation can be determined. The height and the evolution of the boundary layer and night-time residual layer can be defined together with the height and thickness of different cloud and aerosol layers. The depolarisation channel (355 nm) of the lidar enables us to separate spherical and non-spherical particles. Thus, we are able to identity dust particles and estimate the ratio of ice crystals and water droplets in clouds. The vertical resolution of the system is 30 meters.

The typical backscattering and extinction profiles and other properties for the seasonal aerosol will be calculated. The evaluation of planetary boundary layer (PBL) will be defined.

The local summer (Dec-Feb) had most distinct PBL evolution on most days. A very shallow aerosol layer was observed during the night and an increase up to 2-3 km during the day on average. The maximum layer thickness was about 5 km. This period was the cloudiest period of the year and in contrast, winter (Jun-Aug) was almost totally cloud free. Strong and complex multilayered structure of the aerosol was observed throughout the year, most frequently in autumn (Mar-May). Winter and partly spring (Sep-Nov) showed mostly a stable aerosol layer up to 1-3 km height. Furthermore, the diurnal variation was the weakest in winter.

An Aerosol Dipole

P.R.C.Rahul*, P.S.Salvekar*, P.C.S.Devara*

*Indian Institute of Tropical Meteorology, Pune, India

* rcreddy@tropmet.res.in

Abstract

Using Aerosol Optical Depth [AOD at 550nm] from the MODerate Resolution Imaging Spectroradiometer [MODIS], Surface winds, Outgoing Long wave Radiation (OLR) from NCEP/NCAR reanalysis and rainfall from Tropical Rainfall Measuring Mission [TRMM] data sets, we report for the first time, a dipole like variability in the aerosol concentration over the region [40ºE-130ºE; 10ºS-10ºN] during September, October and November 2006. Positive AOD anomalies [+0.4 to +0.6] (relative to the 2000-2008 climatological average) along the equatorial East Indian Ocean and Indonesia and negative AOD anomalies [-0.2 to -0.4] over the western, northwestern and central Indian Ocean characterize an aerosol dipole like variability. This east-west variability of the aerosol loading along the Indian Ocean is linked to the anomalously weak easterlies associated with the 2006 Indian Ocean Dipole (IOD) event. The weaker easterlies lead to the hovering of the aerosol plume over Indonesia/Sumatra coast (98ºE), enhancing the positive anomalies of AODs, while excessive rainfall over the central Arabian Sea caused the negative AOD anomalies.

Atmospheric aerosols - Specific Aerosol Types

Shipboard characterization of particle and gas emission from a Danish inland ferry

A.G. Hemmersam[1], T.N. Jensen[2], K.G. Nielsen[2], H. Tarp[2], M.K. Lykkegaard[1] and M. Poulsen[1]

Presenting author email: agh@dti.dk

Several studies show that emissions from ship traffic influences the air pollution in port cites severely. Especially NO_x and ultrafine particle levels are found to be elevated due to ship traffic in the harbor area. High NO_x and ultrafine particle levels are known to affect human health.

Mainly two ways for limiting the emissions from ships are presently being exploited, lowering of the sulfur content in the fuel and implementation of different types of emission reducing technologies such as filters and scrubbers. Regulation of the sulfur content in fuel for ships entering the North Sea is expected to be limited to 1% within 2012. Today Danish ferries are already running on marine diesel in which the sulfur content is limited to 0.1%, which is significantly lower than the average sulfur content of 2.6% in heavy fuel oil used for ships.

Emission data from single ships running on different types of fuel is highly needed in order to better understand the impact of reducing the sulfur level with respect to particle and gas emissions. However, to achieve reliable and precise emission data from single ships is a challenge, therefore only a limited number of studies are presently available.

In this study emission data from a Danish inland ferry running on marine diesel is presented.

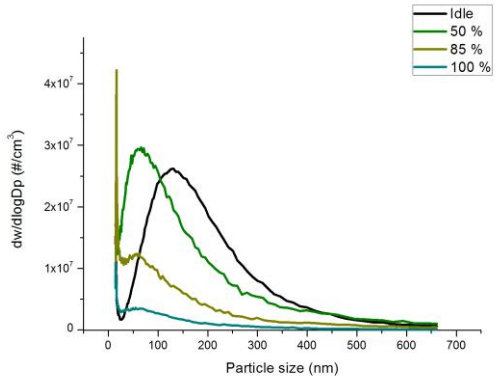

Figure 1. Size distribution of particles emitted in the interval 15-680 nm as a function of engine load.

The emission data show NO_x levels at 8.33 g/kWh which is comparable to EURO 2 heavy duty diesel engine for trucks and below the TIER II regulation for ships. NO_2 and SO_4 were found to be 0.99 and 0.01 g/kWh. CO and HC levels were measured and found to be within the specifications of EURO 5 or 6 for heavy duty engines for vechecles. The particle size distribution was measured during different engine loads by a scanning mobility particle sizer (SMPS) in combination with a rotating disc diluter system and particle mass was collected on filter according to ISO8178. The mean particle size was found to depend on engine load, but was below 150 nm during all engine loads. The largest particles were seen when the ferry was operating at idle in the harbor during load and unload. Particle number concentration was found to peak at an engine load of 50% and decrease at engine loads of 85% and 100%.

In conclusion all emission data were below the TIER II limit for ships.

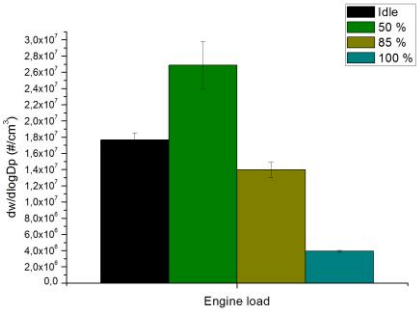

Figure 2. Mean number concentration of particles emitted as a function of engine load.

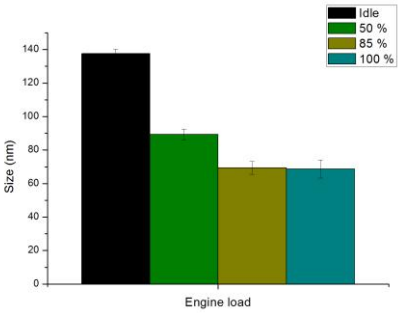

Figure 3. Mean size of the particles emitted as a function of engine load.

Quantitative real time sea salt measurements by HR-ToF AMS

J. Ovadnevaite, D. Ceburnis, J. Bialek, C.D. O'Dowd and H. Berresheim

School of Physics & Centre for Climate and Air Pollution Studies, Ryan Institute, National University of Ireland Galway, University Road, Galway, Ireland
Keywords: Aerosol mass spectrometry, sea salt, marine aerosols
Presenting author email: jurgita.ovadnevaite@nuigalway.ie

Global importance of marine aerosol to the cloud condensation nucleus (CCN) formation was demonstrated several decades ago, starting with the secondary sulphate activation presented with CLAW hypothesis (Charlson et al., 1987), and emphasizing the impact of primary sea spray particles (O'Dowd et al., 1999). It was also shown that correct CCN parameterization depends on the accurate representation of aerosol size and chemical composition.

Here we report first long-term measurements of sea salt by High Resolution Time-of-Flight Aerosol Mass Spectrometry (HR-ToF AMS). The measurements were made in conjunction with CCN and cloud microphysics measurements to improve our understanding of cloud microphysical processes. With its original design for real-time measurement of size-resolved non refractory aerosol chemical composition HR-ToF AMS can quantitatively detect non refractory aerosol organics, sulphate, nitrate and ammonium and achieve direct separation of most ions at the same nominal m/z (DeCarlo et al., 2006). In contrast to previous assumptions our continuous operation of an HR-ToF AMS instrument since 2009 at the Mace Head Global Atmosphere Watch (GAW) station on the west coast of Ireland has clearly revealed that the instrument is also capable of quantitatively measuring sea salt, a significant mass fraction of the marine aerosol.

For this purpose the instrument was calibrated using artificial sea water (35 ‰ salinity) made from artificial sea salt mixture (Sea salts, SIGMA) and deionized water. The solution was nebulized with a TSI atomiser (model 3076), and DMA pre-selected particles (300nm) were sampled into the AMS inlet, while relative humidity in the sample line was maintained at about 65%. This calibration enabled sea salt quantification in the ambient aerosol measurements. Although sea salt is considered to be refractory material, the sea salt aerosol particles would be in a liquid phase at the relative humidity (RH) typical for the marine environment (usually above 70%), due to much lower efflorescence RH. Since sea salt efflorescence occurs at about 40% RH, the sea salt particles experiencing RH above the efflorescence RH could be treated as liquid spheres. Though drying in the inlet line could occur, RH measurements showed that it does not decrease below 50% when sampling maritime air. This suggests that sea salt particles could be efficiently vaporised at standard HR-ToF AMS operating temperature (~600^{o}C). While the exact fragmentation pattern was found to be slightly dependent on the heater temperature (ranging from 500 to 800^{o}C) it generally did not affect the quantification. Moreover, increased vaporizer temperature decreased instrument's collection efficiency due to increasing bounce-off of particles from the vaporizer suggesting that the standard operation temperature is even preferable to higher temperatures for the quantification of the sea salt in the marine aerosol particles.

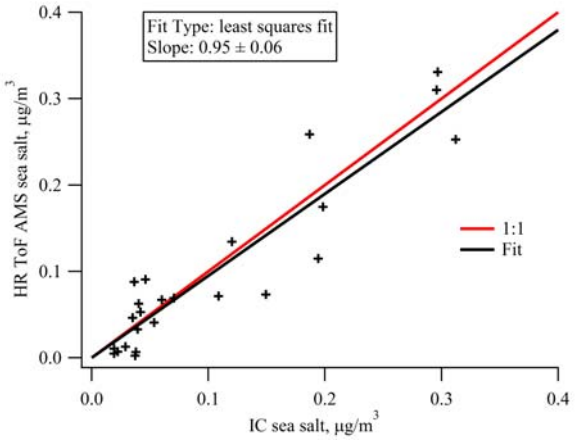

Figure 1. A comparison between HR-ToF AMS and Ion chromatography sea salt measurements.

PM1 sea salt concentrations derived from HR-ToF AMS measurements were compared with measurements from the off-line filter analysis using standard ion chromatography method (Figure 1). A good agreement between off-line chemical analysis and AMS sea salt measurements indicates the possibility of quantitative sea salt measurement with aerosol mass spectrometer in real time.

Presenting author email: Petri.Vaattovaara@uef.fi

Marine biologically active regions (e.g., coasts, ice edges, and open water areas with plankton blooms) are known to produce a range of compounds that interact with atmosphere effecting directly and indirectly on particle production, composition, and properties in marine atmosphere. While CLAW hypothesis (Charlson *et al*., 1987) supports the idea on the importance of marine biological activity on ultrafine (d<100nm) particles composition, properties and effects and focus on the role and importance of secondary sulfate production via DMS in those particles compositions, the CLAW hypothesis does not take into account the secondary organic fraction in the composition of the ultrafine particles. So far, recent observations about the presence of a remarkable marine origin secondary organic fraction in ultrafine particles have been indicated down to nucleation mode size particles (d<15nm) on Irish coastal waters on Atlantic Ocean (Vaattovaara *et al*., 2006), Arctic Ocean close to ice edges (Vaattovaara *et al.*, ICNAA 2009), and Australian sub-tropical Pacific Ocean waters (Modini *et al*., 2009). In spite of the importance of secondary particles to atmospheric radiatively active sizes, marine produced particle composition is still unknown in various other marine biologically active locations around the world.

This study about the composition of nucleation (d<15nm) and the lower end of Aitken (20nm<d<60nm) modes particles is focused on particle production at one such region the Chatham Rise region (New Zealand; latitude 42°S-44°S, longitude 174°E-177°W) during the SOAP (Surface Ocean Particle Production) pilot project voyage (austral summer period from 1.2.2011 to 12.2.2011). The location is on the southern Pacific Ocean with a sub-tropical front and intensive austral summer phytoplankton blooms.

The ultrafine particle composition was studied using the UFO-TDMA and the VH-TDMA methods on board of RV Tangaroa (NIWA, Wellington, New Zealand). Auxiliary data were collected from the ship weather station and marine information observations, SMPS particle size distribution measurements, total particle count CPC measurements with 5 nm and 10 nm cut-off sizes, and black carbon measurements. Marine biological activity was checked with MODIS satellite data and supported by *in situ* chlorofyll and dissolved DMS measurements. Marine air masses origin was followed with HYSPLIT trajectories.

The TDMA measurements show that in the biologically active marine area observed nucleation and Aitken mode sized particles include a clearly detectable organic fraction. During intensive solar radiation periods (e.g., 4.2., 6.2., 9.2., and 10.2.) secondary organic contribution is highly probable in those ultrafine particles. Furthermore, the comparison between *in situ* bubble burst chamber and atmospheric particles composition measurements strongly support secondary origin of the atmospherically observed ultrafine particles. The comparison of the secondary organic fraction observations on Atlantic, Arctic, and Pacific Oceans reveals that even the secondary organic fraction clearly exists in ultrafine particle phase in the different biologically active marine regions the properties of the fraction can be dependent on the marine area conditions.

This study was supported by COST action 735, NIWA (New Zealand), QUT (Australia), and the Academy of Finland. We thank whole research team and the crew and captain of RV Tangaroa for pleasant voyage.

Sea spray aerosols are of major interest to global climate models due to their large uncertainty in indirect and direct radiative forcing and poorly understood emission characteristics. A new experimental sea spray aerosol bubble tank is characterized and preliminary results are presented for bubble generation, bubble size distribution, and particle emissions.

In this study, the major processes of bubble formation are examined with respect to particle emissions. It has been suggested that a plunging jet, formed by a continuously flowing nozzle placed vertically above a water surface, closely resembles breaking wave bubble entrainment processes and subsequent bubble size distributions (Fuentes et al. 2010). The physical characteristics of our bubble tank are shown in Table 1. The tank consists of a stainless steel cylinder closed at both ends with fittings for recirculating flow for the jet and aerosol sampling.

Table 1 Sea spray tank characterization

Tank Dimensions	
H = 46.2 cm	V_{tot} = 16.3 L
D = 21.2 cm	V_{sample} = 9 L
A = 353 cm^2	$H_{headspace}$ = 20.7cm
Nozzle Parameters	
D_{nozzle} = 4 mm	$v_{jet,\ o}$ = 4.3 m s^{-1}
H_{nozzle} ~ 20 cm	$v_{jet,\ surf}$ = 4.7 m s^{-1}

The sub-surface bubble plume characteristics can be calculated using parameters specified by Claret & Lasheras (1997) and are given in Table 2. When the Weber number (We) is less than unity, surface tension forces are greater than inertial forces and bubbles will remain intact until reaching the surface.

Table 2 Bubble plume characteristics (1mm bubble)

Angle of Plume Cone = 12.5°
$v_{1mm,\ T}$ = 0.22 cm s^{-1}
$H_{1mm,\ T}$ = 21.6 cm
$W_{1mm,\ T}$ = 7.8 cm
We_{1mm} = 6.7 × 10^{-5}

In addition to calculated values, bubble spectra were analyzed for a frit placed in the bottom of the tank at range of air flow rates (

Figure **1**). Particle size distributions for both the frit placed in the tank and the plunging jet are shown in Figure 2.

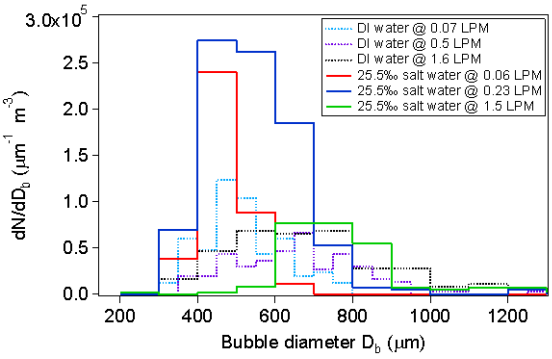

Figure 1 Preliminary photograph-analyzed bubble size distributions for the frit placed in the bottom of the tank.

The difference between the particle size distributions could be caused by high particle loss due to scavenging and entrainment processes of the plunging jet (Bin 1993). The difference in concentration could also be attributed to the shear forces exerted on bubbles that rise to the surface causing incomplete bursting which could also partly explains the disparity in particle size distributions.

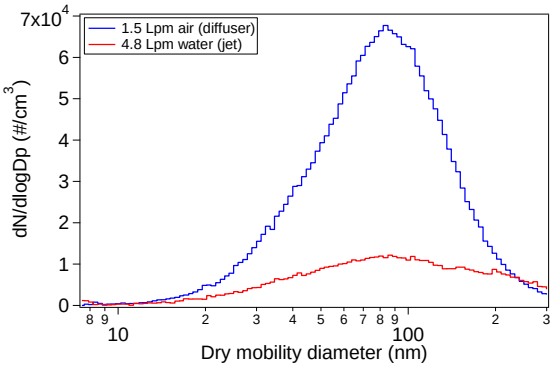

Figure 2 Particle size distributions for the frit and the plunging jet for artificial sea water of salinity 35‰.

The cloud condensation nucleus (CCN) activity of sodium chloride and artificial sea salt particles are presented herein. Although many studies have reported the observed and theoretical CCN activity of NaCl, its reliability as a calibration standard is diminished due to its uncertain morphology. Wang et al. (2010) show a dependence of the morphology (i.e., shape factor χ) on the drying rate of NaCl particles. Similar tests are repeated in our laboratory for NaCl and sea salt particles that are generated from an aqueous solution using a TSI atomizer.

We also employ a bubble-bursting tank to simulate the production of NaCl and sea salt particles in a marine atmosphere. Bubble production is effectuated either by pushing clean air through a diffuser situated at the bottom of the stainless steel tank filled with 10 L of artificial seawater, or by recirculating water from the bottom of the tank to the water surface via a plunging jet. Further description of the tank is provided in a companion abstract (Butcher et al.). The CCN activity of the particles produced from bubble-bursting is included in this study, and the observed data are compared to the observations from atomized particles as well as to the theoretical CCN activation of the respective salts (Figure 1). All theoretical values are calculated using Kohler theory, in which the water activity term is predicted from the Aerosol Inorganics Model (Wexler and Clegg, 2002).

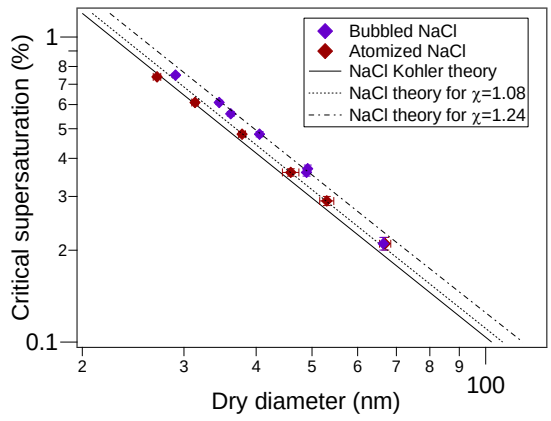

Figure 1. Observed and predicted CCN activation of NaCl particles from atomization and bubble-bursting.

The fraction of organic matter in the particle phase can be estimated from the difference in observed mixed-particle CCN activity from that of the inorganic components. Thus, a thorough understanding of the CCN activity of sea salt is necessary. The motivation for exploring the organic fraction stems from the observation in previous studies that the concentration of organic carbon in primary submicron marine aerosol particles may be highly enriched relative to the organic concentration in source ocean water (Blanchard, 1964). This enrichment has also been suggested to increase with decreasing particle size (Facchini et al., 2008, Keene et al., 2007). Consequently, the possibility that the mixed-particle morphology is dependent on drying methods and on particle size could significantly influence the estimation of the contribution from organic matter. Figure 2 shows preliminary estimates of organic fraction as a function of dry particle size. In these experiments, particles are generated in the bubble-bursting tank, which is filled with a solution containing NaCl (35‰ salinity) and an organic compound (i.e., fructose or oleic acid). The mass ratio of NaCl to organic in the solution is 10:1. A shape factor of 1.00 is assumed in Figure 2. The downward-trending bars are for illustration purposes and indicate the theoretical adjustment for shape factors up to 1.08 for mixed particles containing fructose.

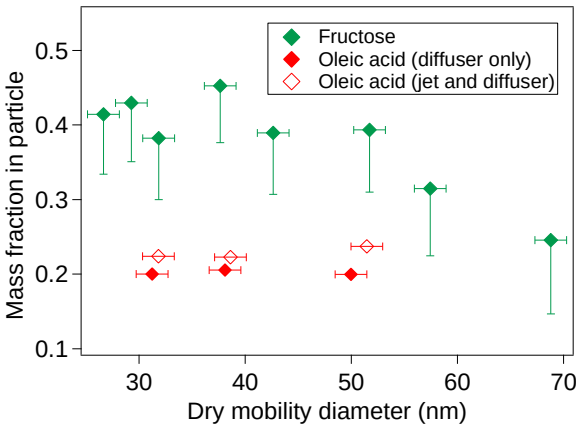

Figure 2. Size-dependent mass fraction of the organic constituent in the particle phase. Bubbles are produced using the diffuser except in the case illustrated by open diamonds, where the diffuser is used simultaneously with the plunging jet.

Aerosol Modelling

A new reduced complexity thermodynamic methodology (PF-FiTE) to calculate equilibrium vapour pressures of organic compounds above a multi-component solution

D. Topping[1,2], D. Lowe[2]

Introduction

Gas to particle partitioning, driven by a difference in equilibrium and partial pressures, is a key process that dictates the evolving chemical composition of atmospheric aerosol particles, thus their environmental impacts. As described by Raoults law, the equilibrium vapour pressure above a solution is a function of 3 key properties: 1) Po the pure component vapour pressure; 2) f the activity coefficient of the condensate in solution; and 3) x the mole fraction of component in solution. In a previous publication a new hybrid reduced complexity ionic mixing rule for calculating 'f', thus equilibrium vapour pressure of inorganic condensates was presented (Topping et al 2009). PD-FiTE, or Partial Derivative Fitted Taylor Series Expansion, was based on the observation that the logarithm of activity coefficients varied linearly as a function of water activity when expressed in terms of equivalent mole fractions. This is identical to the approach described by Zaveri et al for the model MTEM (Zaveri et al 2005). Following this, Topping et al (2009) developed a numerical expression based on ion-pairs and optimised interaction parameters using the thermodynamic model ADDEM (Topping et al 2005). In the following report we develop a similar reduced complexity expression for the activity coefficients of organic solutes, currently targeted at aqueous solutions

Results

A simple, flexible mixing rule is presented which allows the calculation of activity coefficients, thus equilibrium vapour pressures, of organic condensates above a multicomponent aqueous solution:

$$\ln f_A(x_B',\ldots x_w) = \ln f_A^o + \left(\frac{\partial \ln f_A}{\partial x_B}\right)_{(x_w)} x_B'$$

Where f_A is the activity coefficient of solute 'A', x_B the 'dry' mole fraction of solute 'B' and x_w the mole fraction of water. Based on the same fitting methodology as a previously published inorganic model (PDFiTE), organic PDFiTE treats interactions between binary pairs of solutes in the term $\left(\frac{\partial \ln f_A}{\partial x_B}\right)$, with variable sets of polynomials, used to describe behaviour within a mixture. Using 14 compounds chosen using a published reduction methodology, the framework is benchmarked against the UNIFAC model. For 100 randomly derived concentration ranges and 10 relative humidities between 10-99%, the average deviation was calculated to be 3.8%. Whilst compound specific deviations did vary, the median and inter-quartile values across all relative humidity range always fell within +/- 20%. The computational cost of both variants was compared to the use of UNIFAC for the same amounts of water. The fully coupled and uncoupled organic PDFiTE routines are up to a factor of 12 and 66 times more efficient than calling the UNIFAC model using the same water content, respectively; and 313 and 1751 times more efficient than an iterative model using UNIFAC.

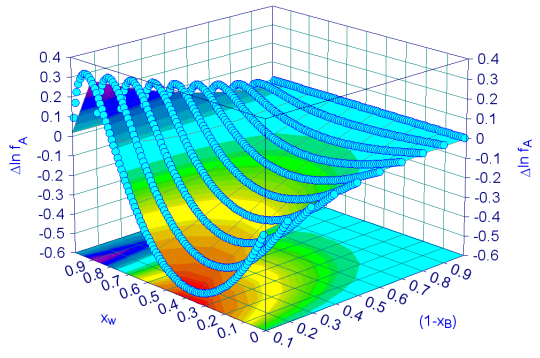

Figure 1. A surface representation of the difference in activity coefficient for solute 'A' as a function of mole fraction of water 'x_w' and 'dry' solute mole fraction '$(1-x_B)$' for a ternary mixture of 'A' and 'B' .

Results are also presented from incorporating PDFiTE into an aerosol box model (Lowe et al, 2009). This forms the basis of additional evaluation against more complex schemes, as well as an analysis of chamber data, before incorporation into the WRF-CHEM regional climate model. The latter will form the focus of future work.

This work was support by UK National Centre for Atmospheric Sciences (NCAS) funding.

Modelling $PM_{2.5}$ concentrations over Europe

E. Tagaris[1], R.EP. Sotiropoulou[1], N. Gounaris[1] and S. Andronopoulos[1]

[1] Environmental Research Laboratory, NCSR Demokritos, Aghia Paraskevi Attikis, 15310 Athens, Greece
Keywords: particulate matter, modelling, Europe
Presenting author email: tagaris@ipta.demokritos.gr

INTRODUCTION

Atmospheric particulate matter is a focus of attention, because of their important role in many areas, including human health, atmospheric reactions, acid deposition and the earth's radiation budget. The World Health Organization using population exposure estimates of PM_{10} concentrations for the year 2002 estimates that 865,000 people die prematurely each year from causes directly attributable to outdoor air pollution; from those deaths about 80,000 comes from the member states of the EU (www.who.int/quantifying_ehimpacts/countryprofilesebd.xls). The objective of this study is to simulate $PM_{2.5}$ concentrations over Europe using the Community Multiscale Air Quality (CMAQ) Modelling System (Byun and Schere, 2006)

METHODS

Meteorological fields are derived using the Penn State/NCAR Mesoscale Model (MM5) (Grell et al., 1994). Meteorology Chemistry Interface Processor (MCIP) (http://www.cmascenter.org) is used to provide the meteorological data from the MM5 outputs needed for the emissions and air quality models (177 × 217 grid cells of 35 km × 35 km, with 14 vertical layers).

Emissions are processed by the Sparse Matrix Operator Kernel Emissions (SMOKE v2.6) Modelling System (http://www.smoke-model.org). SMOKE is used to convert the resolution of the data in an emission inventory to the resolution needed by the air quality model. TNO has provided a gridded anthropogenic emissions database for the year 2006 over Europe in a 0.1 × 0.1 degrees resolution (ftp:// neptunus.tno.nl). The Biogenic Emission Inventory System, version 3 (BEIS3) is used for processing biogenic source emissions (http://www.epa.gov/asmdnerl/biogen.html).

The Community Multiscale Air Quality (CMAQ v 4.7) Modelling System with the Carbon Bond mechanism (CB05) (http://www.camx.com/publ/pdfs/CB05_Final_Report_120805.pdf) is used for the regional air quality modelling.

RESULTS AND DISCUSSION

Elevated $PM_{2.5}$ concentrations are simulated locally and regionally over the entire domain (Figure 1). Sulfate is dominant (up to about 60% locally) followed by nitrate (up to about 30% locally), organic carbon (up to about 25% locally) and ammonium (up to about 20% locally).

$PM_{2.5}$ model performance is evaluated by comparing the predicted concentrations with observation data from monitoring stations across Europe, using the air quality information system maintained by the

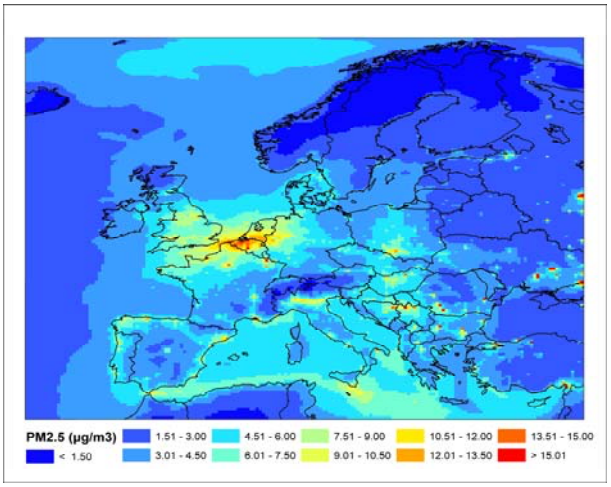

Figure 1: Daily average ground $PM_{2.5}$ dry mass concentrations for July 2006

European Environment Agency (http://www.eea. europa.eu). In general, model underestimates $PM_{2.5}$ concentrations. Particle-bound water constitutes 20-35% of the annual mean $PM_{2.5}$ concentrations (Tsyro, 2005); in our simulations aerosol water has not been included in $PM_{2.5}$ simulated values. Moreover, representation of secondary organic aerosol formation is uncertain, and low organic carbon has been noted in the CMAQ approaches (e.g., Kroll et al., 2006).

This work was supported by the FP7-REGPOT-2008-1grant No 229773. We gratefully acknowledge the first Air Quality Model Evaluation International Initiative (AQMEII) activity.

Keywords: SOSA, BVOCs, chemotype

BVOCs are essential in atmospheric chemistry because of the reactions to produce and destroy tropospheric ozone, the effects on aerosol growth and formation and the potential influence on global warming. Regional measurements and estimates are urgently needed to research carbon budgets and global climate. However, since various factors such as vegetation type, temperature and radiation have complicated impacts on BVOC emissions, comprehensive inventories are not so often reliably defined. To further track BVOC gas concentrations and their chemical transformations, BVOC emission rates are input into atmospheric transport and chemistry models [e.g., Poisson *et al.* 2000; Boauchet *et al.* 1999] (Levis *et al.* 2003). In this study, a new model SOSA (model to Simulate the concentrations of Organic vapours and Sulphuric Acid) which is a combination of meteorological transport, BVOC emissions and chemistry is applied to investigate Scots pine (*Pinus sylvestris*) tree emissions in a boreal coniferous forest in the SMEAR Ⅱ at Hyytiälä, Finland. To test the reliability of the model, simulation outputs are compared with measurement data collected from on-line chambers analysed by proton-transfer-reaction mass spectrometry (PTR-MS) analyzer. Results indicate that modeling and observations agreed reasonably well. The predominant species emitted from these coniferous trees is monoterpene with the main composition of α –pinene and $\triangle^3$–carene. Diurnal and seasonal variations are demonstrated in both quantity and quality of emitted compounds. Another significant phenomenon for BVOC emitters is discrepancy between branch scale emissions and above-canopy concentrations. In order to reduce uncertainty in measuring and modeling, a more detailed chemotypic characterization of BVOC blends needs to be constructed. In this research, SOSA is also used to estimate the contribution of different BVOC emissions especially monoterpenes and sesquiterpenes to the total OH reactivity.

Model comparison between global and regional climate-aerosol models ECHAM5-HAM and REMO-HAM: European aerosols

Presenting author email: joni-pekka.pietikainen@zmaw.de

REMO-HAM is a regional climate-aerosol model, which can be used to investigate aerosol-cloud-climate interactions starting from 10 km grid resolution. The model is a hydrostatic, three-dimensional atmospheric model, that has been developed at the Max-Planck-Institute for Meteorology in Hamburg (Jacob, 2001). The aerosol model in REMO is based on the HAM-M7 aerosol module (Stier *et al*, 2005).

We have done simulations with REMO-HAM and global climate-aerosol model ECHAM5-HAM. The data from ECHAM5-HAM has been used as driving field on the boundaries of REMO-HAM. The meteorological fields, as well as the nudging fields for ECHAM5-HAM, are from the European Centre for Medium-Range Weather Forecasts (ECMWF) operational data. So far, the simulation have been done for the year 2005, taking into account the spin-up times of the models. The resolution for ECHAM5-HAM was T63L31 (horizontally ∼210 km), and for REMO-HAM we used two different resolutions: 0.44° (50 km) and 0.088° (10 km).

The physics and chemistry part of the aerosols is similar in both models. The main differences are coming from the dynamical core of the models (for example the advection of tracers). The main switches of the models are chosen to be as close to each other as possible. Moreover, both of the models are using the AEROCOM (http://nansen.ipsl.jussieu.fr/AEROCOM/) vertically dependent emission data.

The Fig. 1 shows the measured and modelled sulfur dioxide (SO_2) gas phase concentrations and the total number concentrations from Hyytiälä for the year 2005. We can clearly see that ECHAM5-HAM overestimates the SO_2 concentrations, whereas REMO-HAM follows the measurements throughout the year. From the total number concentrations, we can see that REMO-HAM seems to underestimate the concentrations, whereas ECHAM5-HAM does not differ significantly during the year 2005. Nevertheless, based on our analysis, the high SO_2 concentration leads to an overestimation of nucleation mode particles due to the used binary sulfate/water based nucleation.

The models have only an emissions based proxy for the secondary organic aerosols. Moreover, the boundary layer nucleation was not used during the simulations. These both would only increase the total number concentrations, and thus we believe that the results from REMO-HAM are actually more realistic than the ones from ECHAM5-HAM.

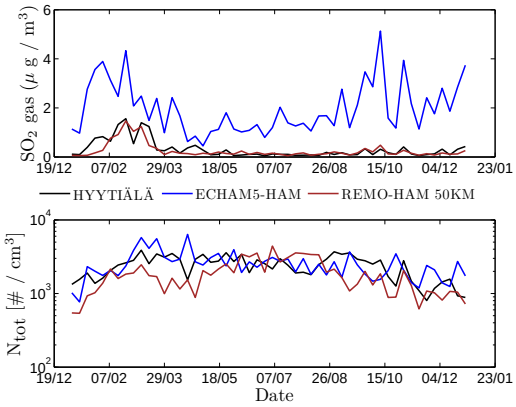

Figure 1: Measured and modelled gas phase sulfur dioxide (SO_2) concentrations as well as aerosol total number concentrations from Hyytiälä for the year 2005.

We have also done analysis for other measurement sites than Hyytiälä. The results from Melpitz, Mace Head and Jungfraujoch measurement sites show similar patterns as seen from the Fig. 1. Moreover, at the European scale, the spatial concentrations of nucleation mode particles seem to be too high in ECHAM5-HAM, especially in Northern Europe during the spring. Too high SO_2 concentrations increase the sulfuric acid (H_2SO_4) concentrations, which affects the nucleation rates directly.

In the future, we will concentrate on investigating the differences between the two models. The main focus will be in the gas phase SO_2 concentrations, H_2SO_4 formation, and in the nucleation. More detailed analysis and the main findings will be presented during the conference.

High pollution episodes associated to anticyclonic meteorological conditions happen often in Italy, in particular in the northern part of the peninsula. This study investigates the increase of PM10 concentrations from 13 to 15 July 2005 using atmospheric modelling and measurements. The simulations were carried out with the Atmospheric Modelling System (AMS) of MINNI project (Zanini et al, 2010). The PM10 measurements were provided by the Italian air quality database BRACE.

Fig. 1 shows the percentage increases in PM10 concentrations modelled and measured at 7 stations. All the stations are of background type, apart the station 21021, which is a traffic station. The location of the stations as well as the differences in PM10 concentrations from one day to another are shown in Fig. 2. The results show that the AMS model is able to reproduce the increase in PM10 concentrations under high pressure conditions (Fig1). Moreover, it can be noticed that increases in PM10 concentrations from 3 to 9 µg/m^3 exist not only in the Po Valley, but also in other areas (Fig. 2).

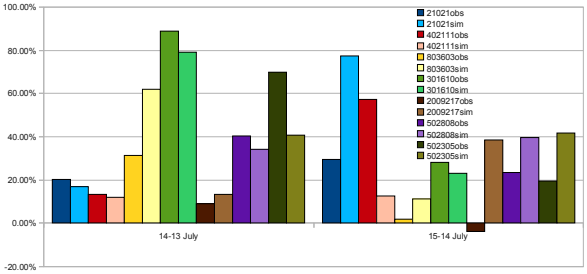

Figure 1. Percentage variations in aerosol concentrations for PM10 observations and model simulations.

The contribution of different species to the aerosol buildup during this period in relation to the emissions and meteorological conditions is also investigated.

This work is part of the MINNI (Integrated National Model in support to the International Negotiation on Air Pollution) project, funded by the Italian Ministry for Environment and Territory and Sea and carried out by ENEA.

Validation of the regional aerosol climate model REMO-HAM under East Asian conditions

Presenting author email: stephanie.fiedler@hzg.de

One of the most discussed influences of micro-physical processes in the climate system is the role of aerosols. They interact with radiation through scattering and absorption, which may lead to a change in the regional energy budget directly. Further the particles may act as possible cloud condensation nuclei and, thus, alter the cloud development. This, in turn, might have an impact on the regional water and energy balance indirectly. Despite these discussions, the majority of climate models represent aerosols by simplified, mostly out of date approaches.

This work presents the first high resolution climate simulation for East Asia from the new regional aerosol climate model REMO-HAM (Pietikäinen *et al*, 2011). REMO-HAM is based on the regional climate model REMO (e.g. Jacob, 1997). The size-resolving aerosol micro-physics module HAM-M7 (Vignati, 2004) and the double-moment cloud micro-physics scheme by Lohmann (2007) is implemented to describe the aerosol effect in the climate system with more detail. Following the standard global driving aerosol climate model ECHAM5-HAM (Stier, 2005), the represented aerosol species in REMO-HAM are black carbon BC, mineral dust DU, sea salt SS, particulate organic matter POM and sulphate S. These aerosol species are distributed into four discrete aerosol modes, namely the nucleation mode for an effective radius r < 5nm, the accumulation mode with r = (5nm; 50nm] , the Aitken mode for r = (50nm; 0.5µm] and the coarse mode with r > 0.5µm.

East Asia is known to experience heavy aerosol loads relative to other regions on Earth. Representing aerosols in the regional climate model may be a major factor to produce robust climate information under both current and possible future conditions for this area. A model domain in East Asia is chosen to test the reliability of REMO-HAM under comparably large aerosol concentrations. The usage of a limited area model enables to increase the horizontal resolution. Climate relevant features are described with more detail than in global aerosol climate models which simulate aerosol-climate information on a typical horizontal grid distance of 100km.

REMO-HAM is run on a horizontal grid of 0.22° (~25km) for the year 1993. The lateral boundary data of the meteorological fields are taken from the ERA-interim reanalysis. ECHAM5-HAM is nudged to reanalysis of ECMWF to provide the lateral driving data for the aerosol fields. Aerosol emissions are based on the AEROCOM emission inventory for 2000. The model is expected to show the closest results to observed climate under these boundary conditions. It is the first application of REMO-HAM outside of European conditions for which it has been developed.

The model is shown to simulate both aerosol and meteorological fields reasonable well under East Asian conditions. For instances, differences between the summer mean near surface air temperature from REMO-HAM (Figure 1) and observed conditions lie within the observation uncertainty in most areas over land. This reliability of REMO-HAM is the basis for robust future climate and climate change studies including regional aerosol-climate effects.

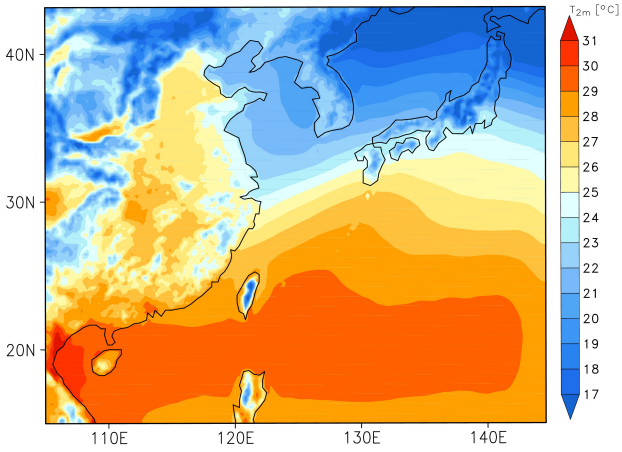

Figure 1. Summer (JJA) mean near surface air temperature from REMO-HAM 1993.

We acknowledge the usage of ERA-interim reanalysis of ECMWF. This work was supported by the Helmholtz Centre Geesthacht.

Nucleation is one of several scientific phenomena which are presently under investigation. A lot of complex chemical processes occur in the Atmospheric Boundary Layer (ABL) and it is essential to have a thorough understanding of these processes. This actually defines the chemistry and the aerosol dynamics in the atmospheric boundary layer (ABL). To do so we have developed a spatial and temporal high resolution 3 dimensional model which attempts to reconstruct the emissions, transport and chemistry and aerosol processes in the mixed layer. The new code integrates a meteorological module, an emission module, a chemical kinetics module and an aerosol dynamics module.

The meteorological model is based on the coupled biosphere-atmosphere boundary layer model SCADIS (SCAlar DIStribution). SCADIS is based on Reynolds-averaged Naviers-Stokes equations (RANS). The model was initially described in (Sogachev et al., 2002). Turbulent fluxes are expressed as the product of eddy diffusivity and the vertical gradient of a mean quantity. The model is based on the E - ω closure where E is the turbulent kinetic energy (TKE) and $\omega = \varepsilon/E$ is the specific dissipation, where ε is the dissipation rate of TKE.

Emissions from the canopy were simulated using the Model of Emissions of Gases and Aerosols from Nature (MEGAN). This is a system for estimating the net emissions of gases and aerosols from terrestrial ecosystems in to the atmosphere. The model estimates the leaf area, plant species composition and species specific emission factors for a given specific location. MEGAN is a global model with a base resolution of approximately 1 km. This makes it favourable to be used in regional as well as in global models. The driving variables in MEGAN include land cover, meteorological factors and atmospheric chemical composition. These driving variables are obtained from different models, satellite and ground observations (Guenther et al., 2006).

The chemistry which accounts for most of the simulation time was taken from the Master Chemical Mechanism (MCM). MCM is a near explicit chemical mechanism that describes the degradation of about 135 volatile organic compounds (VOC). This mechanism is implemented in to Fortran 90 using KPP (The Kinetic PreProcessor). The KPP is a general analysis tool that generates a FORTRAN or C code that computes the time evolution of the chemical species starting with a specification of a chemical mechanism which in our case is the MCM.

The aerosol dynamics is integrated in to the model using the University of Helsinki Multicomponent Aerosol model (UHMA). The main objective of this model is to study the new particle formation under clear sky condition in the troposphere (Korhonen et al., 2004). The size-segregated, sectional box model included all basic aerosol dynamical processes: nucleation, condensation, coagulation and dry deposition,

The new developed model utilizes parallel computing using MPI (Message Passing Interface). It is now possible to run the code on multi-core clusters and thus reducing the time per simulation, which gives us the possibility for long-term investigations with reasonable computational costs. The main focus was to study various nucleation theories (e.g binary nucleation of sulphuric acid and water or ternary nucleation for sulphuric acid, water and ammonia) in and above the ABL for the SMEAR II in Hyytiälä, Finland. Further we studied the chemical processes and feedback mechanisms crucial for aerosol formation and nucleation processes. The presentation will give concentrate on the simulations performed for Hyytiälä in comparison with ground and air-born achieved measurements.

Numerical study of performances of RespiCon sampler in calm air

S. Zaripov[1], W. Koch[2]

[1]Kazan Federal University, Kazan, 420008, Russia
[2]Fraunhofer Institute Toxikologie und Experimentelle Medizin, Hannover, D-30625, Germany

Keywords: aerosol sampling, collection efficiency, calm air, CFD
Presenting author email: shamil.zaripov@ksu.ru

The results of a numerical study of performances of the RespiCon sampler in calm air are presented. The obtained theoretical curves of collection efficiencies agree well with experimental data and conventional curves of corresponding dust fractions. The results of the numerical study were used to design a new Respicon sampler with a higher volume flow rate.

The RespiCon sampler for personal, time-resolved concentration monitoring and sampling of aerosol particles was designed in Fraunhofer Institute Toxikologie und Experimentelle Medizin (Koch et.al., 1999). The RespiCon sampler consists of a sampling inlet and two virtual impactor stages and offers an opportunity to use a single sampling device for collecting simultaneously either the personal or area samples of the respirable, thoracic and inhalable fractions of airborne dust. The sizes of particles of these fractions are defined in European and U.S. standards for health-related dust measurements at the workplace. The RespiCon sampler has a circular inlet around the inlet-head perimeter (fig.1). Because of this the aerosol is aspirated into the inlet uniformly from all wind directions. The virtual impactor serves as a classifier of particle sizes and concentrator of coarse particles. The performances of RespiCon were experimentally studied by Koch et.al. (1999), Li et.al. (2000), Koch et.al. (2002) and Feather&Chen (2003).

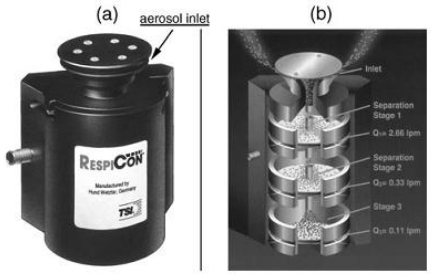

Figure 1. Picture and schematic drawing of RespiCon sampler. Source: catalog of TSI,Inc.

In this work a mathematical model of an aerosol flow around and inside the RespiCon sampler in calm air was developed. The gas flow is described by the Navier-Stokes equations of axisymmetric stationary viscous incompressible flow. The Navier-Stokes equations are numerically integrated by CFD code FLUENT. The particle trajectories are found by the numerical solution of equations of particle motion in the calculated gas flow velocity field. In so doing the values of flow velocity components are found by interpolation.

Far from the sampler the particles move downward in still air by gravity action with the settling velocity $\bar{V}_s = \tau \bar{g}$ (τ is the particle relaxation time). The tube of the limiting particles trajectories that divides the sampled and unsampled particles is found. The aspiration efficiency of the sampler inlet is calculated using the value of cross-section area of the tube of limiting trajectories far from the sampler. The collection efficiency of virtual impactor stages are found by means of an analogous approach.

The aspiration efficiency of the inlet and the collection efficiencies of the impactor stages as a function of the particle diameter are shown in fig.2. The obtained dependencies agree well with experimentally determined efficiencies and three conventional curves of particle fractions. To extend the region of application of RespiCon sampler a new device with twice the flow rate was constructed. The performances of the new device were also studied numerically. The results of the numerical study confirm that the performances of the new device are acceptable for measurements of the aerosol concentration in indoor workplaces at higher flow rates.

Chennai, the Capital of Tamil Nadu, with a population over 4 million is among the fastest growing urban conurbations anywhere in the world. A huge population lives below the poverty line in slums distributed throughout the Chennai Metropolitan area especially in North Chennai as in shown in Figure 1 (created using GIS based software MAPINFO).

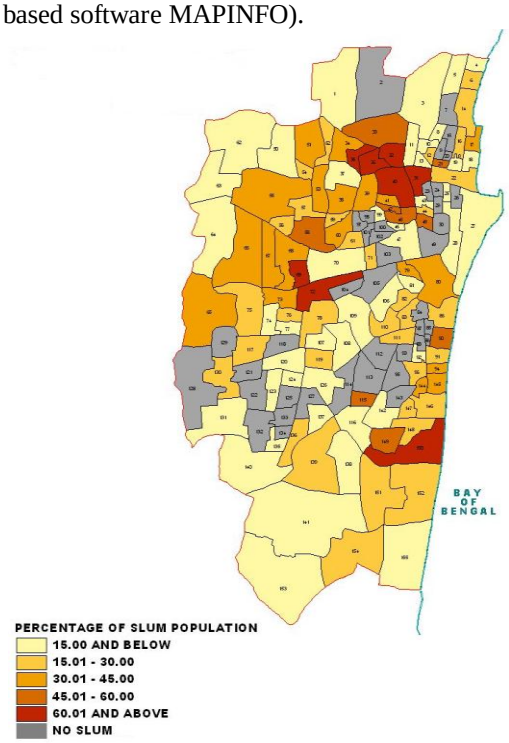

Figure 1. Percentage of total population (per division) living in slums in Chennai

Cow dung cakes and firewood constitute around 25% of the total fuel used by slum dwellers for cooking (Chandramouli, 2003). The main aim of this first study is to quantify the extent of BC and SO_2 pollution from domestic bio-fuel consumption using published demographic information. The results can be used for Environmental Impact Analyses, Regional Pollution Forecasts (CPCB 2010) and eventually as inputs to climate models concerned with direct, indirect as well as semi-direct effects. Recent studies (Ghosh et al. 2007; Rap et al. 2009) have shown that cloud droplet number concentrations are not always directly proportional to aerosol number concentrations, particularly when the activation domain comprises of multiple aerosol types. In a polluted city like Chennai, one would expect the BC particles to contain soluble sulphates enabling them to activate into cloud droplets. We use the AERMOD software (USEPA) with an area source option and variable emission rates, based on local cooking patterns, to compute BC (in terms of PM10) and SO_2 distributions.

Emission factors are calculated according to the procedures outlined in Habib *et al* (2004). Representative weather information was obtained from published literature (Pavuluri et al., 2010; CPCB 2010) and the World Wide Web. The weather in Chennai is generally hot and humid. The winds blow in from the east-southeast from February to May then reverse direction from June to September and finally bring in the northeast monsoon in October which lasts until January.

In this abstract we show results of BC for a typical August day (late summer) where we have considered emissions from areas in Chennai city in which the slum population exceeds 60% (Figure 2). Figure 2 reveals high BC concentrations from just domestic fuel consumption in Chennai slums. These results will be compared with observations.

Further experience with low emission zones in Germany: will the next stage do the job?

S. Wurzler[1], P. Bruckmann[1], V. Diegmann[2], F. Pfäfflin[2], A. Brandt[1]

[1] North Rhine Westphalia State Agency for Nature, Environment, and Consumer Protection, Wallneyer Str. 6, 45133 Essen, Germany

Keywords: PM10, NO_2, emission reduction, air quality, low emission zone

Urban road traffic poses a problem not only to German cities but also to cities all over Europe. Air quality in street canyons with high traffic densities is still far from meeting the air quality limit values required by the EC air quality directives. Especially the number of days with average PM10 concentrations above 50 µg/m³ and the annual average NO_2 concentrations frequently exceed the respective limit values. Allowed are 35 days with average PM10 concentrations above 50 µg/m³ and an annual average value of 40 µg/m³ for NO_2.

In order to reduce the pollution loads measures must be taken. One possible measure is the implementation of low emission zones. In many parts of Europe low emission zones have been implemented and their number has been growing in recent years. Low emission zones are areas inside conurbations where measures are taken to reduce the emission load. Currently, most implementations focus on measures to reduce road traffic emissions with the aim to improve air quality significantly. The measures comprise road traffic regulations, i. e. vehicles that do not meet certain emission standards are prohibited inside the low emission zones.

Meanwhile quite a bit of experience has been collected with stage 1 of the low emission zones in Germany. Even though stage 1 proved to be an effective measure to reduce the pollution loads, there still remain numerous street canyons with such high concentrations of air pollutants (especially NO_2) that the limit values are still exceeded. Therefore further measures must be taken. One of those measures is stage 2 of the low emission zones. The aim is to reduce road traffic emissions further. Stage 2 comprises even stronger road traffic regulations in the low emission zones, i. e. only vehicles with state of the art emission standards are allowed to enter. However, the question remains whether stage 2 of the low emission zones will do the job.

Quantifying the effects of low emission zones on air quality is not a trivial task. Model studies have been carried out in order to investigate the potential benefits of such zones, e. g., by the authors for the Ruhr Area.

This paper reviews some of the German experiences with low emission zones, with special focus on the Ruhr Area. A review of the results (field observations and modelling) obtained with stage 1 will be given and model results of the potential effects of stage 2 will be shown. The focus is on the effects on air quality with respect to PM10 and NO_2.

Our paper shows that the modelled and the measured effects of stage 1 of the low emission zones are of the same magnitude. For the potential effects of stage 2 only model results exist and will be reviewed. Fig. 1 shows model results for some selected street canyons in the Ruhr Area. Stage 1 and stage 2 of the low emission zones have in common that the effect on air quality is proportional to the traffic density.

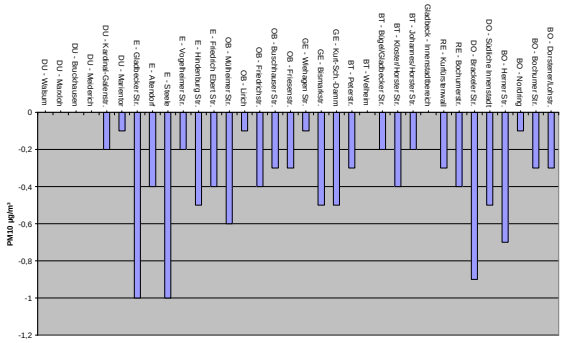

Figure 1. Reduction of the PM10 load (annual average in µg/m³) in some selected street canyons in the Ruhr Area. Increased effect obtained by stage 2 as compared to stage 1 of the low emission zones.

Even though many low emission zones have been implemented lately, most of them comprise only stage 1. There are no annual measurements of the effects of stage 2 available yet. More investigations and experiences, also from further cities and nations, are needed to fully evaluate the effects of low emission zones.

Stabilizing action of the vertical wind on spatial distribution of stratospheric aerosol

V.I. Gryazin and S.A. Beresnev

Aerosol Physics Laboratory, Ural State University, Ekaterinburg, 620083, Russia
Keywords: aerosol modelling, stratospheric aerosols, aerosol dynamics, vertical wind.
Presenting author email: sergey.beresnev@usu.ru

This study continues and summarizes analysis and estimations of transport opportunities of the vertical wind in stratosphere. Characteristics of vertical component of wind velocity is of interest not only for qualitative description of its altitude-, seasonal- and latitude dependences, but also for quantitative description of features of the aerosol vertical transport in the middle atmosphere (Gryazin and Beresnev, 2011).

The first purpose of given report – to present results of climatological analysis of vertical wind in the stratosphere. High-altitude, temporal, and latitude dependences of zonal mean averaged vertical wind velocity for the period of 1992-2006 from the UKMO atmospheric general circulation model are analyzed (Figure 1). It is shown that monthly averaged amplitudes of the vertical wind are approximately ±5 mm/s, while annual averaged ones are ±1 mm/s (Beresnev *et al*, 2008). We have carried out the comparison of the received results with the NCEP-NCAR reanalysis data, and have found out their qualitative agreement.

The upward wind can provide the vertical lifting against gravity for sufficiently large (up to 3-5 μm) aerosol particles with a density up to 1.0-1.5 g/cm^3 at stratospheric and mesospheric altitudes. The vertical wind, probably, is a substantial factor for particles motion up to altitudes of 30-40 km, and can change essentially the sedimentation velocities and the residence times of stratospheric aerosols. The structure of the averaged fields of vertical wind supposes the opportunity of formation of dynamically stable aerosol layers in the middle stratosphere (Beresnev *et al*, 2009).

For the problem about action of a permanent source of monodisperse particles near the stratopause, it is shown that action of the averaged vertical wind along with the gravitational sedimentation and turbulent diffusion changes the standard vertical profiles of the relative concentration of particles cardinally. Estimations for the levitation heights for particles of different densities and sizes in the stratosphere under action of gravity and vertical wind are presented also (Gryazin and Beresnev, 2010).

The method of comparison of vertical motion characteristics for spherical and fractal-like aerosol particles in stationary atmosphere and in atmosphere under action of the averaged vertical wind is introduced. It consists in introduction of suitable equivalent radius (sedimentation radius) for fractal-like particles, and in comparison of subsidence velocities identical on mass of introduced spherical particle and the real fractal-like aggregate. It is shown, that subsidence velocities of compact spherical and fractal-like particles can differ essentially in this case.

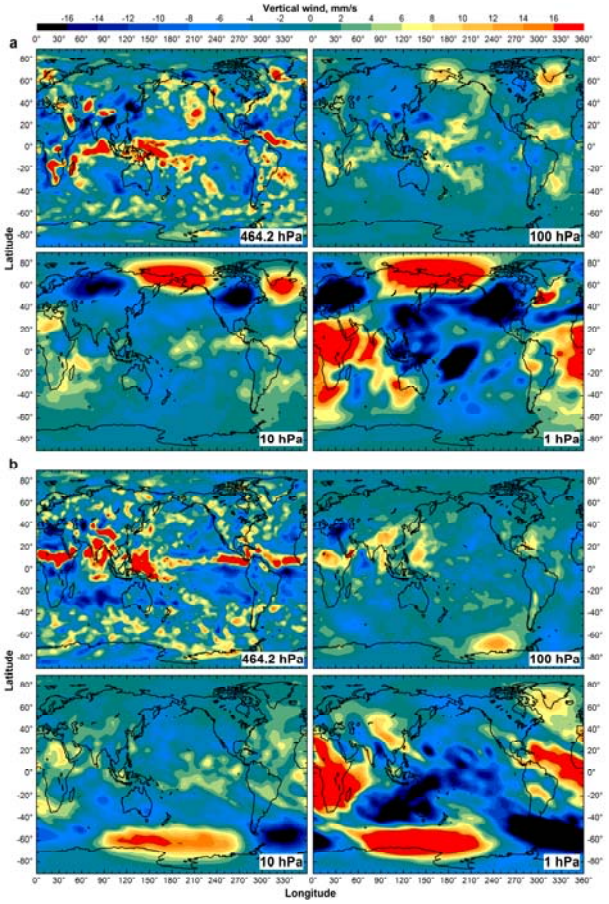

Figure 1. Geographic distribution of monthly-averaged vertical wind velocity at two characteristic altitudes for January (a) and July (b), 2005.

Bayesian forecast of urban particle number concentrations

B. Mølgaard[1], T. Hussein[2], J. Corander[3] and K. Hämeri[1]

[1]Department of Physics, University of Helsinki, Helsinki, 00014, Finland
[2]Department of Physics, University of Jordan, Amman, 11942, Jordan
[3]Department of Mathematics and Statistics, University of Helsinki, Helsinki, 00014, Finland
Keywords: urban aerosols, number concentration, statistical analysis
Presenting author email: bjarke.molgaard@helsinki.fi

Aerosol particle concentrations are often elevated in cities due to traffic and other anthropogenic sources. These particles may cause adverse health effects. The concentrations also depend on weather conditions. Clear links between the number concentration of fine particles and temperature and wind have been established in other studies (Hussein *et al*, 2006, Olivares *et al*, 2007, Jones *et al*, 2010).

We have developed a statistical model which provides forecast of particle number concentrations. The model is of the form:

$$\log(N) = f(X) + \varepsilon,$$

where N is the number concentration of some size fraction, X is a vector of covariates (predictors), and ε is a normal distributed error term. f is linear in its parameters and we included autoregression on the error term ε as suggested by Chib (1993). As covariates we used temperature, wind speed and direction, relative humidity, traffic intensity, time of day, time of week, and time of year. We have applied the model to the number concentrations of two size fractions: 3 – 100 nm (ultra-fine particles, UFP) and 100 – 950 nm (accumulation mode). Our data are from an urban background station in Helsinki. The model was implemented in a Bayesian framework, so it provides probability distributions as forecasts. We used learning data starting from beginning of 2005 and made forecasts for the years 2006 – 2008 with time resolutions of 1 hour and 3 hours. The forecasts were made for one day at a time assuming particle data known until noon the previous day.

A common measure of model performance is the R^2 value provided in Table 1. Here we see that the model performs best for UFP. The reason is probably that the UFP concentration is stronger affected by local sources (such as traffic) and local weather conditions. A scatter plot of the values which were used for calculating the best R^2 is given in Figure 1. Here we see that the model has less difficulty in predicting the highest concentrations correctly than in predicting the lowest.

Table 1. R^2 values for the two size fractions at the two time resolutions.

	1 hour resolution	3 hour resolution
UFP	0.627	0.669
Accumulation mode	0.516	0.572

While testing the model we used actual measured values for the covariates. In a real life implementation of the model future weather and traffic intensity would only be known through forecasts, and the performance of the model would be affected quality of the weather and traffic forecasts.

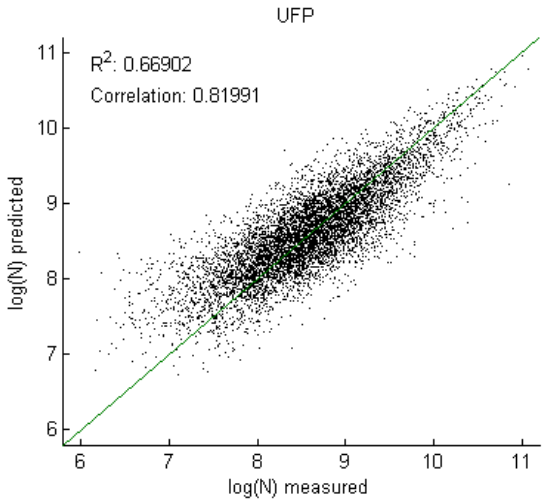

Figure 1. Comparison of forecast and measurement. Natural logarithm used. The unit of the number concentration N is particles/cm^3.

This work is a part of the Ubicasting 2 project funded mainly by TEKES. We thank the Finnish Transport Agency (Liikennevirasto) for providing traffic data.

Regional chemical weather modelling of the UK using WRF-Chem as part of the RONOCO project

S. Archer-Nicholls[1], S. Utembe[1], D. Lowe[1] and G. McFiggans[1]
[1]Centre for Atmospheric Sciences, SEAES, University of Manchester, UK, M13 9PL
Keywords: Regional modelling, WRF-Chem, NO_3 chemistry, nitrate aerosol, secondary organic aerosols.
Presenting author email: scott.archer-nicholls-2@postgrad.manchester.ac.uk

The ROle of Night time chemistry in controlling the Oxidising Capacity of the atmOsphere (RENOCO) campaign is a project being funded by NERC and being carried out by a collaboration of UK Universities. The primary objective of the is to better understand the role of the NO_3 radical on the chemistry of the night time atmosphere, and thus its overall effects on the composition of the troposphere. It is believed that NO_3 is the primary oxidant at night time, significantly impacting ozone formation, rain acidification and the formation and transformation of aerosols, particularly through the formation of the ammonium nitrate particulate. However, many of the basic chemical processes controlling the formation and removal of NO_3 and its reactions with volatile organic compounds (VOCs) are still poorly understood. The investigation of these processes is essential to gain a better understanding of how NO_3 chemistry affects the aerosol burden and composition on a regional and global scale.

As part of the RONOCO project, an extensive modelling campaign has been undertaken to investigate night time chemistry. A multi-tiered approach has been taken, whereby detailed box-models have been used to study individual processes, with these results feeding into larger models used to investigate the wider impacts on regional and global scales. The goals of the regional scale modelling have been to compare the extent of night time NO_3-VOC chemistry with that of daytime NO. This in turn helps us better understand how oxidation with NO_3 affects radical budgets and ozone formation. In addition, we have estimated the contribution of N_2O_5 hydrolysis to the formation of the nitrate aerosol, investigating how this process may control NO_3 concentrations and hence how aerosol composition may impact the night time atmospheric lifetime of VOCs.

To investigate the regional impacts of these processes, we have used the Weather Research and Forecasting model with Chemistry (WRF-Chem), a state of the art regional climate model with fully coupled air quality and meteorological components allowing for better resolution of aerosol and gas-phase chemistry (Grell et. al., 2005). A UK domain has been simulated at a fine, 5km resolution and nested within a more coarse domain covering a wider area over Northern Europe and the Atlantic. Detailed emission inventories have been inputted and varied within the model.

Recent extensions to WRF-Chem have been developed and used in this application, enabling the representation of several key processes being investigated within the RENOCO campaign, making WRF-Chem an ideal model to use for the purposes of this investigation. In particular, the Common Representative Intermediates scheme (CRIv2-R5) (Watson et. al., 2008), a reduced chemical scheme designed to simulate the atmospheric degradation of 220 species of hydrocarbons and VOCs, is used to simulate gas-phase chemistry. Condenced-phase chemistry is represented using the MOSAIC aerosol scheme (Zaveri et al, 2008), which has been extended to include a reduced complexity condensed organic phase consisting of 13 semi-volatile and 2 involatile species (Topping and Lowe, 2011). These two additional schemes have been coupled together, allowing for WRF-Chem to better simulate how the NO_3 radical reacts with various organic compounds found in the troposphere and how this in turn contributes to the formation of secondary organic aerosols, impacting the loading and composition of atmospheric particulates.

We will present results from the application of WRF-Chem to model the regional climate about the UK under changing emission profiles and oxidant conditions. Findings on role of the NO_3 radical on the formation and transformation of tropospheric aerosols and the resulting composition of particulate matter will be displayed. The wider impacts of these processes on the regional climate and air quality will be further discussed.

Motion of charged aerosol particles in a cylinder array

T. Zaripov, A. Egorov, D. Demidov

Institute of Mathematics and Mechanics, Kazan Federal University, 420008, Kazan, Russia

Keywords: aerosol filtration, collection efficiency, charged particles, CFD
Presenting author email: zaript@gmail.com

The motion of charged aerosol particles in the porous medium consisted of an array of circular cylinders is theoretically studied. The mathematical model is based on the solution of gas flow equations, equations of particle transport and electric potential. The particle concentration, electric potential distributions and collection efficiency are studied.

The transport and deposition of aerosol particles in the porous medium have many experimental and industrial applications. The diffusion, impaction and gravity actions are not enough to provide the deposition of aerosol particles in the intermediate range of sizes ~0.1-1 μm. In this case the particle charging is used to increase the deposition by the electrostatic force action (Yu&Chandra, 1977, Alonso&Alguacil, 2007).

The motion of charged aerosol particles in a periodic bar of an array of circular cylinders is numerically studied (fig.1). Under the assumption of a steady incompressible fluid flow the gas velocity field is found by numerical solution of the Navier-Stokes equations using CFD code FLUENT.

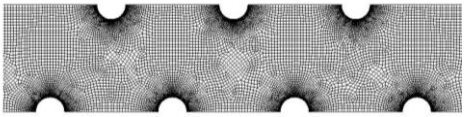

Figure 1.

At the given distribution of space concentration C of charged particles the potential F of electric field can be found from the Poisson equation

$$\Delta F = -qC/\varepsilon_0 \qquad (1)$$

where q is the charge quantity, ε_0 is the permittivity of the air. The stationary equation for particle flux J due to convection, diffusion and electrostatic migration is written as

$$\nabla \cdot J = \bar{U} \cdot \nabla C - D\Delta C + qb\nabla \cdot \left(C\nabla F\right) = 0 \qquad (2)$$

where D is the diffusion coefficient, $\bar{U}$ is the gas velocity, $b = C_c/3\pi\mu d$ is the particle mobility, d is the particle diameter, C_C is the Cunningham correction factor. In a non-dimensional form equations (1,2) can be rewritten as

$$\bar{u} \cdot \nabla c - Pe^{-1}\Delta c + \alpha\nabla \cdot \left(c\nabla\varphi\right) = 0 \qquad (3)$$

$$\Delta\varphi = -c \qquad (4)$$

where $\bar{u} = \bar{U}/U_0$, $Pe = hU_0/D$, $\varphi = F\varepsilon_0/qC_0$, $c = C/C_0$, $\alpha = q^2C_0b/hU_0\varepsilon_0$, h and U_0 are the length and velocity scales, C_0 is the input concentration of particles.

The boundary conditions on the cylinders surfaces are $c(r_f) = 0$, $\varphi(r_f) = 0$ (r_f is the cylinder radius). On the top and bottom sides of the bar the symmetry conditions are given. The relative input concentration of particles is equal unity $c(0, y) = 1$. Equations (3-4) with the boundary conditions are solved in the velocity field obtained from the numerical solution of the Navier-Stokes equations.

The particle concentration, electric potential distributions and collection deposition efficiency were studied numerically at various values of particle size, initial particle concentration, quantity of particle charges, array porosity and flow Reynolds number. In fig.2 the gas flow stream lines (a), izolines of electric potential φ (b) and particle concentration c at the values $\mathrm{Re} = 50$, $\mathrm{Pe} = 100$, $\alpha = 0.001$, ε =0.95 are shown ($Re = 2r_f\rho U_0/\mu$ is Reynolds number, U_0 is the undisturbed gas velocity, ρ is the gas density and viscosity, ε is the porosity of the cylinder array).

As part of the European Global Monitoring for Environment and Security (GMES) program, the Monitoring Atmospheric Composition and Climate (MACC) project will provide a system for monitoring and predicting the characteristics of atmospheric constituents. Our contribution to this work is the incorporation and evaluation of the GLOMAP-mode microphysical aerosol scheme (Mann et al., 2010, GMD) within the ECMWF Integrated Forecasting System (IFS). The two-moment modal GLOMAP-mode scheme includes new particle formation, condensation, coagulation, cloud-processing, and wet and dry deposition. GLOMAP-mode is already incorporated as a module within the GLOMAP-TOMCAT chemistry transport model and within the UK Met Office HadGEM3 general circulation model. In these frameworks, the scheme compares well against a wider range of benchmark observational datasets including measurements from short-term field campaigns and long term monitoring sites.

Presented here are the results of tests of GLOMAP-mode in the IFS, comparing the new aerosol scheme with the mass-only scheme developed during GEMS. The use of a microphysical, process-based model allows a more realistic representation of the properties of the multi-component aerosol and will enable aerosol-cloud interactions to be robustly simulated within the IFS system. Sophisticated regional aerosol-chemistry models will also benefit from the new GLOMAP-mode-IFS system via improved boundary condition information.

This work is part of the EU FP7 project ‘Monitoring Atmospheric Composition and Climate’

Atmospheric new particle formation can have a large contribution to present-day anthropogenic cooling by increasing availability of cloud condensation nuclei (CCN). Sulphuric acid is thought to be the main precursor for nucleation (Kulmala *et al.* 2006). It is studied that the global anthropogenic emissions of sulphur dioxide may already have peaked and that emissions reductions and control measures could lead to a large decrease (even 90%) of global sulphur dioxide emissions by end of century. If sulphuric acid is governing atmospheric nucleation, the reduction in sulfur dioxide emissions would reduce the aerosol indirect effect and lead to more warming from greenhouse gases. The effects of lowered nucleation rates could potentially be offset by an increase in emission of biogenic volatile organic compounds (BVOCs), as they provide more growth for sub-CCN particles. If organics play a role also in the early steps of new particle formation (Metzger *et al.* 2010), the reduction in aerosol cooling by the end of century could be more subtle.

We use global climate model ECHAM5-HAM (Stier *et al.* 2005) to simulate present-day (year 2000) and future (year 2100) aerosol forcing. Anthropogenic emissions are obtained from AeroCom inventory (http://dataipsl.ipsl.jussieu.fr/AEROCOM) for year 2000 and "Representative Concentration Pathways" (http://www.iiasa.ac.at/web-apps/tnt/RcpDb) for year 2100. Biogenic organic emissions are estimated from two independent models: LPJ-GUESS (Schrugers *et al.* 2009) and MEGAN (Guenther *et al.* 2006). We test several parametrizations for nucleation: binary sulphuric acid-water (Vehkamäki *et al.* 2002), activation-type (Kulmala *et al.* 2006), and different formulations for sulphuric acid+organic nucleation (for e.g. Paasonen *et al.* 2010). Condensation of BVOCs takes place in the boundary layer, and the condensational fluxes are calculated according to condensation sink of each size mode.

All applied anthropogenic sulphur dioxide emission datasets show a significant reduction until 2100, ranging from 80 to 90%. This reduction together with lower primary emission rates lead to roughly 50% decrease in boundary layer CCN concentration, when activation-type nucleation is used. Analysis of radiative fluxes shows that the total aerosol forcing (direct+indirect effects) goes from a strong present-day cooling of -1.6 W/m^2 to -0.2 W/m^2 in year 2100. Most of the change is due to reduction in cloud droplet number and resulting change in cloud properties (albedo and lifetime).

The response of biospheric organic emissions to changing climate is rather poorly understood. The LPJ-GUESS model assumes that monoterpene production is affected by increasing CO_2 concentration and shows close to zero change in monoterpene emissions between 2000-2100. The MEGAN model, however, predicts a 30% increase in monoterpene emissions due to warming climate and higher vegetation productivity. This additional organic matter available for condensation on small particles enhances growth from nucleation to CCN size. Our simulations show that with activation-type nucleation, even an strong future increase of 50% in BVOC emissions could not counteract the effect of decrease in particle nucleation in terms of particle number or aerosol forcing. However, if we assume that nucleation is dependent on both sulphuric acid and organics, the decrease in aerosol forcing between 2000-2100 is somewhat smaller.

Keywords: secondary organic aerosols
Presenting author email: steven.utembe@manchester.ac.uk

It is now well established that organic material is a significant variable component of tropospheric aerosol accounting for between 10-90 % of fine particle mass. However, most models underestimate organic aerosol mass mainly because of lack of adequate treatment of the role of water in aerosol composition and transformation, Another possible reason which may contribute to this underestimation is insufficient carbon mass flux of condensable vapours. In this work, a reduced chemical scheme, the Common Representative Intermediates (CRIv2-R5) (Watson *et al*. 2008) which describes the tropospheric degradation of methane and 22 emitted non-methane hydrocarbons and oxygenated volatile organic compounds (all together comprising of 220 species in 609 reactions), and is traceable to the Master Chemical Mechanism (v3.1), has been coupled to an explicit aerosol microphysics model to enable prediction of the transformation of multicomponent aerosol in the oxidizing atmosphere. The aerosol microphysics model uses the hyprid Partial Derivative Fitted Taylor Expansion (PD-FiTE), a computationally efficient method for calculating gas/liquid equilibria in atmospheric aerosol particles. We present model results from sensitivity studies of its use in sectional Microphysical Aerosol Numerical box-model Including Chemistry (MANIC) (Lowe *et al.*, 2009) and its application in a regional model (WRF-CHEM) to simulate the formation and transformation of tropospheric aerosols in the UK under a range of changing emission profiles and oxidant conditions.

Estimate of the Saharan dust contribution to PM_{10} concentrations over Italy: a modelling approach

A. Pederzoli[1], M. Mircea[2] and S. Finardi[3]

[1]Joint Research Centre, Via E. Fermi 2749, 20127, Ispra, Italy
[2]ENEA, Via Martiri di Monte Sole 4, 40129 Bologna, Italy
[3]ARIANET s.r.l. via Gilino, 9, 20128 Milan, Italy

Keywords: boundary conditions, Saharan dust, aerosol concentrations, Italy
Presenting author email: mihaela.mircea@enea.it

This study aims to investigate the possible contribution of mineral dust to air quality predictions over Italy by adding dust concentrations from a dust transport model (SKIRON) into Lateral Boundary Conditions (LBCs) of a regional air quality model (FARM). A dust episode (26^{th}-29^{th} July 2005) has been simulated running FARM on a 20x20 km^2 resolution domain over Italy. Three sensitivity tests have been performed in order to assess the impact of the new LBCs to PM_{10} concentrations modelled by FARM: NDC ("no dust" case), DC ("dust" case) and DC1.3 ("dust multiplied by a factor 1.3" case).

NDC In the "No Dust Case" concentrations from the EMEP model are used as LBCs in FARM. EMEP concentrations do not include the contribution of Saharan dust. EMEP fields have been interpolated from 50 x 50 km^2 to FARM resolution and re-projected onto the four sides of model domain.

DC In the "Dust Case" simulation, hourly SKIRON fields are interpolated to 20 x 20 km^2 and re-projected onto the four sides of the FARM grid. Size-resolved dust concentrations by SKIRON are added to the LBCs used in the previous case (NDC). Dust particles are within four sizes, based on the amount of clay, small silt, large silt and sand particles inside desert soils. The first SKIRON class has been added to the accumulation mode of unspecified anthropogenic mass (c_A25J) and the second class to the soil mass aerosol species (c_ASOIL) in FARM. Contribution from the last two classes was not considered (no addition was performed) as particles of large silt and sand, due to their large dimensions, are rapidly removed from the atmosphere through dry deposition processes.

DC1.3. SKIRON dust concentrations are multiplied by a factor 1.3 (Kallos et al., 2007) in order to reduce the bias of the model (30%). The same procedure used in the DC is then applied and new LBCs are created.

Results have been compared to each other and to PM_{10} ground measurements from the Italian Air Quality Network. The comparison with ground measurements reveals that:

The addition of dust contribution to PM_{10} improves FARM aerosol mass concentration predictions. The underestimation of PM_{10} concentration is reduced from approximately 77% to 59% (table 1).

However, the results suggest that the dust concentrations correction introduced in DC1.3 may be not suitable over Italy: differences in PM_{10} concentrations between DC1.3 and NDC are comparable with the differences in DC-NDC for all days. More experimental and modelling studies are needed for finding a correction factor more suitable for the Italian contest.

.

Table 1. Statistical parameters for the simulations NDC,DC, DC1.3

Statistic	NDC	DC	DC1.3
NMB	-77%	-65%	-59%
FAC2	0.06	0.14	0.28
NMSE	3.00	1.31	1.05

Presenting author email: shubhaverm@gmail.com; shubha@iitkgp.ac.in

Atmospheric aerosols perturb the climate system by scattering and absorbing the solar radiation (direct effect) and by altering the radiative properties and lifetime of clouds (indirect effect). Aerosols due to emissions from anthropogenic sources, including combustion of fossil fuels (coal and oil) for energy and transportation, industrial and agricultural activities, biomass burning, and deforestation are a major concern in this context. Evaluation of emissions over the Indian subcontinent based on emission fluxes aggregated spatially show distinct emission patterns over the different parts of India which could lead to regional variation in the chemical and optical characteristics of aerosols, and consequently could lead to a climate response due to aerosols different on a regional scale than the global. It is therefore, necessary to understand the chemical and optical characteristics of aerosols, their sources, and climate impacts over Indian subcontinent and ocean through integration of measurements and modelling studies.

Observational studies during the Indian Ocean Experiment (INDOEX) [Ramanathan et al., 2001] and more recent field campaigns in the Bay of Bengal and the Arabian Sea have established the widespread occurrence of aerosols and trace gases of anthropogenic origin over ocean regions adjoining India. Chemical characteristic of aerosols measured during INDOEX showed that aerosol mass contained substantial amounts of both inorganic and organic pollutants and revealed the simultaneous presence of different tracer substances characteristic for biomass burning and fossil fuel burning influenced by polluted air masses originating over India or Southeast Asia and Arabia. In order to characterise aerosols present over the Indian main land, land campaigns were carried out under Indian Space Research Organisation Geosphere Biosphere (ISRO-GBP) program. Measurements during the ISRO-GBP land campaign (Jayaraman et al., 2006) and spatio-temporal characteristics of aerosols retrieved from satellite based observations indicated stations over the Indo-Gangetic plain (IGP) to have higher aerosol optical depth (AOD) compared to off-IGP stations over the Indian subcontinent. Measurements of AOD over the oceanic regions of Arabian Sea (AS) and Bay of Bengal (BoB) showed the presence of their higher values over the AS compared to the BoB.

In the present work, we carry out an analysis of aerosol distribution over the Indian subcontinent from aerosol transport simulations in LMDZ-INCA [*Schulz et al.*, 2006] which couples the Laboratoire de Meteorologie Dynamique general circulation model (LMDz) and the Interaction with Chemistry and Aerosols (INCA) model. AOD simulated over the Indian subcontinent and ocean was estimated to be dominated by dust and sulfate during the southwest monsoon compared to sulphate, organic matter, and BC, during the winter monsoon. Model estimated AOD evaluated over the Bay of Bengal (BoB) and the Arabian sea (AS) showed the domination of sulphate and organic matter over the BoB while sulphate and dust over the AS (Figure 1). Evaluation of GCM simulated aerosol optical properties over the Indian subcontinent with the ground-based measurements during the various campaigns and satellite-based observations will be presented. The chemical constituents to the AOD measured and their probable sources will be evaluated.

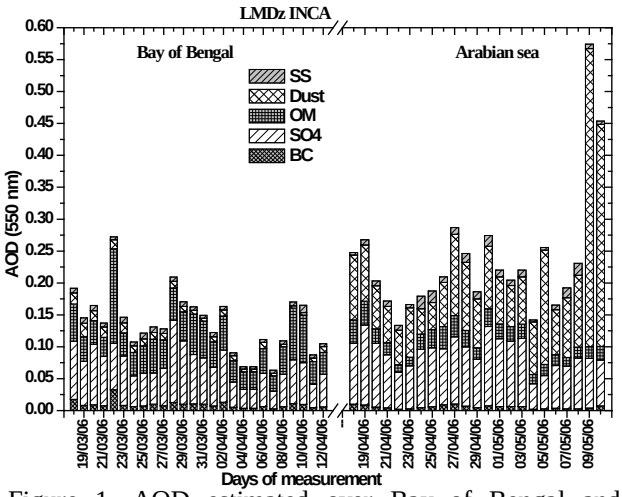

Figure 1. AOD estimated over Bay of Bengal and Arabian sea from LMDz-INCA simulations during the days of ship-cruise measurements

Distribution function for daughter droplets at theoretical law of parent drop motion

A.G. Girin[1]

[1] Odessa National Maritime University, Odessa, 65029, Ukraine
Keywords: dispersion, droplets, size distribution, aerosol modelling.
Presenting author email: club21@ukr.net

It was found (Girin[1], 2011), that mass history of shattering drop depends directly on law of drop displacement in gas stream and is defined by ratio $h = A/3C$ of rate of mass efflux $A = 0.46(1+\alpha^{\xi})^{-1}(\mu^2/\alpha)^{1/6}$ to the rate C of relaxational decreasing of relative velocity of drop and gas. An approximate theory of shattering drop was built (Girin[1], Girin[2], 2011) with use of empirical law of drop motion $X_{\rm d}(\tau)$. In view of lack of empirical data about $X_{\rm d}(\tau)$ for various gas-droplets systems it is important to obtain the main relations of shattering drop kinetics on the reliable ground of theoretical laws. They are found analytically below as solutions of system of non-linear differential equations of drop motion, drop mass efflux and quantity of torn droplets in a speedy uniform gas stream at neglecting by drop deformation influence.

In case $h=1$ the solution has an exponential character, so, ablation law, law of motion and distribution function of daughter droplets quantity by sizes coincide with those obtained on base of empirical law of drop motion (Girin[1], 2011). At $h\neq 1$ integration gives power functions for parent drop velocity and radius: $W = 1-\left(1-C(h-1)\tau\right)^{\frac{1}{h-1}}$, $\tilde{R} = \left(1-C(h-1)\tau\right)^{\frac{h}{h-1}}$. The quantity Δn of droplets of radius $\tilde{r} = r/R_0$, that are contained in elementary fraction $\Delta\tilde{r}$, must be found by integration of equation for $\Delta n(\tilde{r})$ (Girin[2], 2011) between lower and upper limits φ_l, φ_{up} in a strip $\Delta\tilde{r}$, which surrounds the line $\tilde{r}(\varphi,\tau) = const$ (φ is polar angle of any ground on drop surface). The approximation of integration path $\tau = \tau(\varphi)$ and choice of its effective slope $a_{\rm ef}(\tilde{r}, h)$ are similar to those of (Girin[2], 2011) and lead now for natural $\eta = 3h/(h-1)$ to the following expression for distribution function:

$$f_{\rm n}(\tilde{r}) = \frac{\Delta n}{\Delta\tilde{r}} = \frac{3hB_1^3B_2}{A(h-1)\tilde{r}^4}\left(\frac{P_{\eta+1}(\varphi)}{b(\eta+1)} - F_\eta(\varphi)\right)_{\varphi_l}^{\varphi_{up}}, \quad (1)$$

where $P_\eta(\varphi) = (a+b\varphi)^\eta$, $P_\eta^{(k)}$ – its k-th derivative, $a = 1-C(h-1)(\tau_l - \varphi_l/a_{\rm ef})$, $b = C(1-h)/a_{\rm ef}$, $F_\eta(\varphi) = \frac{\sin 2\varphi}{2}\sum_{k=0}^{\mathrm{E}(\eta/2)}(-1)^k\frac{P_\eta^{(2k)}}{2^{2k}} + \frac{\cos 2\varphi}{2}\sum_{k=1}^{\mathrm{E}((\eta+1)/2)}(-1)^{k-1}\frac{P_\eta^{(2k-1)}}{2^{2k-1}}$;

parameters $B_1 = 1.60\alpha^{1-2\xi}\,\mathrm{Re}_{\rm d}^{-0.5}$ and $B_2 = 0.15\mathrm{Re}_{\rm d}^{1.5}\alpha^{7\xi-3.5}(1+\alpha^{\xi})^{-1}$ are the character scales for droplets sizes and quantity (here $\xi = \log_\alpha(\alpha\mu)^{1/3}$ is parameter of mutual viscous engagement of media in boundary layers on drop surface, $\alpha = \rho_{\rm g}/\rho_l$ and $\mu = \mu_{\rm g}/\mu_l$ are their density and viscosity ratios). To natural $\eta > 3$ corresponds series of discreet values of h: $1 < h = \eta/(\eta-3) \le 4$, while to integer $\eta < 0$ – values, which belong to interval $0.25 \le h < 1$ of incomplete shattering. In this case $f_{\rm n}(\tilde{r})$ expresses in $\mathrm{Si}(\varphi)$, $\mathrm{Ci}(\varphi)$. Named set of η values covers compactly enough all the practically important diapason of h values.

Formula (1) permits to calculate intermediate distribution of droplets torn to any time moment $\tau < \tau_{\rm b}$ and to find the approximated expressions for the moment of drop breakup $\tau_{\rm b}$ and for whole quantity of torn droplets N. The distributions were calculated for $h = 1.5; h = 2.0; h = 4.0$ and showed negligibly weak influence on $\Delta n(\tilde{r})$ of two above mentioned methods of determination of parent drop motion law. For example the distributions of all stripped droplets $N = 1.5\cdot 10^7$, which calculated for $h = 1.5$, are presented on figure 1 and show good mutual agreement.

Thus, the two approaches of determination of drop motion law, which are based on theoretical and empirical methods, have lead eventually to similar distribution functions. Presented here theoretical approach has the advantage being independent from lack of empirical data, so formula (1) is applicable to any gas – droplets system.

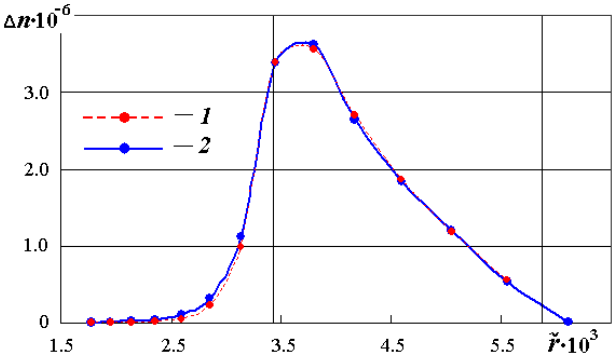

Figure 1. Calculated at $h = 1.5$ dependencies $\Delta n(\tilde{r})$; ***1*** – by formula (1), ***2*** – by formulae of Girin[2] (2011). Vertical lines are the limits of base diapason.

Regional modelling of the tropospheric multiphase system using COSMO-MUSCAT

R. Schrödner[1], A. Tilgner[1] and R. Wolke[1]

[1]Institute of Tropospheric Research, Leipzig, 04318, Germany
Keywords: Aerosol cloud interaction, Multiphase chemistry, Modelling (regional), Cloud microphysics.
Presenting author email: roland.schroedner@tropos.de

Clouds play a major role in the atmosphere due to their influence on the Earth's radiative budget, on the hydrologic cycle and on the tropospheric chemical composition (e.g. Ramanathan et al., 2001). Cloud lifetime is driven by the dynamics of the atmosphere at the synoptic scale and, in close interaction, by microphysical processes (e.g. nucleation of cloud droplets and ice crystals, condensation and evaporation, collision/coalescence processes, freezing, sedimentation of hydrometeor) on the small scale.

These processes depend on the chemical composition of particles and cloud droplets. In addition, microphysical processes redistribute chemicals among the various reservoirs: gaseous, particulate, liquid and ice phases. Clouds favor the development of "multiphase chemistry" since they are an ideal reaction medium for this: (1) clouds support very efficient photochemical processes inside droplets; (2) certain homogeneous chemical reactions within clouds can be usually faster than the equivalent reactions in the gas phase, and reactions such as those involving ionic species, can be important; (3) finally, interactions between the aqueous and solid phase can contribute additionally to chemical processes in clouds (for example dissolution of soluble particulate species). The evaluation of multiphase chemistry versus overall tropospheric chemistry and its role in the Earth's radiative budget is challenging since microphysical and chemical processes occurring at different time scales within clouds are still poorly known.

The model system COSMO-MUSCAT consists of MUSCAT (Wolke et al., 2004a) and the forecast model of the German Weather Service (DWD) COSMO (Schättler et al., 2008). Both models are coupled online. MUSCAT was extended to consider cloud-chemical processes (chemical aqueous phase reactions and phase transfer processes) on the regional scale replacing the former aqueous phase parameterization.

Based on the increasing kinetic and mechanistic knowledge on chemical aqueous phase reactions in the last two decades, advanced aqueous phase chemical mechanisms such as the Chemical Aqueous Phase Radical Mechanism (CAPRAM) are continuously developed (Tilgner and Herrmann, 2010). CAPRAM is an almost explicit mechanism which describes relevant chemical aqueous-phase conversions of both inorganic and organic compounds. A reduced version of the mechanism, applicable for 3D chemistry transport models was created (Deguillaume et al., 2009).

With the advanced model system, 2D-sensitivity-studies have been conducted for an urban and a remote case. The comparison of two different mechanisms (simple inorganic and detailed organic mechanism CAPRAM) have revealed agreements but also interesting differences for important chemical subsystems e.g. in the modeled multiphase HO_x budget and pH whereas the simple mechanism leads to always less acidic cloud droplets than CAPRAM. Invesigation of reaction fluxes show that this is due to additional organic acidification in CAPRAM. The difference in pH leads consequently to different regimes for the S(IV)-oxidation leading to about 5% less S(VI) using CAPRAM instead of a simple mechanism.

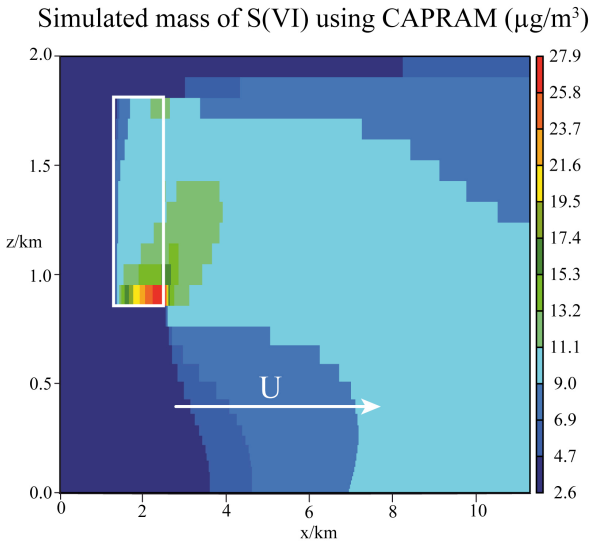

Figure 1. Height profile in x-direction of the simulated mass of S(VI) using CAPRAM in a remote scenario in µg/m³. The cloud is located inside of the white square. Species stream in from the left-hand side.

A modelling approach to study PM2.5 dispersion and transformation in Venice area

E. Pecorari[1], S. Squizzato[1], M. Masiol[1], F. Visin[1], G. Rampazzo[1]

[1]Dipartimento di Scienze Ambientali, Informatica e Statistica, Università Ca' Foscari Venezia, 30123, Venice, Italy

Keywords: aerosol modelling, emissions, PM2.5, dispersion

Presenting author email: squizzato@unive.it

$PM_{2.5}$ formation and dispersion are still a research target that depend on specific meteorological and emission sources of the area studied. The use of mathematical models permits to better understand pollutants spatial and temporal distribution becoming a complementary tools respect to field campaigns. Despite their limitations, in fact, models enable to study the diffusion of air pollution in not-controlled areas where measurements entail high costs and lots of human resources. This approach has been useful in a very peculiar site: Venice lagoon. This is, in fact, a very delicate ecosystem located between the Adriatic Sea and the Po Valley , which is recognized as the most industrialized district of Italy. A multidisciplinary project has been developed with the aim of better understand $PM_{2.5}$ primary sources and secondary formation and compositions.

The model system used, distributed by ARIANET S.p.A., consists of three main components: a diagnostic meteorological model (*MINERVE*) (ARIANET, 2001), a turbulence model (*SURFPRO*) (ARIANET, 2005a) and a photochemical-eulerian dispersion model (*FARM)* (ARIANET, 2005A).

Four periods have been considered during different seasons for which both organic and inorganic measured data were available. Input data has been collected, calculated and formatted as requested by models. Taking advantage of the large number of available measurements, meteorological data from 27 surface stations have been collected. Upper data has been calculated as integration of Rass/Sodar measured data with RAOB soundings from the nearest point available. Emissions used as model input have been referred to EMEP/CORINAIR Emission Inventory Guidebook (EMEP, 2007) groups in Venice area during year 2005. Even though experimental period refers to 2009-2010, 2005 emissions are the only data guaranteed by public administration. A specific work has been conducted to calculate 2009's emissions for principle industrial sources in Venice area that have been considered as point source (*stacks*).

Different approaches has been followed to best evaluate model prediction capacity based on statistical parameter typically used to test model performance and multivariate analysis. Three stations have been controlled during measurements: Punta Sabbioni, Via Lissa and Malcontenta. Data have been compared for the three stations and during different seasons. Model performed well in predicting $PM_{2.5}$ concentrations and its temporal and spatial distributions. An example is reported in figure 1. Further water soluble inorganic ions have been considered to test model capacity in describing $PM_{2.5}$ inorganic composition. Spatial and temporal ions distribution has been investigated respect to the three stations and to the different seasons.

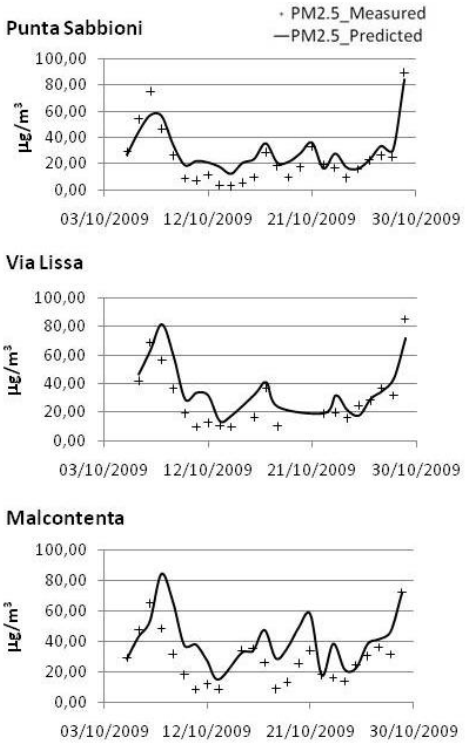

Figure 1. Model $PM_{2.5}$ data comparison for the three stations during autumn period.

Keywords: radioactivity, atmosphere, ionising radiation, monitoring.
Presenting author email: vsyakovleva@tpu.ru

Large-scale research of temporal and spatial dynamics of radon and its aerosol decay products (DP) volumetric activity (VA) in atmosphere surface layer is necessary for investigation of electrical properties of atmosphere and climate global change forecasting. Air radioactive aerosols and gases and their balance regulate the surface layer of atmospheric plasma. Radiation equilibrium factor F determines the balance between radon and its DPs and depends on meteorological conditions. Equilibrium factor F and its changing range are little-studied for atmosphere. The most influencing factors have not determined yet.

The main aim of the work was to investigate the degree of radioactive disequilibrium between radon and its PDs in surface layer and to determine the degree of external factors influence. For this aim the model of radon and its decay products transport in atmosphere was developed. The following processes are considered: molecular D_M and turbulent D_T diffusion transport; transport by vertical wind; removal due to radioactive decay and deposition under gravity force v_F and precipitation v_R. One dimensional transport equations in steady-state conditions are:

$$(D_{M_i} + D_T)\frac{\partial^2 A_i(z)}{\partial z^2} - v_W \frac{\partial}{\partial z} A_i(z) - \lambda_i A_i(z) = 0, \text{ for i=1;}$$

$$(D_{M_i} + D_T)\frac{\partial^2 A_i(z)}{\partial z^2} - (v_W + v_F + v_R)\frac{\partial}{\partial z} A_i(z) + \lambda_i A_{i-1}(z) - \lambda_i A_i(z) = 0,$$

for i=2-5.

The equation system is solved with boundary conditions

$$(D_{M_i} + D_T)\frac{\partial A_i(z)}{\partial z}\bigg|_{z=0} - v_W A_i(z)|_{z=0} = q_i, \text{ for } i=1,$$

$$(D_{M_i} + D_T)\frac{\partial A_i(z)}{\partial z}\bigg|_{z=0} - (v_W + v_F + v_R)A_i(z)|_{z=0} = 0, \text{ for } i=2\text{–}5,$$

$$A_i(z) \to 0, \; z \to \infty.$$

Here $A_i(z)$ is VA of i-radionuclide; index i=1-5 is respectively for ^{222}Rn and DP: ^{218}Po, ^{214}Pb, ^{214}Bi and ^{214}Po; q_i is radon flux density (RFD) from the earth surface. When v_w has negative value, wind blows down to the earth surface, when it is positive – up.

The analysis of numerical simulation of radon and its DP transport in atmosphere revealed that: 1) RFD value determined integral value of radionuclides VA; 2) turbulent diffusion coefficient and vertical wind velocity and direction are the most important factors which influence vertical distribution of Rn and its DP activity in surface layer.

Fig. 1. shows the results of numerical simulation of equilibrium factor dependence on D_T value at different height. It is seen that F depends on D_T weakly. Radioactive equilibrium can be observed at 100 m height.

Fig. 2 represents the results of numerical simulation of equilibrium factor dependence on v_w value. Arrows indicate wind direction. Disequilibrium in radon chain occurs mainly under the wind directed up from the earth surface, and increases when wind becomes stronger. On the contrary, wind blowing down to the earth surface restores the radioactive equilibrium between radionuclides of radon chain (Fig.3).

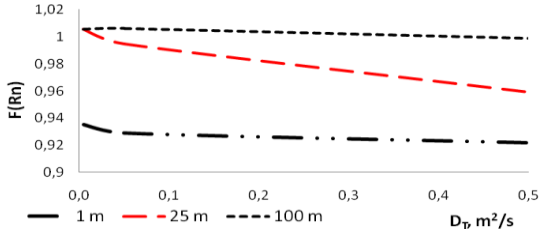

Figure 1. The dependence of F on D_T and height

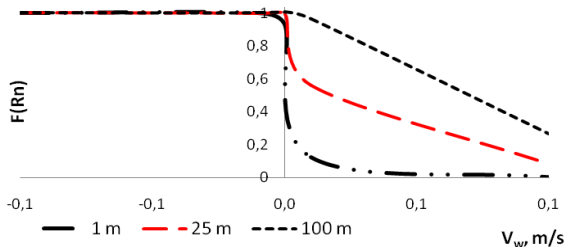

Figure 2. The dependence of F on v_w and height

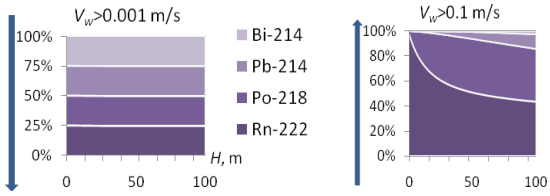

Figure 3. The radionuclide activity proportion at different height H and vertical wind velocity

The comparison of measured and calculated data was performed in the work taking into account real meteorological conditions.

Atmospheric Aerosols - Aerosol Processes and Properties

Passenger exposure to nanoparticles inside a transport microenvironment

Pouyan Joodatnia[1] and Prashant Kumar[1, 2]

[1]Division of Civil, Chemical and Environmental Engineering, Faculty of Engineering and Physical Science (FEPS), University of Surrey, GU2 7XH, United Kingdom
[2]Environmental Flow (EnFlo) Research Centre, FEPS, University of Surrey, GU2 7XH, United Kingdom
Keywords: transport microenvironment, exposure, nanoparticles, particle size distribution
Presenting author email: P.Joodatnia@Surrey.ac.uk

Emissions from conventional fuel driven vehicles contribute considerably to particle number concentrations in the atmospheric urban environment. Their adverse effects on human health and the environment have raised concerns and attracted attention of research community and policy makers. Exposure to freshly emitted nanoparticles during typical road journeys (i.e. walking, travelling in buses, cars or taxis) in urban areas is widespread. Studies have found about an order of magnitude larger concentrations of nanoparticles in transport microenvironments, compared with hourly averaged concentrations in cities (e.g. London), where general public is routinely exposed.

This study aims to assess the short–term particle number concentration and size distribution, both inside and outside a car cabin during the journeys in a typical UK town. The other objective includes the determination of the influences of particle transformation processes on particle number and size distributions.

Number and size distributions of particles in the 5–560 nm range at a sampling frequency of 10 Hz were measured inside the cabin (air conditioning on medium speed) of a moving car using a fast response differential mobility spectrometer (DMS50). Inlet of the sampling tube was placed near the front seat at an approximate height of passenger breathing zone (i.e. 1.5 m above the car floor). For minimising the particle losses in the tube, the shortest possible length (0.50 m) was chosen. The sampling tube was electrically and thermally conductive and has 5 mm internal diameter, giving ~0.3 s residence time at a sampling flow rate of 6.5 lit min^{-1}. Simultaneously, digital images were also collected using a video camera for keeping the log of emission events and correlating the influence of traffic volume on exposure level.

Measurements were separately made both during peak and off–peak hours for mimicking the daily passenger exposure to nanoparticulate pollution under different traffic conditions. The chosen route is 2.7 kilometres long and connects the University of Surrey campus with Guildford town centre. Journey times for both the peak and off–peak hours were estimated as 10±4 and 6±2 minutes, and average vehicle speed as 18±3 and 22±4 km h^{-1}, respectively. For minimising the variability in measured number and size distribution data, a total of 40 trips, equally distributed during peak and off–peak hours, were completed.

During a typical off–peak journey, average particles number concentrations (PNCs) over the entire journey were found to be about $5.1\pm3.7\times10^4$ cm^{-3} compared with $21.8\pm29.9\times10^4$ cm^{-3} during peak time journey (Fig. 1). As expected, one of the common observations during peak and off–peak journeys were the largest PNCs inside our car cabin when a bus, lorry or car were moving (or idling at the traffic light) just before our car. Correlation analysis of video images and measured PNCs during such events, raising the PNCs up to two orders of magnitude (i.e. ~1.33×10^6 cm^{-3}) larger than the background concentrations (~1.30×10^4 cm^{-3}); the latter is assumed as the lowest concentrations during each journey, generally the ones at the starting point when there were no emission sources (see Fig. 1).

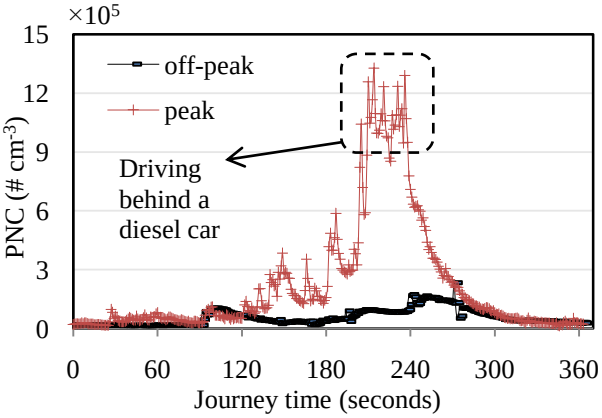

Figure 1: PNCs during peak and off–peak journeys

Initial results demonstrate that the average PNCs (7.98×10^4 cm^{-3}) over all journeys in a typical UK town like Guildford were at the lower end of those reported by Kaur *et al.* (2005) at a heavily trafficked route in London (9.9×10^4) and similar to those found by Knibbs *et al.* (2010) for Sydney (7.5×10^4 cm^{-3}). This could presumably be due to our measurements taken at 10 Hz, compared with 1 Hz or lower sampling frequencies used by other studies, allowing us to capture the events in real–time. Secondly, our measurements covered particle diameters up to 5 nm but the lower cut–off diameters in above studies were limited either to 10 or 30 nm.

Detailed analysis of the data is under progress. For assessing the variation in exposure to all passengers, further experiments are going on involving pseudo–simultaneous measurements both outside and inside the car cabin, and at four different passenger seats.

PK thanks both the EPSRC grants (DTA and EP/H026290/1) for supporting this work. Authors also thank Prof. Alan Robins for his support and discussions.

Atmospheric circulation role on PM fractions

St. Pateraki[1,2], Th. Maggos[1], D. N. Asimakopoulos[2], H. A. Flocas[2] and Ch.Vasilakos[1]

[1]Environmental Research Laboratory/INT-RP, National Centre for Scientific Research "DEMOKRITOS", 15310 Aghia Paraskevi Attikis, P.O.B. 60228 Athens, GREECE
[2]Department of Environmental Physics and Meteorology, Faculty of Physics, University of Athens, University Campus, building PHYS-5, 157 84, Athens, GREECE

Keywords: PM_{10}, $PM_{2.5}$, meteorology, urban pollution.

There are well known issues surrounding particulate matter (PM), especially concerned their relation to cardiorispiratory disease, morbidity and mortality. Although there is still a fundamental lack of understanding the underlying mechanisms of their toxicity, one of the widely accepted hypotheses is that toxicity of particulates depends on their size and composition both of which depend on location, time of year, meteorological conditions and long range-transport effects (Harrison et al., 2000, Akyüz et al., 2009).

A study of twenty one daily PM_{10}, $PM_{2.5}$ concentrations has been carried out in a suburban area of Athens, Aghia Paraskevi during the period 13/12/2004-14/6/2006. $PM_{2.5}$ were collected with the use of a R&P TEOM (model 1400a), PM_{10} with a low volume gravimetric sampler Derenda (LVS3.1/PNS3.1-15) while the 24-h $PM_{2.5-10}$ concentrations were calculated from the abstraction of the daily $PM_{2.5}$ value from the daily PM_{10} value. The sampling station is located easterly of the Athens basin in the National Center of Scientific Research (N.C.S.R.) 'Demokritos'. The site is at the outskirts of a highly populated area, on the foot of Hymettos mountain within a forest of pine trees. O_3, NO and NO_2 data were provided by the Ministry of Environment while the meteorological data (WD, WS, T, RH) were provided by a meteorological mast, operating under the responsibility of NCSR 'Demokritos'.

The understanding of the ambient PM characteristics as a function of atmospheric circulation was the main motivation of the specific work. The $PM_{2.5}$ hourly variation during the different circulation types as well as the particles correlations' with inorganic conventional pollutants (NO, NO_2, O_3, SO_2) would be also investigated.

PM_{10}, $PM_{2.5-10}$ and $PM_{2.5}$ mean values were 31.7 μg/m^3, 16.0 μg/m^3 and 15.7 μg/m^3, respectively. Only the bigger diameter particles found to be statistically significant correlated between each other (R=0.96), while in the 38.1% of the sampling days PM_{10} appeared to be mainly composed by the coarse.

In order to investigate the connection of the surface synoptic scale atmospheric circulation with the PM distribution over the examined area, day by day synoptic conditions were classified over the Greater Athens Area. According to Kassomenos et al., (1998) the atmospheric circulation at the isobaric level of 850 hPa is closely related to the observed surface local flows. Eight synoptic categories (SW, NW, LW, CL, Zonal, OA, CA, HL), which are demonstrated to be statistically distinct are selected with respect to the atmospheric circulation in the lower troposphere.

Table 1 presents the statistical analysis results' for the PM fractions during the different prevailing circulation types as well as the % frequency of appearance for each category. It is worthy to note that CA days were not detected. The peak values for the bigger diameter particles were obtained during the OA days while for the fine ones during the Zonal. PM_{10} and $PM_{2.5-10}$ proved to be always strongly associated (R: 0.61-0.98) between each other, irrespectively of the investigated case. During the CL days, the coarse particles domination was verified ($PM_{2.5}/PM_{10} \leq 0.50$).

Table 1: Statistical analysis for the PM fractions during the different prevailing circulation types

		PM (μg/m^3)			
Type	Frequency (%) of appearance	PM_{10}	$PM_{2.5-10}$	$PM_{2.5}$	$PM_{2.5}/PM_{10}$
SW	14.3	24.9	8.45	16.4	0.66
NW	9.52	29.8	12.5	17.3	0.54
LW	9.52	32.4	16.0	16.3	0.62
CL	14.3	39.4	25.3	14.2	0.58
Zonal	9.52	28.0	9.76	18.2	0.58
OA	19.0	37.7	22.0	15.8	0.44
CA	0.00				
HL	23.8	28.4	14.0	14.4	0.51

Studying the inorganic pollutants their behaviour was differentiated. The maximum NO and NO_2 values were recorded during LW and Zonal days while O_3 concentrations were favoured by OA type. Only the Pearson coefficients between PM10 and NO2 proved to be unsusceptible to the circulation changes being always strong correlated (R: 0.61-0.98).

Dispersion of nanoparticles in vehicle wake – Part II: analysis of wind tunnel work

Matteo Carpentieri[1, 2], Prashant Kumar[1, 2] and Alan Robins[2]

[1]Department of Civil, Chemical and Environmental Engineering, Faculty of Engineering and Physical Sciences (FEPS), University of Surrey, GU2 7XH, United Kingdom
[2]Environmental Flow (EnFlo) Research Centre, FEPS, University of Surrey, GU2 7XH, United Kingdom
Keywords: wind tunnel, flow and dispersion, ultrafine particles, dispersion modelling, vehicle wake.
Presenting author email: m.carpentieri@surrey.ac.uk

Understanding the transformation of nanoparticles emitted from road vehicles is essential for developing appropriate methods for treating fine scale particle dynamics in dispersion models (Kumar *et al.* 2010). Field measurements and modelling studies have highlighted the very short time scales associated with nanoparticle transformations in the first stages after their emission (Carpentieri *et al.* 2011). These transformations strongly interact with the flow and turbulence fields immediately behind the vehicle, hence the need of characterising in detail the mixing processes in the vehicle wake (Kumar *et al*. 2009).

In order to develop parameterised models for the dispersion of nanoparticles, there is first a need to understand sufficiently the dispersion of inert gases. In the present study, a systematic wind tunnel experimental campaign was undertaken in order to support and extend analogous field campaigns aimed at understanding nanoparticle dispersion in the wake of a moving car.

The experiments were carried out in the EnFlo (Environmental Flow Research Centre) wind tunnel at the University of Surrey, where reduced scale models (1:20 and 1:5) of the diesel car used for our field experiments (separate abstract submitted as Part I of this study) were tested (see Fig.1).

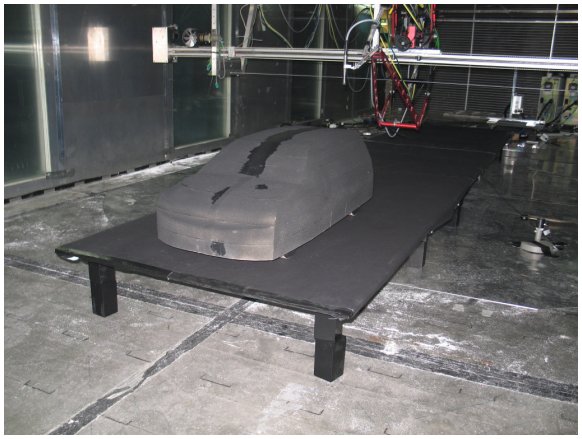

Figure 1. Vehicle model (1:5 scale) in the EnFlo tunnel.

In order to reduce the unrealistic effects of a growing boundary layer at the wind tunnel surface, the models were placed at the leading edge of a false floor (i.e. 23 cm above the tunnel floor). The flow and turbulence fields were characterised both in the near and the far wake of the modelled vehicle by using a 2–component laser Doppler anemometer (LDA). The probe was used in two different positions (measuring velocity components both in the x-y, and x-z planes) in order to have a complete three–dimensional map (e.g. see Fig.2). A more in–depth spatial analysis of the flow and turbulence characteristics in the near wake was then made by using particle image velocimetry techniques.

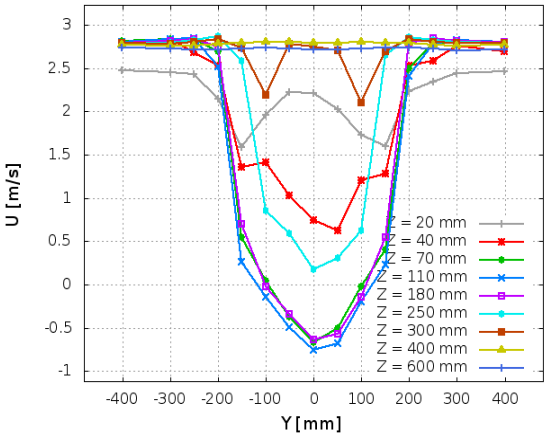

Figure 2. Horizontal LDA profiles of wind speed (U) at different heights, X = 80 mm from the model.

Concentration measurements were obtained by using a fast response (frequency >350 Hz) flame ionisation detector and a hydrocarbon tracer gas released from the modelled tailpipe.

The high resolution experimental database obtained from these experiments, in conjunction with a large nanoparticle concentration data set obtained from field measurements, will be used for deriving mathematical parameterisations for operational nanoparticle dispersion models. Further experiments are planned using a newly built rolling road wind tunnel facility in the EnFlo laboratory that can remove any unrealistic effects of the surface boundary layer and further improve the quality of the experimental database.

PK acknowledges the receipt of the EPSRC grant EP/H026290/1 which is supporting this work. The authors thank Dr. Paul Hayden and Mr. Allan Wells for their support with the wind tunnel work.

Aerosol entrainment footprints over the South East Pacific as observed during VOCALS

G. Allen[1], H.M.A. Ricketts[1], G. Vaughan[1] and H. Coe[1]

[1]Centre for Atmospheric Science, University of Manchester, Oxford Road, Manchester, M13 9PL, UK
Keywords: aerosol cloud interaction, long-range transport, cloud microphysics, boundary layer.
Presenting author email: h.ricketts@manchester.ac.uk

The South East Pacific region is a key area of uncertainty in regional climate models, which inaccurately represent stratocumulus cloud decks beneath the capping inversion of the descending branch of the Walker circulation. The causes for such uncertainty relate to complex local interactions between land, sea and atmosphere in the region as a result of the High Andes, the cold Humboldt ocean current and the Walker Circulation, respectively. Furthermore, a key component of uncertainty in cloud radiative properties relates to the aerosol composition of the marine boundary layer below and the potential entrainment of aerosol into cloud from the free troposphere, which displays a clear concentration gradient with distance offshore from the South American coast.

This study uses a combination of aerosol lidar and in situ optical measurements of aerosol layers in the free troposphere from the BAe-146 and Dornier-228 aircraft recorded during the VAMOS Ocean Cloud Atmosphere Land Study (VOCALS) field campaign, which was conducted near the west coast of Chile in October/November 2008. Using ECMWF reanalysis data, we shall use forward trajectory analysis to study the statistical footprint of entrainment of aerosol layers during the period of VOCALS, which were observed as discrete but concentrated layers of particulate pollution, advected and descending over the SEP from both long-range jet-stream transported organic sources to the west, and more local industrial and geogenic sulphate sources to the free troposphere to the east lofted by Andean upslope pumping of the continental boundary layer. Such entrainment is expected to contribute to significant radiative and life-cycle changes in marine stratocumulus, with higher concentrations of cloud condensation nuclei known to manifest as higher cloud droplet number and weaker precipitation rates.

Exposure level of traffic-related air pollutants near a busy road in Seoul, Korea

S.-B. Lee, D.-H. Lee, S.J. Lee, H.C. Jin, J.H. Choi, S.-H. Park, N.T.Q. Hung, G.-N. Bae

Global Environment Center, Korea Institute of Science and Technology, Seoul, 136-791, Korea
Keywords: vehicles emissions, ultrafine particles, NO_x, traffic.
Presenting author email: sblee2@kist.re.kr

It is important not only to improve the averaged air quality of the mega-cities but also to reduce exposure level of hazardous air pollutants. Air pollution due to vehicle exhaust at urban area in mega-cities like Seoul, Korea is known as local hot-spot pollution phenomena. Urban people who prefer to live at the location closest to major roads to save commuting time are worrying about exposure of traffic-related air pollutants such as ultrafine particles and nitrogen oxides nowadays.

Some previous studies reported the decreasing trends of particle concentrations within a few hundred meters apart from highways or freeways (Hitchins *et al*., 2000; Zhu *et al*., 2002). California State, USA introduced legislation, SB 352 Escutia, to prohibit siting new schools within 500 feet (168 m) of a busy road for protecting the health of students (Green *et al*., 2004).

In this study, roadside measurement was carried out at several locations with different distances from a busy road in Seoul, Korea, using a mobile laboratory to understand the exposure levels of traffic-related air pollutants and to obtain backup data for establishing environmental policy related to vehicles.

Measurements

Figure 1 shows the seven locations from A to G of roadside measurement measured in this study, which are 17, 67, 117, 167, 217, 317, and 417 m, respectively, apart from Dongbu express way (~150,000 vehicles/day), one of the busiest roads in Seoul.

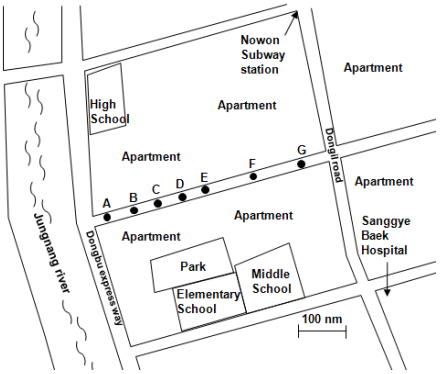

Figure 1. Location of the roadside measurement between Dongbu express way and Dongil road.

The number concentration of particles > 5 nm, size distribution of particles ranging 6-523 nm, black carbon concentration of $PM_{2.5}$, and NO and CO concentrations were measured for about 10 min at each location using condensation particle counter (Grimm 5.404), fast mobility particle sizer (TSI 3091), Aethalometer (Magee Scientific AE-42), NO_x and CO analyzers (Environment S.A AC32M, CO12), respectively, which were installed in the multi-functional mobile laboratory. The inlet height was about 3 m above from the ground. Although wind direction was not fixed, wind mostly flew from the Dongbu express way to measurement site, and average wind speed was 0.7 m/s.

The averaged number concentration of particles > 5 nm and NO concentration measured 17 m apart from the Dongbu express way were approximate 50,000 particles/cm^3 and 120 ppb, respectively, and presented similar decreasing trends with increasing distance from the road as shown in Figure 2. This level of particle number concentration was lower than half of Zhu *et al*. (2002) results near a freeway 405, USA (333,600 vehicles/day). However, the exponential coefficient of the decreasing curve for the concentration of particle number and NO within 117 m with distance from the Dongbu express way was -0.007 and -0.009, respectively, which are similar to -0.01 of the freeway 405, USA.

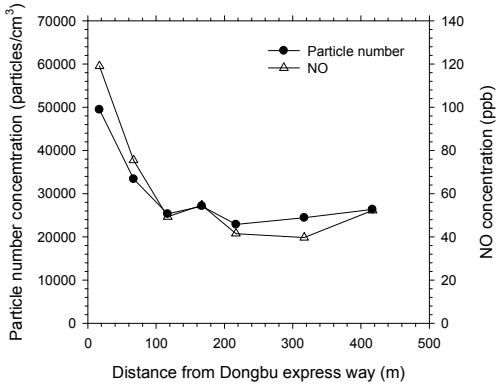

Figure 2. Concentrations of particle number and NO with distance from Dongbu express way.

This study was supported by the CEFV (Center for Environmentally Friendly Vehicle) of Eco-STAR project from MOE (Ministry of Environment, Republic of Korea).

Atmospheric Aerosols – Specific Aerosol Types

Assessing PM_{10} source reduction in urban agglomerations for air quality compliance

V. Aleksandropoulou[1], M. Lazaridis[1] and K. Eleftheriadis[2]

[1]Department of Environmental Engineering, Technical University of Crete, Chania, Polytechneioupolis, 73100, Greece
[2]Institute of Nuclear Technology and Radiation Protection NCSR Demokritos, Ag. Paraskevi, Attiki, 15310, Greece
Keywords: urban aerosols, legislation and policy.
Presenting author email: lazaridi@mred.tuc.gr

The objective of this work was to study PM_{10} concentration data available from monitoring stations in three large urban agglomerations in Greece and to estimate the emissions reduction required for compliance with the EU Air Quality Standards for PM_{10} (annual mean concentration less than 40 μg/m^3; 50μg/m^3 not to be exceeded for more than 35 days per year).. The cities studied are namely the Athens and Thessaloniki Metropolitan Areas (AMA and TMA, respectively) and the Greater Volos Area (GVA). The dataset was retrieved from the EEA public air quality database (AirBase) and was gap-filled with data available on line by the Hellenic Ministry of environment, energy and climate change.

PM_{10} concentrations during the period 2001-2009 have been evaluated for 14 air quality monitoring stations (depicted in Table 1) in the three urban areas. Measurements revealed that the concentrations of PM_{10} during the period studied constantly exceeded the threshold values at GVA and at the traffic and industrial stations in TMA and most of the traffic sites in AMA. Most of the occurrences of non-attainment to AQSs were observed during the winter period at all areas (more pronounced for TMA and GVA).

The reduction R in current emission source strength to meet the air quality goal was calculated by the rollback equation (Seinfeld and Pandis, 1998):

$$R = (E\{c\}-E\{c\}_s)/(E\{c\}-c_b)$$

where $E\{c\}$ is the current annual mean of the pollutant concentration, $E\{c\}_s$ is the annual mean corresponding to the air quality standard c_s, and c_b is the background concentration assumed to be constant. The rollback equation can be applied assuming that changes in emissions levels by a factor of k correspond to the same change in concentration levels. The source distribution remains the same and the pollutant is non- reactive. The methodology was applied to daily averaged concentrations of PM_{10} in each metropolitan area. The data were initially screened as regards the availability (hourly-averaged data >65%). Time periods with data available for consecutive years were chosen. A distribution that best fits the PM_{10} day-averaged concentrations over the selected period was found for each station. We examined the applicability of the most common distributions for PM_{10} concentrations namely the lognormal and Weibull distributions (other distributions were also checked using statistical software). The lognormal distribution was found to best fit the frequency distributions of PM_{10} concentrations at the selected stations. The parameters of the lognormal distribution were calculated using the maximum likelihood-least squares method (Lu, 2002). The predicted concentrations were compared with the observed ones for the whole period and separately for each year. The results showing the geometric measured PM_{10} mean concentrations along with the minimum required emission reduction in order to meet the current AQS are presented in Table 1 for each station.

Table 1. Level of PM_{10} emissions reduction required for compliance with the 24-h average EU AQS at each monitoring station.

Monitoring Station (Type)	Geo. mean concentration (μg/m^3)	Required emission reduction (%)
Athens Metropolitan Area		
Aristotelous (TU)	54.32	40.16
Marousi (TU)	47.59	41.24
Pireaus (TU)	47.28	35.47
Lykovrisi (BS)	56.38	45.82
Thrakomakedones (BS)	29.73	3.75
Zografou (BS)	31.83	4.89

Sindos (IU)	48.68	35.02
Greater Area of Volos		
Volos (TU)	47.94	35.19

* data available for less than 5 consecutive years
B: background, I: industrial, T: traffic, U: urban, S: suburban

The minimum reduction required in order to meet the AQS at the areas of interest ranges from approximately 35 to 46% and from 4% to 15% for traffic and background stations in the AMA (Lykovrisi station was accounted for as traffic station). Reductions in the range of 35% for background and 52% for industrial suburban areas in TMA are also required. Finally, reductions of 35% are required for the GVA.

Prague - the capital city of the Czech Republic with a population of approximately 1.25 million inhabitants is situated in the central part of the Bohemian basin between 200 and 350m above sea level. A large part of the built-up area lies in a valley of the river Vltava and on surrounding flat plains. This geography favours winter and summertime inversions. Traffic is the main source of air pollution. We were interested in the PAH levels in schools, in differences between the localities and in the penetration efficiency of the PAHs from outdoors. The results will be discussed in terms of the pupil's exposure to air pollutants during exercise.

We have monitored twenty-four hour mass concentration of size segregated aerosol simultaneously in three school gyms and in their outdoor vicinity in and around Prague (centre, periphery, suburban). The air was sampled by means of low volume (9l/min.) Personal Cascade Impactor Samplers with 5 stages A to P (A: 2.5-10µm; B: 1.0-2.5µm; C: 0.5-1.0µm; D: 0.25-0.5µm; and F-final or backup filter <0.25µm) and determined by gravimetry. This work deals only with the quasi-ultra fine particulate matter (QUFPM) collected on the 37mm PTFE F-filters (<0.25µm). Twenty campaigns 7-12 days long offered in total 177 days of 24-hour indoor and outdoor sampling. After gravimetry a reflectometer (EEL model 43, Diffusion System Ltd., London, UK) was employed to measure the absorbance of the particulate matter (PM) collected on the filters. Each filter was measured 5 times and the average was used in further calculations. The reflection was reset to 100% before each measurement with a blank filter. The reflectance was transformed into an absorption coefficient using the following equation: a = (0.5*A)*ln(R0/Rf)/V, where a is the absorption coefficient (absorbance), A describes the loaded filter area (in m^2), R0 the reflection of the blank filter (in %), Rf the reflection of the loaded filter (in %) and V the total sampled volume of air (in m^3)(ISO 9835). After reflectance the filters were placed in 2ml crimped vials and extracted with organic solvents (hexane:acetone, 3:1, V:V) in ultrasonic bath. Concentrations of 16 PAHs were identified with gas GC MS.

Figure 1 shows that the three schools studied revealed different levels of particle-associated PAHs. The reasonable association between the variables documented that indoor concentrations were influenced by the outdoor ones which is indicative of high penetration of outdoor particles indoors. The urban and rural (suburban) schools showed an order of magnitude higher PAHs than the periphery situated one. We suggest that while the urban school air was presumably affected by dense traffic, the rural school air was presumably influenced by local heating (coal and wood burning).

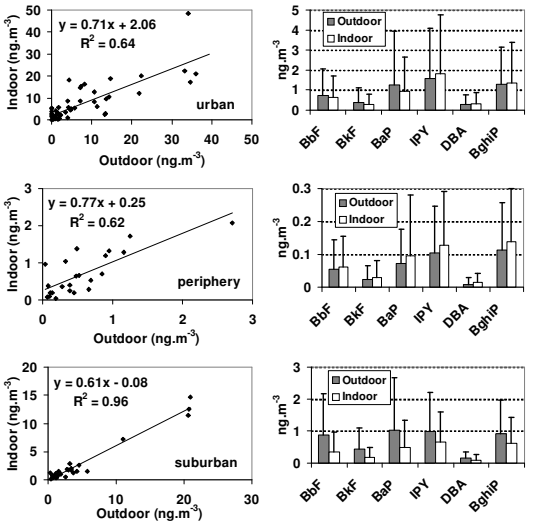

Fig. 1: Left: Association between indoor and outdoor sum of low-volatile PAHs - BBF BKF BAP IPY DBA BGP (winter only); Right: All-season average of six low-volatile PAHs concentrations.

Our results suggest that pupils at schools are exposed to high concentrations of PAHS namely in areas where local transport or local heating significantly contribute to airborne fine PM levels. Further research will be aimed at source identification at the three locations.

The project was supported by the Ministry of Education, Youth and Sports of the Czech Republic under the NPVII research programme, grant No. 2B08077 (Project INAIR).

$PM_{2.5}$ Source Profiles for Resuspended Road Dust in Seoul and Incheon, Korea.

Sehyun Han, Woojoong Kim, Yoonho Seo, Minsang Yoo and Yongwon Jung

Department of Environmental Engineering, Inha University, 253 Yonghyun-Dong, 402-751, Incheon, Korea
Keywords: $PM_{2.5}$, non-exhaust, resuspension, paved road.

.

Presenting author email: jungyw@inha.ac.kr

Non-exhaust particulate matter (PM) is defined as any PM associated with road transport that is not directly emitted in vehicle exhaust. It includes tire wear, brake wear, road surface wear, and resuspension of deposited PM on the road surface. As exhaust emission control has been improved and the resulting reduction in PM emissions has been recently achieved, the relative contribution of non-exhaust PM to total PM emissions in road and the concerns regarding its health risk have increased gradually throughout the world, especially in EU countries (Thorpe and Harrison, 2008; Amato et al., 2010). In Korea, recently there have also been growing concerns about the health impact of resuspended road dust together with PM from vehicle exhaust.

According to a previous study on emission inventory based on CAPSS (Clean Air Policy Support System) developed by the Korean Ministry of Environment, resuspended road dust is likely to be one of the largest PM_{10} emission sources not only in the road transport sector but also in the entire PM_{10} emission inventory for the Seoul metropolitan area including the city of Incheon. There are still ongoing debates, however, about the actual percentage contributions of resuspended road dust to ambient PM_{10} and $PM_{2.5}$ concentrations due to the large uncertainties in the estimation of fugitive dust emissions based on U.S. EPA AP-42, and the possibility of existence of unidentified PM emitting sources.

The primary objective of this study is to obtain source profiles of resuspended road dust by characterizing the $PM_{2.5}$ sampled from the paved roads at carefully chosen sites in Seoul and Incheon, The resulting source profiles of resuspended road dust will be used as a basis for receptor modeling as well as for the estimation of the health impact of resuspended road dust in Korea.

For elemental analysis, Al, Fe, Ca, K, Mg, Ti, Zn, Mn, Ba, Cu, Pb, Cr, Sr, Sb, Na, V, Sn, Co, Cd, P and Ni were analyzed using ICP MS/OES. For EC and OC analysis, Carbon Aerosol Analyzer (Sunset) was used. The more detailed information on sampling and both physical and chemical analysis of road dust will be presented later.

Analysis results as shown in Fig. 1 indicate that the most abundant elements in the sampled road dust are Al, Ca, Fe, and K. This implies these elements have the origin of soil components. The ratio of OC to EC in $PM_{2.5}$ ranged from 2.9 to 11.5. The ratio of Cu to Sb in $PM_{2.5}$ ranged from 4.4 to 12.0, which implies these elements are originated from wear of brake materials.

The $PM_{2.5}$ source profile for the resuspended road dust in Seoul metropolitan area is similar to that of U.S. EPA SPECIATE. Further refinement of sampling methodology and chemical analysis of newly sampled road dust are currently being carried out. These results will also be presented.

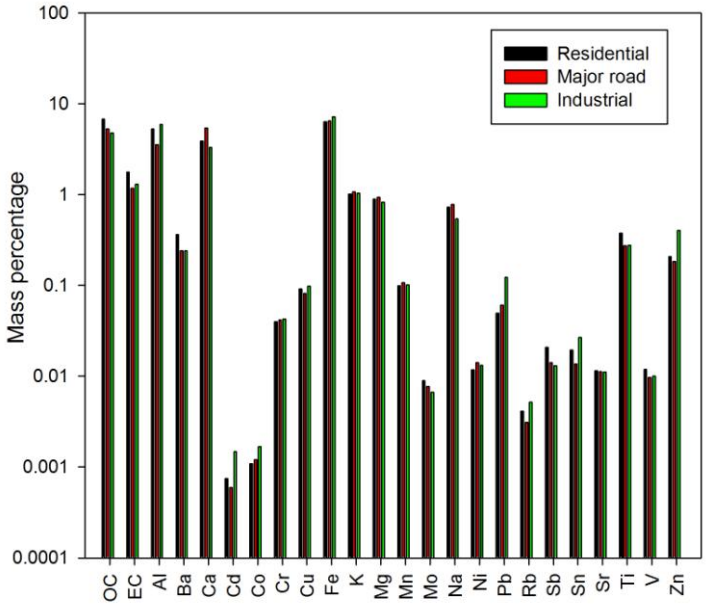

Figure 1. $PM_{2.5}$ Source Profile for Resuspended Road Dust in Seoul Metropolitan Area.

Comparison of organic compounds in atmospheric aerosols in urban areas in the Czech Republic

K. Křůmal, P. Mikuška, M. Vojtěšek and Z. Večeřa

Institute of Analytical Chemistry of the ASCR, v.v.i., Veveří 97, 602 00 Brno, Czech Republic
Keywords: organic compounds, organic tracer, PM1, urban aerosols.
Presenting author email: krumal@iach.cz

Atmospheric particulate matter (PM) is known to play an important role in many environmental problems. During last years much attention has been paid to the identification of emission sources of PM. To track the contributions of the main sources to composition of atmospheric aerosols, various source-specific organic and inorganic tracers are analysed in collected PM.

Atmospheric aerosols in the size fraction PM1 were sampled for a week over 24-h periods using the high-volume sampler (DHA-80, Digitel, 30 m^3/h) on quartz filters during winter and summer period of 2009 and 2010 at two locations, Brno and Šlapanice. Brno is the second largest in the Czech Republic with 370 thousands inhabitants. Šlapanice, small city with 6 thousands inhabitants, is located 3 km southeast from Brno.

Collected aerosols were analysed for organic carbon (OC), monosaccharide anhydrides (MAs), polyaromatic hydrocarbons (PAHs), hopanes/steranes (H/S) and monocarboxylic acids (MCA). Analysis of MAs includes extraction of parts of filters with dichloromethane under ultrasonic agitation, derivatization of extracts with mixture of MSTFA/TMCS, dryness, redissolution in hexane and GC-MS analysis. Analysis of PAHs and H/S includes extraction of parts of filters with mixture of dichlormethane and hexane, fractionation on column with silicagel, dryness to 1 mL and GC-MS analysis. Analysis of MCA includes extraction of parts of filters with methanol under ultrasonic agitation, esterification of extracts with mixture BF_3/methanol, extraction to hexane and GC-MS analysis.

Analysed compounds include:

- MAs: levoglucosan, mannosan and galactosan.
- PAHs: fluorene, phenanthrene, anthracene, fluoranthene, pyrene, retene, benzo[a]anthracene, chrysene, benzo[b+k]fluoranthene, benzo[e]pyrene, benzo[a]pyrene, perylene, indeno[1,2,3-c,d]pyrene, dibenzo[a,h]anthracene and benzo[g,h,i]perylene.
- H/S: 17α(H),21β(H)-hopane, 22*RS*-17α(H),21β (H)-homohopane, 17α(H),21β(H)-norhopane and $\alpha\alpha\alpha$ (20*R*)-cholestane.
- MCA: C7 – C20 saturated monocarboxylic acids and palmitoleic and oleic acid.

Figure 1 compares the concentrations of PM1, OC, MAs, PAHs, H/S and MCA in Brno and Šlapanice in winter of 2009. Detailed results including comparison of analysed organic compounds in winter and summer of 2009 and 2010 will be presented.

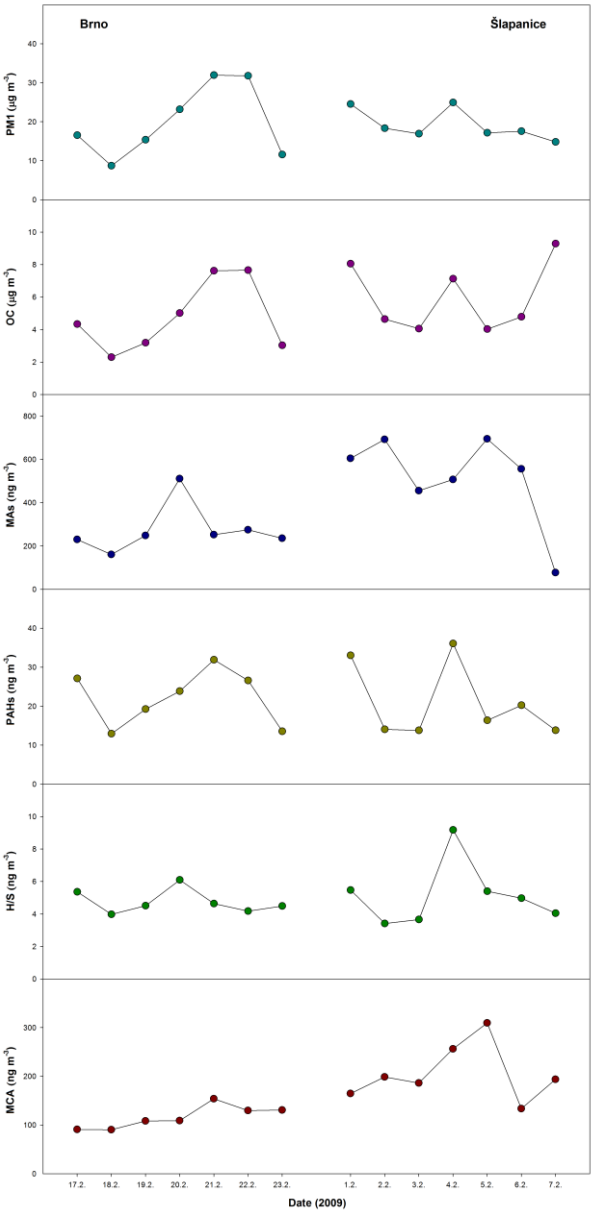

Figure 1. Comparison of PM1, OC, MAs, PAHs, H/S and MCA concentrations in Brno and Šlapanice in winter 2009.

This work was supported by Ministry of the Environment of the Czech Republic under grant No. SP/1a3/148/08, by Ministry of Culture of the Czech Republic under project NAKI DF11P01OVV028 and by Institute of Analytical Chemistry of ASCR under an Institutional research plan No. AV0Z40310501.

Source apportionment and health effects of winter urban atmospheric aerosol

B. Turóczi[1], A. Hoffer[2], Á. Tóth[1], N. Kováts[1], A. Ács[1], A. Gelencsér[1]

[1]Institute of Environmental Sciences, University of Pannonia, Veszprém, Hungary

Keywords: PM10, urban aerosols, source apportionment, health effects of aerosols
Presenting author email: turoczi.beatrix@indamail.hu

In large cities air pollution is a very complex issue, showing strong seasonality and dependence on meteorological factors, sometimes culminating in severe and dangerous smog episodes. In winter important sources of the atmospheric aerosol are biomass and fossil fuels burning which are relevant sources of organic matter and black carbon and increase the mass concentration of the PM10 in the urban atmosphere. The atmospheric particulate matter with aerodynamic diameter less than 10 μm (PM10) is now identified as one of the most dangerous pollutants on human health because this size range overlaps with the range of respirable particles which may cause respiratory symptoms.

Effective air quality regulation and control requires the knowledge of the contribution of potential sources to urban particulate matter. The aerosol source apportionment relies on chemical analyses of the major components and specific tracer compounds, mass balance calculations, and supported with meteorological information.

Urban atmospheric PM10 was collected at the Main Observatory of Budapest-Lőrinc between December 2009 and March 2010 with a MSP personal aerosol sampler for 24h. Simultaneously mass concentration values were determined with a β-gauge PM10 monitor. The mean mass concentration of winter PM10 was 45.2 μg m^{-3} (standard deviation 18.9 μg m^{-3}).

From the collected samples total carbon, levoglucosan and water-soluble inorganic ions concentrations were determined. Contributions of the biomass and fossil fuel combustion were estimated by concentrations of levoglucosan, organic and elemental carbon (Fine *et al*, 2004, Watson *et al*, 2001, Kupiainen *et al*, 2005, Gelencsér *et al*, 2007).

Among inorganic ions the major sources for NH_4^+ is the organic decomposition, for K^+ are soils, biomass burning and anthropogenic sources, for secondary SO_4^{2-} is the oxidation of SO_2 which is produced by fossil fuels burning, and for NO_3^- is the oxidation of NO_x which produced by traffic and combustion processes (Wang *et al*, 2001). The main species forming of water-soluble inorganic ions in PM10 are $(NH_4)_2SO_4$, K_2SO_4, $CaSO_4$, NaCl, NH_4NO_3, $CaCl_2$ and KNO_3 (Verma *et al*, 2010). PAHs were analyzed which are key tracers in different combustion processes.

Ecotoxicity of each winter urban aerosol samples (20.01.2010.-11.02.2010) was directly determined by *Vibrio fischeri* bioluminescence inhibition bioassay in a special instrument developed for the analysis of solid sediment samples (Lappalainen *et al*, 1999). This method is directly linked to microbial respiratory activity, and it gives a good indication on the effects of pollutants on the metabolic activity of the test organism. The results show that emissions from both fossil fuel and biomass combustion contribute to the ecotoxicity of urban PM10. The specific ecotoxicity of the PM10 samples proved to be a sensitive and meaningful parameter that may supplement source apportionment studies and chemical analyses of urban PM10 pollution.

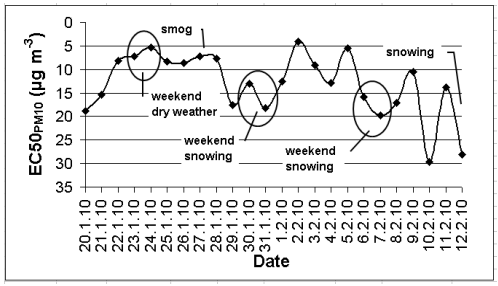

Figure 1. Variations of measured ecotoxicity of urban PM10 and PM10 mass concentrations. Lower $EC50_{PM10}$ values indicate higher ecotoxicological effects. Note that the scaling of the vertical axis is reversed.

Keywords: road dust, resuspension, street washing, road dust chemical profile, source apportionment.

Several studies conducted in urban areas have pointed out that road dust resuspension contributes significantly to PM concentration levels (Thorpe and Harrison, 2008). The main objective of this study was to quantify the contribution of road dust to airborne particulate matter (PM_{10}), evaluate the effects of street washing on the mitigation of resuspension and determine any changes in the road dust chemical profile.

With this purpose an intensive campaign was carried out in a heavily trafficked central road of Madrid (Spain) including PM_{10} monitoring, sampling of road dust and chemical analysis. PM_{10} daily levels during dry, unwashed conditions were 2- 15 % higher than those present during the day after nightly street washing. However, this reduction was lower than the standard deviation of the PM_{10} measurements. The diurnal variation of PM_{10} revealed that a reduction in PM_{10} was noticeable only during the morning hours, Figure 1.

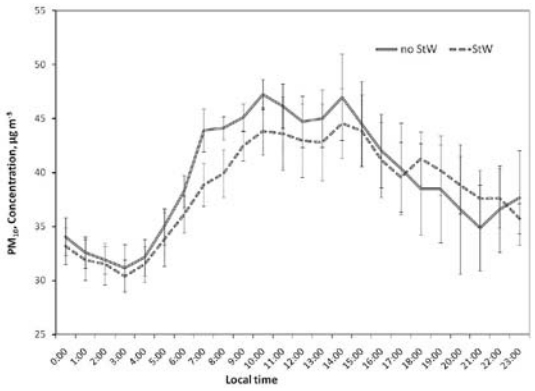

Figure 1. Daily variability of PM_{10} concentrations between street washing (StW) days and no street washing (no StW) days

The emission sources for the urban area of Madrid were resolved by means of a receptor model, Positive Matrix Factorization, PMF. The results showed that the main sources were vehicle emissions, road dust, secondary aerosol including sulfate and nitrate, and soil. Vehicle emissions and road dust were the major contributors to PM_{10} particle mass with similar average contributions of 31% and 29% respectively. The effect of street washing was evaluated by examining the daily variation of the road dust source contribution between days with (StW) and without street washing (noStW) (Karanasiou et al., in press). The mass contribution from the road dust source was ~2 µg m^{-3} lower during the days that street washing was implemented with this corresponding to a reduction of 15% of its mass contribution during the days that the road surface was left untreated, Table 1.

Table 1. PM_{10} source mass contribution, in µg m^{-3} between StW days and no StW days

Average mass contribution, µg m^{-3}	Road dust	Soil	Secondary aerosol	Vehicles emissions
StW	12.4	7.9	6.9	14.6
no StW	14.6	8.9	8.4	13.9

Consequently, the influence of street washing activities in the load of road dust was investigated. The PM_{10} road dust load showed small differences between the treated site where the road surface was washed daily and the untreated site where the road was left untreated. The average concentration in the untreated site was 2.61 mg m^{-2} while in the reference site was 2.32 mg m^{-2}. Furthermore there was not observed an increase of the road dust load from day to day or between morning and evening samplings. The major components in PM_{10} fraction of road dust were Ca (18 ± 8.5%), OC (14 ± 8%), Fe (10 ± 3%), S (7 ± 5%) and Al_2O_3 (7 ± 4.7%). Comparing the chemical composition of road dust in two sites, the concentrations of all major components in the reference site (with daily StW) were lower (about 30%) indicating the positive effect of washing activities.

This project (SERCA) was financed by the Spanish Ministry of the Environment and Rural and Marine Affairs (058/PC08/3-18.1).

Keywords: PM_{10}; Saharan dust events; Volos; Greece.
Presenting author email: giproias@prd.uth.gr

Volos, a coastal medium-sized city in the region of Thessaly extended along the northern part of the Pagassitikos Gulf at the eastern seaboard of Central Greece, is among the cities which suffer from the air pollution in Greece. The case of Volos is an interesting example, where in the last decades the urbanization and the increased industrialization have resulted in the degradation of the air quality within the area, triggering health impacts. Meteorological factors play an important role in the air pollution development, while the complex topography of Volos exacerbates air pollution episodes.

In this study, the relationships between PM_{10} (particulate matter with diameter less than 10 μm) and meteorological parameters such as wind speed, relative humidity and air temperature have been analyzed from 2005 to 2009 on the basis of 24-hour continuous measurements. According to the results obtained from the multiple linear regression analysis, there is a strong relation between meteorological parameters and the particulate matter (Table 1) concentrations in Volos city. More specifically, the PM_{10} concentrations remain above the European Union (EU) limit values (Figure 1) for the whole part of the examined period (2005-2009) and this can be attributed to anthropogenic (industry and car traffic) and natural sources (Saharan episodes) of particulate pollution. The percentage of the total variance of PM_{10} concentrations explained by a single meteorological parameter for the cold period gets up to 10.6% (r^2) whereas, for the 5-year period, up to 6.8%. On the contrary, for the warm period it appears that the percentage of the total variance of PM_{10} concentrations explained by a single meteorological parameter gets up to only 2.5%.

Table 1. Pearson's correlation coefficients between the mean daily PM_{10} concentrations (μg/m^3) and the three meteorological parameters. Statistically significant values (at the 99% confidence level) are presented in bold.

Period	WS (m/s)	T (°C)	RH (%)
2005-2007	**-0.260**	**-0.184**	**-0.213**
Cold	**-0.326**	-0.092	**0.243**
Warm	**-0.159**	0.107	-0.078

Moreover, the calculation of the 72-hour air mass back trajectories during (eight) Saharan dust events, took place within the examined period, was carried out by applying the HYSPLIT 4 model of Air Resources Laboratory of NOAA for three different levels: 500, 1500 and 4000 m (a.m.s.l.). It is worthy to remark the high PM_{10} values observed, indicating the contribution of such natural events in exacerbating the air quality in the area of Volos.

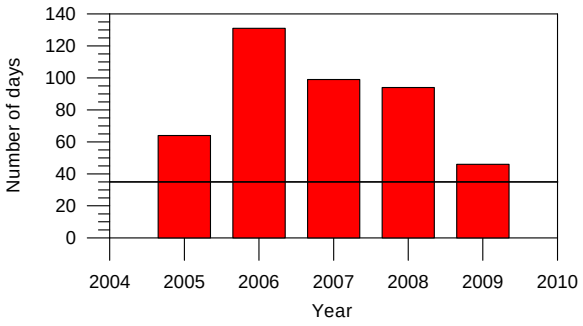

Figure 1. Temporal evolution of annual exceedances of mean daily PM_{10} concentrations at the city of Volos (2005-2009; the horizontal line indicates EU limit).

Mass and number concentration of particulate matter in Lahore, Pakistan.

Ian Colbeck and Zaheer Ahmad Nasir
Department of Biological Sciences, University of Essex, Colchester, CO4 3SQ, U K

Keywords: PM, Number concentration, Lahore , Pakistan

In South Asian countries substantial economic growth and urbanization has lead to a poor air quality in urban centers. Pakistan, with rising types and number of emission sources and minimal air pollution control strategies, is struggling to arrest the excessive levels of air pollution in urban areas. Among a range of pollutants particulate matter is of greatest concern. The increase in the number of vehicles is a key source of particulate matter. The present study was carried out to investigate the levels of mass and number concentration of particulate matter by the roads in Lahore – the second largest city of Pakistan. Scattered studies on mass concentration of particulate matter have been reported from different parts of the country. However no studies on number concentration have been reported so far.

The measurements were carried out during June – August, 2008 over a period of two weeks. The mass concentration of PM_{10}, $PM_{2.5}$ and PM_1 was monitored by GRIMM: analysers (Model 1.108 and Model 1.101). The calibration factor was determined as 0.80. The number concentration was measured with condensation particle counter (TSI 3781). A dilution system was used due to high concentration of particulate matter.

During the week days the mean hourly average concentration of PM_{10}, $PM_{2.5}$, PM_1 and $PM_{10} - PM_{2.5}$ by the main city roads was 305 $\mu g/m^3$, 84 $\mu g/m^3$, 61 $\mu g/m^3$ and 222 $\mu g/m^3$, respectively (Table 1). The coarse size fraction was particularly large and exhibited a wide variation. In contrast, during the weekend, the average concentration of PM_{10}, $PM_{2.5}$, PM_1 and $PM_{10} - PM_{2.5}$ showed a substantial fall. The biggest drop was seen in the coarse size fraction and levels of PM_{10} were 136 $\mu g/m^3$ in comparison to 305 $\mu g/m^3$ during weekdays. The concentration of $PM_{2.5}$ and PM_1 dropped to 60 $\mu g/m^3$ and 40 $\mu g/m^3$, respectively (Table 1).

This suggests that a considerable amount of particulate matter was in the coarse size fraction and resuspension of road dust during the traffic movement was probably the principal contributor in mass concentration. The hourly average concentration of PM_{10}, $PM_{2.5}$, PM_1 and $PM_{10} - PM_{2.5}$ at a background site during the week days was 206 $\mu g/m^3$, 63 $\mu g/m^3$, 31 $\mu g/m^3$, and 143 $\mu g/m^3$, respectively.

Table 1 .Hourly average mass concentration of particulate matter ($\mu g/m^3$) by the road sides during weekdays, weekends and at a background site.

	PM_{10}	$PM_{2.5}$	PM_1	PM_{10} - $PM_{2.5}$
Weekdays				
Ave.	305	84	61	222
Max.	534	107	85	440

Ave.	206	63	31	143
Max.	259	71	32	187
Min.)	160	56	30	105
Std.Dev	42	6	1	36

Ave. (Average), Max. (Maximum), Min. (Minimum), Std Dev. (Standard Deviation).

The mean hourly average number concentration during weekdays, by city roads, was 417,003 #/cm³. On the other hand, adjacent to roads at the University, the mean hourly mean concentration was 97,300 #/cm³ (Table 2).

Table 2. Hourly average number concentration (#/cm³) of particulate matter by the city and university road sides

	city road sides	By University road
Average	417003	97300
Maximum	659068	104859
Minimum	111365	87359
Std Dev	206549	8990

Std Dev. (Standard Deviation).

Overall, the levels of particulate matter were almost double during weekdays than weekends. This suggests a significant contribution from road traffic. A large fraction of particulate matter was in size range $PM_{10} - PM_{2.5}$. The increasing trend in number of vehicles, poor emission controls, ageing fleet of public transport and poor road conditions are the most likely sources of the urban particulate matter. Daily commuters, mostly on two wheelers, and residential population in the city slums are at a greater exposure risk.

Spatio-temporal variations of particulate air pollution in Beijing, China

N.J. Schleicher[1], S. Norra[1,2], Y. Chen[3], F. Chai[3], S. Wang[3]

[1]Institute of Mineralogy and Geochemistry, Karlsruhe Institute of Technology, Karlsruhe, 76131, Germany

Keywords: Urban aerosols, PM2.5, Chemical composition, Anthropogenic aerosols, Megacity
Presenting author email: nina.schleicher@kit.edu

Air quality constitutes a huge challenge for urban areas and Megacities in particular. In China, the urban population is exposed to high levels of particulate air pollution. The individual burden for the inhabitants can vary significantly with regard to seasons and spatial distribution. Therefore, this study focuses on spatio-temporal variations of $PM_{2.5}$ concentrations and composition in Beijing.

Samples were continuously collected on a weekly basis at five sampling sites along a transect from the NW to the SE of Beijing. Additionally, day- and night-time samples were distinguished. Element concentrations of all samples were determined by HR-ICP-MS after acid digestion. Moreover, water-soluble ions and black carbon (BC) were studied.

With regard to spatial patterns, the north-western parts of the city (site 1) were less polluted than regions in the south-eastern (especially site 4) areas (Figure 1).

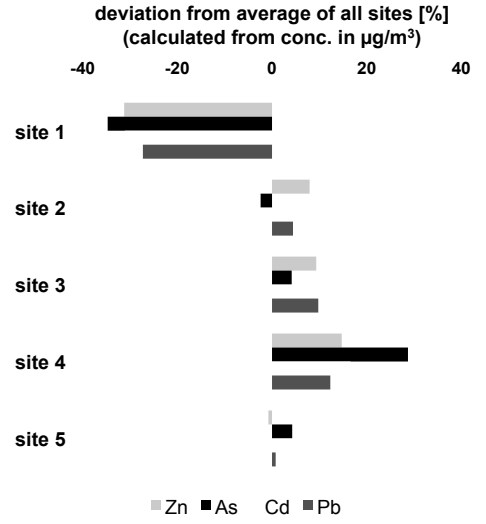

Figure 1. Deviation of anthropogenic element concentrations (in µg/m^3) calculated for each site from the NW to the SE of Beijing from the average of all sites.

It is noteworthy to highlight the observation that the spatial variations are very different if concentrations are expressed in µg/m^3 or in µg/g (Figure 2). In this context the situation at site 3 located just near to the central Tienamen Square should be pointed out. At this site Zn, As, Cd, and Pb concentrations are lower than at site 4 if expressed in µg/m^3, but highest of all sites if expressed in µg/g. Consequently, for the monitoring of toxic element concentrations in urban areas, the values expressed in µg/g would provide further valuable information for the assessment of potential health effects in different parts of the city and should be considered in future.

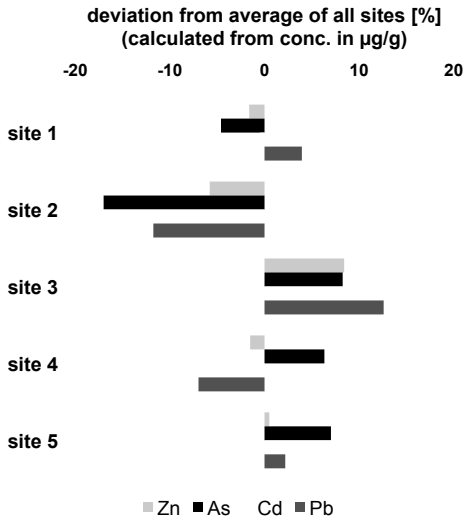

Figure 2. Deviation of anthropogenic element concentrations (in µg/g) calculated for each site from the NW to the SE of Beijing from the average of all sites.

Over the annual course, the different sites had a similar trend. The lowest aerosol concentrations occurred during summer, due to meteorological conditions (e.g. most rainfall occurs during summer months in Beijing) and the lack of certain sources (especially emissions from heating processes). In spring, high aerosol concentrations are predominantly caused by geogenic particles, whereas the concentrations of toxic elements from anthropogenic sources were considerably lower. Conclusively it can be stated that the burden of air pollution for the inhabitants of Beijing are highest during winter due to stagnant meteorological concentrations on the one hand, and additional sources, especially coal combustion for heating purposes, on the other hand. During this time, especially the high concentrations of potentially toxic elements, such as Cd, As, and Pb, are of great concern for human health.

Analysis of a time series of particulate sulfate in a suburban site

M. A. Revuelta, F.J. Gómez-Moreno, L. Núñez and B. Artíñano

Department of Environment, Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas (CIEMAT), Madrid, 28045, Spain
Keywords: sulfate, urban aerosols, sulfur dioxide, PM1.
Presenting author email: maranzazu.revuelta@ciemat.es

The Madrid Metropolitan Area is located in the centre of the Iberian Peninsula. The population is nearly 6 million inhabitants, involving a car fleet of almost 3 million vehicles with very intense traffic on weekdays on the two existing ring roads and the roads connecting Madrid with the surrounding towns. Since industry consists essentially of light factories, the Madrid plume is typically urban.

Semicontinuous PM_1 sulfate concentration is being registered in a suburban site (40º27.5'N, 3º43.5'W) since June 2009. The instrument used is a Thermo 5020 sulfate particulate analyzer (SPA) (Schwab et al, 2006) on a time basis of 20 minutes. It reduces sulfate aerosol by thermal catalysis and analyzes the resulting sulphur dioxide gas by pulsed fluorescence. Laboratory conversion efficiencies are higher for ammonium sulfate than for mineral-type sulfates. The measurements are corrected by comparison against filter-based measurements.

Precursor gaseous species were measured by a DOAS spectrometer (OPSIS AR-500). The jointly analysis of particulate sulfate, gaseous species (SO_2) and meteorology allowed identifying different kinds of sulfate events at the sampling point.

A significant reducing trend in gaseous SO_2, leading to a decrease in sulfate levels has been observed from the 80s at other European sites (Jones and Harrison, 2011). A SO_2 decreasing trend has also been recorded in Madrid from 1998 to 2007 (Ayuntamiento de Madrid, 2008). In the suburban site, a drop in particulate sulfate levels from 2009 to 2010 was observed. This drop was also seen in other parameters registered in the site, such as particulate nitrate and PM_{10}. Meteorological factors might have contributed to the cleansing of the atmosphere, without discarding other explanations.

Figure 1 shows the timely averaged sulfate concentrations differentiating among weekdays (Monday to Friday), Saturdays and Sundays. The daily pattern indicates a clear traffic influence. Sulfate concentration increases sharply at 7:00, peaking between 10:00 and 14:00. A secondary maximum is seen on weekend nights.

The winter synoptic situation leading to the occurrence of episodic events corresponds to stagnant anticyclone conditions, light winds and clear-sky conditions, with the usual formation of radiative nocturnal surface inversions. Under this atmospheric situation sulfate levels can be rising during more than one week. Sulfate events attributed to aqueous phase formation were also detected. However, the highest PM_1 sulfate values (in occasions over 7 ug m^{-3}) were associated to pollutant transport.

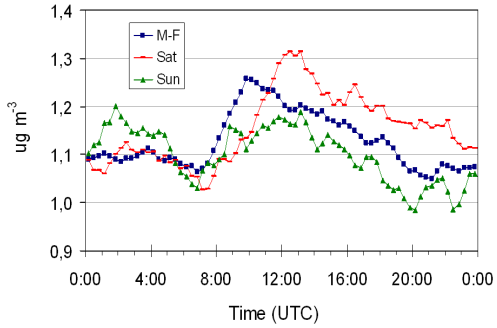

Figure 1. PM_1 sulfate averaged daily patterns for weekdays (blue), Saturdays (red) and Sundays (green) from Jun09 to Dec10

Atmospheric nano-sized particle counting in Tehran air

F. Halek A. Kavousirahim

Department of Energy & Environment, Materials & Energy Research Centre, Tehran, P.O.Box 14155-4777, Iran
Keywords: particulate matter, nanoparticle, particle number, Tehran air pollution.
Presenting author email: f-halek@merc.ac.ir

Nanoparticles, the primary building blocks of many nanomaterials, may become suspended in air as an air pollutant, and they can transport toxic chemicals into the human respiratory system. Although it is unclear whether if mass, number, or even surface area of particles is the most important determinant in causing adverse health affects, toxicological studies have shown that ultrafine particles have a much stronger physiological effect than coarse particles of the same mass. Atmospheric ultrafine and nanoparticles can pose a greater hazard than coarse particles when entering human lungs due to their high number concentration and large specific surface area (Harrison and Yin, 2000; Oberdorster, 2001; Guzman et al, 2006). A group of many scientists in Europe have recently studied the spatial variation of particle number and mass over four European cities (Puustinen et al, 2007), followed by finding the correlation between indoor - outdoor particle number and mass in the cities (Hoek et al, 2008).

The increasing number of motor vehicles and industrial processes involving nanoparticle formation are the main source of nanoparticles emission and their consequences on the environment in large cities such as Tehran (Shi et al, 2001; Halek et al, 2004). In this study, we measured count (number concentrations) of the nanoscale particles found on Tehran's air. None of previous studies reported on particle counting in Tehran's atmosphere (Atash, 2007).

Experimental

The study performed in 5 sampling sites including Azadi Sq. (AS), Jomhouri Sq. (JS), Tohid Sq. (TS), Vali-Asr Junction (VJ) and Jalale-Ale-Ahmad Highway, Sheykh Fazlullah Intersection (JSI). These sites are all located in the west-central parts of Tehran having specific specializations such as heavy traffic, nearing the large residential areas and including main Tehran hospitals. The samples were collected at the height of 1.65 m. Samplings were done in the warm season (July, Aug. & Sep. 2008), followed by the cold season (Jan., Feb. & March 2009). A portable particle size analyzer (Grimm-1.108), was calibrated according to the manufacturer manual and used for the continuous measurement of particles.

Results & Discussion

The average number concentrations of the particles for two different size ranges of > 300 nm and 1.0 - 10 μm at the sampling sites for the two seasons are summarized in Table 1. These data indicated that the average number concentration of particles > 300 nm is 98,970,178 particle/m^3 in warm season and 478,450,460 particle/m^3 in the cold season. Table 2 shows the ISO (International Organization for Standardization) classifications on particle numbers in outdoor air in 3 different sizes.

Table 1. Average number of PM in the sites (Particle/m^3).

	Warm Season		Cold Season	
Site	*> 300 nm*	*1.0-10 μm*	*> 300 nm*	*1.0-10 μm*
AS	104,471,902	2,495,500	739,863,104	5,844,857
JS	128,179,613	2,946,250	458,216,517	5,549,500
TS	92,303,207	2,265,500	518,847,012	7,375,460
VJ	93,484,774	2,298,063	407,209,877	4,780,444
JSI	76,411,392	1,719,963	268,115,799	4,518,243

Table 2. ISO classifications on outdoor particles.

Size	Number of particle/m^3 in outdoor air		
	Dirty	*Normal*	*Clean*
> 100 nm	10,000,000,000	3,000,000,000	500,000,000
> 300 nm	300,000,000	90,000,000	20,000,000
> 500 nm	30,000,000	7,000,000	1,000,000

On the basis of ISO classifications (Table 2) for > 300 nm particles, our results revealed that Tehran's air quality in the case of particle number concentrations is around ''Normal" in warm season, while over than "Dirty" in winter. The data listed in Table 1 indicated that the number concentration of particles with size range of 1.0 μm - 10 μm in the cold season was 2.2 times higher than number concentration of particulate matter in the warm season in Tehran atmosphere. Also, the number concentrations of the smaller particles having the size range of > 300 nm in the cold season were found to be 4.8 times of the warm season.

Our findings indicated that from 5 studied stations, JS has higher concentration and JSI has lower particle concentrations. Heavy traffic and nearing to commercial sectors and large Tehran shopping centers (Bazar) are major reason for higher levels of pollution in JS than other sites.

Studies on ultrafine particles and air quality have mostly focused on vehicle exhaust emissions and on new particle formation in "clean" ambient air. In this study, we apply a fuzzy computer tool, PreFuRGe (Aroba, 2003) to a database of daily average values of PM2.5 chemical composition, black carbon (BC), particle number concentrations (N>2.5 nm) and meteorological parameters, in order to know how ultrafine particles affect ambient air pollution in Huelva (SW Spain), an urban coastal area where significant emissions of gaseous particle precursors take place. These emissions are mostly linked to industrial activities from nearby Industrial Estates: Punta del Sebo, where it should be noted a Cu-smelter plant, given that it is a very significant source of SO_2 and heavy metals as As, Pb and Zn and a phosphoric acid production plants (Fernández-Camacho *et al.*, 2010a); and Nuevo Puerto, whose SO_2, NO_x, NH_3, Ni and V emissions are well documented (Fernández-Camacho *et al.*, 2010a).

N was split into two components N1 and N2 following the methodology of Rodríguez and Cuevas (2007). N1 accounts for vehicle exhaust emissions and may also include compounds nucleating/condensing immediately after emission. N2 is correlated with SO_2 and accounts for new particle formation due to nucleation and rapid particle growth to detectable sizes (Fernández-Camacho *et al.*, 2010b).

The aim of this study is to characterize and interpret qualitatively the association between N1 and N2 with the other variables by using a fuzzy description (Aroba, 2003).

Figure 1 shows six graphical fuzzy rules, where N1 and N2 are the consequents and BC, $SO_4^{2-}{}_{antrop.}$, NO_3^-, NH_4^+, PO_4^{3-}, As, Ni, Cu, Zn, V, Pb, temperature and solar radiation are the antecedents. It is worth noting two behaviour patterns in the concentrations of N1 and N2, corresponding to rules C and D.

Low concentrations of N1 and very high concentrations of N2 (Rule C, Fig. 1) are compatible with medium to high values of SO_4^{2-}, NH_4^+, PO_4^{3-}, As, Ni, V and Pb. Note in this rule that solar radiation is very high and BC is very low.

High concentrations of N1 and medium concentrations of N2 (Rule D, Fig. 1) appear when BC and NO_3^- are very high. Also, we can observe that low to medium values for heavy metals are not compatible with high concentrations of N1.

The results obtained shows how fuzzy logic techniques are very useful for qualitative modelling and identifying the sources contributing to ultrafine particles components N1 and N2 and their relationship with the other variables. The association between N1, BC and NO_3^- (Rule D, Fig. 1) points to vehicle exhaust emissions. The association of N2 with the above heavy metals, SO_4^{2-}, NH_4^+, PO_4^{3-} (Rule C, Fig. 1) is attributed to ultrafine particle formation in industrial plumes. The high solar radiation favours the photochemical processes in those industrial emissions.

Particulate Matter (PM) is an important component of air pollution. A remarkable amount of data concerning air quality is available for the metropolitan area of Mexico City (MC) and its surroundings (Molina et al, 2010). Querol et al (2008) reported 50-56 µg/m3 of PM10 at different urban sites of MC. The contribution of mineral matter to these concentrations was up to 27%. The aim of this study was to characterize mineral dust at an urban background site of MC and to evaluate daily and seasonal variations.

For that purpose PM10 samples were actively collected (4 l/min) on polycarbonate filters on the campus of the Universidad Nacional Autónoma de México (UNAM). Two samples per day were taken from 10am-3pm and 6pm-11pm respectively during two sampling campaigns in July 2008 (rain season: RS) and March 2009 (dry season: DS).

Morphology and chemistry of single particles with sizes 0.4-10 µm were analyzed with computer controlled scanning electron microscopy (CCSEM) and energy dispersive X-ray spectroscopy (EDXS). Each particle was classified based on chemistry into one of the following particle classes: iron and iron oxides (I), aluminium containing silicates (II), aluminium free silicates (III), carbonates (IV) and sulphates/phosphates (V). For each class a mass concentration was determined by multiplying the calculated volume of individual particles with the densities of the class they were assigned to.

Number and mass concentration of most of the samples were dominated by class (II) particles. The most important minerals contributing to this class are clays, which have mainly a geogenic origin. The second important class was class (I) followed by class (IV) and (III) (Fig.1). However it has to be mentioned that only sulphates with Na+ and heavier cations could be detected properly. Samples from the RS show clear differences to the samples from the DS. The median mass and number concentration obtained from samples from July was 2.6 µg/m^3 (maximum: 4.6 µg/m^3) and 281'000 particle/m^3 respectively. Values in February were with 5.8 µg/m^3 (maximum: 14.9 µg/m^3) and 525'000 particles/m^3 twice as high. The higher mass concentration in the dry season is due to an increase of silicates and carbonates. Samples taken during rain periods in the RS have decreased concentrations and become sometimes dominated by class (I) particles. Iron and iron oxides show a constant concentration (~0.55 µg/m^3) in all samples, independently of season and weather condition. A local anthropogenic source is probable for these particles. Also sulphates and phosphates show no clear seasonal differences. However this class is dominated mainly of Ca-carbonates and phosphates in RS and by other sulphates in DS. There are different possible origins for these particles (anthropogenic, biological or volcanic). Daily variations between samples are not evident.

Mineral matter concentrations in MC depend strongly on weather condition and seasonal influences, with a clear increase of silicates and carbonate in DS. The reasons are less vegetation, dry roads and no wash out processes. So more mineral dust gets suspended in the air and can remain longer there. In contrast concentrations of iron/iron oxides, sulphates and phosphates don't show clear weather dependence. A possible explanation is that their sources are aseasonal (e.g. traffic and volcanic activity).

For a better understanding of the influence of mineral matter on MC air quality further samples from a second urban background site and from the high altitude site Altzomoni (Iztaccihuatl volcano, 4000 m.a.s.l.) were taken. Results of these samples will be available soon.

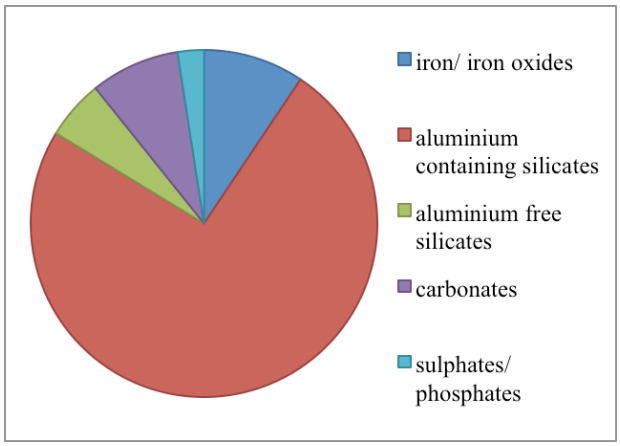

Figure 1: Mineral dust repartition in MC in March 2009.

Introduction

Pollutants associated to atmospheric particles in urban areas have been characterized in many studies throughout the world. Pollutant sources are either natural (e.g. volcanoes, forest fires) or of anthropogenic origin (traffic, industries, central heating). The nature of surfaces and the weather conditions and the atmosphere turbulence influence the aerosol deposition. Previous studies at Nantes (France) on the Pin Sec catchment allowed the chemical characterization of total atmospheric deposition. In order to improve our knowledge of aerosol dry deposition on this catchment an original approach is being developed.

The objective is to present the instruments set up in the district of the Pin Sec to measure dry and wet atmospheric deposits and to show the first results.

Experimental setup

The original approach carried out in this long-term study (18 months) combines particle collectors (Partisol 2000 FRM), a covered pluviometer and frames on which test samples of different urban materials are fixed (tiles, glass, bitumen etc…). A meteorological station and an ultrasonic anemometer supply meteorological and micrometeorological data.

Measuring instruments have been installed on the roof of a 4-store building in the Pin Sec catchment; the data should be representative of the global quality of atmospheric deposition on this catchment. Pollutants studied were heavy metals, pesticides and Polycyclic Aromatic Hydrocarbons.

The analysis of deposited airborne particles on test samples will be done through beryllium 7 (^{7}Be) used as a tracer. Concentration of aerosols is given by Partisol. This analysis will allow calculating a monthly evolution of the dry deposition velocity of particles and determining deposition fluxes.

Finally, in order to validate the use of ^{7}Be as tracer of atmospheric deposition a Low Pressure Impactor (LPI) is used allowing the measurement of aerosol size.

Results

The medium diameter (D50) of ^{7}Be atmospheric on particles varies from 0.50 to 0.59 µm. These values are in good agreement with the literature. It confirm the fixation of ^{7}Be on accumulation mode of atmospheric aerosol.

Figure 1 shows the good correlation between the distribution of Pb mass and ^{7}Be activity. The same pattern is observed for Zn. As a whole, metals are mainly distributed in the fine fraction (0.47<D50<0.62 µm). Therefore, ^{7}Be seems to be representative of the distribution of trace metals.

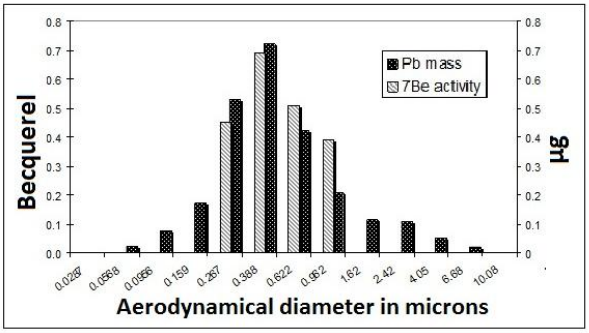

Figure 1: Comparative aerodynamical distribution of Pb mass versus ^{7}Be activity

Conclusions

An original method for the measurement of aerosol deposition has been installed on a small urban catchment. The first results show that ^{7}Be can be used as a tracer of metals. More tests are in progress regarding the correlation of ^{7}Be with polycyclic aromatic hydrocarbons and pesticides. The data on ^{7}Be deposit will allow the calculation of pollutant dry deposition taking into account the nature of urban surfaces and air turbulence.

Statistical distributions of particle number concentrations observed in urban transport microenvironments during commuting

I.D. Longley[1], K.Shrestha[1,2], S.Kingham[2], J.Salmond[3], W.Pattinson[2]

Introduction

People spend a substantial amount of their outdoor time in transport microenvironments which, as well as busy roads, can include the interiors of vehicles, car parks, train stations, subways, bus depots/stops and the road space used by pedestrians and cyclists. Exposure to pollutants in these microenvironments is often highly elevated compared to elsewhere, which results in individuals gaining a significant contribution to their daily exposure to air pollution in general, and ultrafine particles in particular, in a short period of time. Research in London has found *mode* of transport to be a statistically significant determinant of UFP exposure (Kaur and Nieuwenhuijsen, 2009).

Previous observations have revealed that particle number concentrations in such microenvironments are highly variable in time and space. It is not yet clear how much of this variation is random (associated with chance close encounters with individual sources, for instance) and how much is systematic (associated with particular meteorological conditions or characteristic locations, such as intersections, for example).

This paper reports an analysis of a subset of a large observational dataset of personal exposure measurements made whilst commuting by various modes of transport. It aims to describe and summarise the statistical nature of high-resolution particle number concentrations in the different transport microenvironments encountered, as a first step in exploring sources of variability and exposure predictability.

Methods

The full study, its aims, location, dates and study design are detailed in Kingham et al. (2011). In brief, personal measurements of traffic-related air pollutants were made on multiple simultaneous journeys (by different modes) between the same journey origin and destination in Christchurch and Auckland (New Zealand) in 2009.

This paper considers only measurements made in Christchurch (between 26th February 2009 and 26th March 2009) and focuses on particle number concentrations. Sampling was conducted during traffic peak hours on foot, in a car or on buses along three routes in the city encompassing a wide range of traffic volumes. Journeys included time spent at three bus stops, a sheltered car park, and an indoor bus terminus.

Particle number concentration was measured at 1 second resolution using a TSI 3007 portable condensation particle counter sampling via a purpose-made diluter to the design reported by Knibbs et al. (2007). Location was logged at 3 second resolution using a Nokia N82 mobile phone with built-in GPS receiver.

Results

Observed particle number concentrations were sensitive to microenvironment. On average, the lowest concentrations were observed at an outdoor 'waiting' location in downtown Christchurch (~ 20,000 cm^{-3}). Slightly higher mean concentrations were generally observed in the other outdoor microenvironments, including pedestrian walking and outdoor bus stops. However, the data for both of these categories was highly variable by location, with much higher concentrations recorded at a roadside suburban location than at the city centre or less-trafficked suburban locations. Mean concentrations in the car park were ~ 3 times higher than outside. The highest average concentrations were recorded inside both the bus and the car, as well as at the indoor bus stop (mean of 75 – 80,000 cm^{-3}).

The statistical distributions of concentrations for each microenvironment were crudely described by log-normal distributions. Analysis was suggestive of a 'baseline' distribution with a mode in the range 15-30,000 cm^{-3} upon which two additional modes could be superimposed, a higher concentration mode associated with car emissions and a yet higher one associated with bus emissions. Within vehicles these upper modes were dominant and the baseline mode was suppressed leading to higher exposures overall.

Urban aerosol variability from meteoparameters on various time scales

A.A. Jouravlev[1], A.V. Zaripov[1]

[1] Physics Department, Kazan Federal University, Kazan, 420107, Russia
Keywords: aerosol dynamics, air pollution, boundary layer, urban aerosols
Presenting author email: sirarthur@rambler.ru

Aerosol concentration and its spatial distribution are in dependence both from various meteorological parameters, and from other factors, such as concentration of chemical impurity, turbulence, directions of movement of air masses. The purpose of this work is search of similar dependences on various time scales by wavelet analysis.

These researches are based on the data obtained from the continual monitoring of the air condition. The measurements of 5 ecological stations include 11 urban air parameters. They are: air temperature, relative humidity, atmospheric pressure, wind velocity, five gas impurity and aerosol concentration. These stations were situated at city. The researched database contains the data for three years of observation. The measurements are made at 2.4 meters height with one-minute period for meteoparameters and half-an-hour interval for chemical impurities and aerosol mass concentration.

The research method is the following: the wavelet decomposition for each measured parameter was made, the wavelet spectrum was received and then the correlation functions of received coefficients were calculated. The applied method allows to find out interrelations of an aerosol concentration with other meteoparameters and besides to define magnitude of its correlation on each fragment of a wide range of investigated time scales. The advantage of our method in comparison with methods of the direct statistical analysis consists in possibility to establish interrelation between the measured parameters on each part of frequency area of parameters variations.

With use of the described above method the research of values dependences of 5 meteoparameters and concentration 5 impurity gases from concentration of an aerosol has been conducted. Wavelet decomposition and correlation functions of coefficients both for the annual period as a whole, and with selection into seasons (summer and winter) were investigated. The fragment of the received wavelet spectrum for aerosol concentration in a winter season is presented in figure 1.

The closer axis (X) is a time axis and covers a time interval about 4 days. Axis Y represents an axis of time scale of a wavelet spectrum. On axis Z wavelet decomposition coefficients are laid. The elements of two periodic processes – the first one in the bottom part and the second one with lower-frequency in the top are clearly visible on a surface.

Clearly seen periodicity in high-frequency area has the approximate period 48 hours of an order. In a distant part of figure high-period variations was observed and it has the period approximately 3 days.

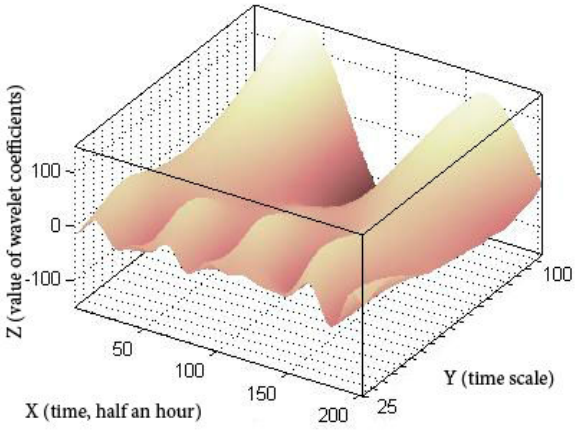

Figure 1. Wavelet spectrum of aerosol concentration for a winter season.

The analysis of wavelet decomposition of impurity concentration and meteoparameters has shown presence of both the already known and obvious periods of variations, and the periods having more difficult nature. For example, authentic variations with the periods of humidity and SO_4 concentration have been revealed for an aerosol.

After correlation analysis being made some received dependences discovered at several stations have appeared to be interesting. With high value of correlation level (above 0.8) there were low-frequency processes with the period approximately 20 days on aerosol spectra, SO_4 and damps which, in our opinion, can't be referred to city or natural cycles.

The received results allow us to make conclusions on deeper correlations between an aerosol, impurity and meteoparameters. This information can help to improve existing models of urban aerosol dynamics.

Continuous Measurements with High Time Resolution of Semi-Volatile Components in the Atmospheric Aerosol

Wolfgang Brunnhuber[1], Hans Grimm[1], T. Külz[1], M. Pesch[1], M. Richter[1] and Friedhelm Schneider[1]

[1]Grimm Aerosol Technik GmbH & Co. KG, 83404 Ainring, Germany
Keywords: Atmospheric Aerosol, Instrument development, PM10, PM2.5, SVC.
Presenting author email: mp@grimm-aerosol.com

EU limit and guideline values for the protection of human health (DIRECTIVE 2008/50/EG) demand a continuous monitoring of the atmospheric aerosol, more precisely its fine dust fraction PM10 and PM2.5. The tresholds are being exceeded in many areas in Europe, primarily in congested urban areas, where many people are affected. Fine dust is rated harmful to health which therefore action needs strongly to be taken, in order to minimize this exposure.

The EU regulates, when exceeding the set limit and guideline values, to develop clean air plans, in which efficient reduction strategies have to be enlisted. These plans are based upon cause analysis, which assigns certain dust exposure to certain sources.

For monitoring the thresholds, many measuring technologies proved well, whereas in the past years especially the optical measuring technology gained in importance. The optical detection of the aerosol enables a non-contact, continuous, and temporally high resolved measurement of the aerosols in real-time, where next to the PM fractions also particle size as well as particle counts can be determined.

A significant part (up to 60% of the particle mass) of the atmospheric aerosol is determined as semi-volatile components (SVC), which varies depending on location and season. This meaningful fraction of the SVC impedes the exact determination of the aerosol mass: The volatile components get lost, when heating the aerosol while sampling, e.g. when using a heated sampling probe for drying the sample, or when dust clogged filters remain several days without cooling inside the sampler.

Thus it is important to determine the volatile fraction of the aerosol for two reasons: On the one hand this fraction is very helpful for the source identification of the dust, because different sources create different SVC fractions, and on the other hand it is very important to measure the SVC for comparing the results of different fine dust measuring devices, which reveal the difference in their losses of SVC while measuring.

Thus the gas-particle-conversion from nitrogen oxides to nitrates and ammonium compounds, or the condensation from gaseous emitted carbon hydrides leads to organic aerosols.

The company Grimm Aerosol Technik GmbH & Co. KG developed a compact, mobile, and highly efficient measuring instrument, which enables the continuous determination of the volatile fraction within the atmospheric aerosol. This device is in possession of two sampling probes with complementary characteristics:

One probe dries the particles by a nafion membrane in such a way, that no volatile aerosols get lost, while in the other probe the aerosol can be heated to a temperature of up to 300 °C. The aerosol is alternating being sucked through the sampling probes and subsequently analyzed inside the same optical chamber. This means, that in one interval all aerosols are analyzed and in the other one only the thermically stabilized aerosols. Forming this difference of both intervals, a determination of the volatile fraction is possible. There the volatile components are classified simultaneously into 31 size channels from 250 nm up to 32 µm, as well as a simultaneous detection of the PM10, PM2.5, and PM1 fractions (figure 1).

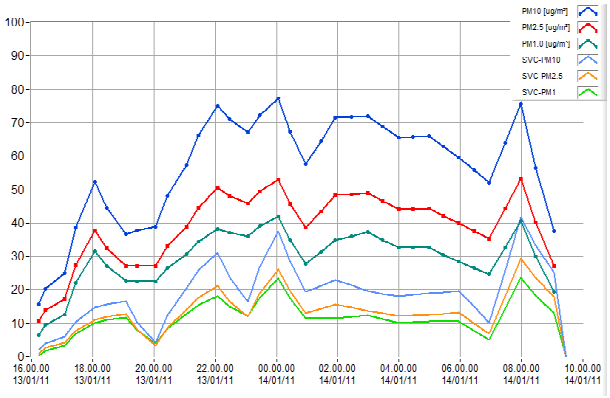

Figure 1: Temporal course of the PM fractions and its volatile components at 100°C

The temporal resolution is 6 seconds. By limiting the size channels, measurements can be executed at 1 Hz, which enables the application of the Eddy-Correlation calculation for determination of aerosol flows.

Measurements at different locations prove the high temporal and spatial variability of the volatile aerosol components, and moreover provide valuable indication for the causes of fine dust exposure as well as a better understanding of the aerosol formation within the lower atmosphere.

Aerosol Modelling

Simulation of Small Ion Aerosol Dynamics

The birth-death equations are well-known differential equations that govern the dynamics of atmospheric aerosols. Solution of these equations (which give the rate of change of the concentration of each cluster type in the vapor with respect to time) enables one to examine steady state concentrations and nucleation rates of a system. Through the use of the Atmospheric Cluster Dynamics Code (ACDC), a collection of Perl and MATLAB scripts, we have solved the differential equations for the sulfuric acid/bisulphate ion/ammonia/dimethylamine system, which is extremely relevant for atmospheric nucleation. One of the most novel aspects of this method is the inclusion of evaporation rates computed directly from quantum chemical calculations. This limits our cluster sizes to those accurately probed with quantum chemistry, but it removes the known inaccuracy of using bulk properties (such as the surface tension) to compute the free energy of very small clusters. This approach also enables us to explore the relative importance of the real physics in the system, examining the effect of various terms such as the coagulation sinks, temperature, ion-neutral collision enhancement factors, monomer source terms, and the method of ion generation on the final cluster concentrations. An analysis of the flux between different cluster sizes and the nucleation path in the system are presented as well, including variations produced by changing the physical parameters of the system. The highly automated nature of the procedure adds flexibility and reliability to the system as well, greatly reducing the possibility of typographical errors while making extension to larger clusters sizes trivial. In the future, the steady-state cluster concentrations obtained from ACDC will be compared to nucleation chamber experiments performed at CERN as part of the CLOUD consortium.

Emulation of a global aerosol model to quantify model sensitivity to uncertain parameters

L. Collins, K. Carslaw, K. Pringle, G. Mann and D. Spracklen
School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, UK.
Keywords: Aerosol model, Sensitivity analysis, Parameter uncertainty, Experimental design.
Presenting author email: l.a.collins@leeds.ac.uk

In this work a global model of aerosol processes (GLOMAP) is used to illustrate how emulation can be used to better understand model behaviour and model diversity via a parameter sensitivity analysis. Parameter uncertainty is a key source of uncertainty in model predictions but the sensitivity to particular poorly constrained parameters is not well quantified. Here a method for quantifying the parameter sensitivities is presented.

The first step to a parameter sensitivity analysis of a complex computer model is the construction of an experimental design giving model developers an opportunity to carefully consider all uncertain model parameters, often the first time since initial model development parameter uncertainties are reconsidered. The experiment is designed to explore model runs throughout the space of the uncertainty in the model parameters. A maximin latin hypercube design is chosen to investigate non-linear model behaviour that is undetected in the usual one-at-a-time model runs used to study uncertain parameter choices. An emulator is then used to carry out a parameter sensitivity analysis by estimating the model output throughout the uncertainty space using information about the model output from the design points. A Gaussian process emulator is used here and the added uncertainty from using emulated output rather than GLOMAP output is quantified. The emulator is tested using verification data from additional GLOMAP runs. The methods are illustrated here by following Spracklen (2005) in which a one-at-a-time sensitivity analysis was carried out. As such the sensitivity of modelled cloud condensation nuclei (CCN) to 5 different model parameters and the driving emissions is explored simultaneously. These 5 parameters are 1) the activation diameter for aqueuos phase oxidation, 2) the accommodation coefficient, 3) the H_2SO_4 nucleation threshold, 4) the nucleation critical cluster size and 5) the activation diameter for nucleation scavenging. The sulphur emissions, sea spray emissions and the anthropogenic particulate emissions are also varied according to their uncertainties.

Since emissions are changed simultaneously with the uncertain parameters the relative importance of each source of uncertainty to uncertainty in CCN estimates is shown. The sensitivity of CCN to each uncertain parameter/emission depends upon the region and altitude; this is shown by comparing parameter sensitivity of CCN in different grid boxes and viewing the vertical distribution of parameter sensitivities. It is shown that in more polluted regions CCN uncertainty is dominated by uncertainty in emissions but in more remote regions CCN uncertainty is dominated by model parameters; model parameters are also more important higher in the atmosphere. The relative importance of each individual parameter will be shown. The importance of sensitivity to the non-linear behaviour of the model is shown; in particular it can be seen that the sensitivity of CCN to uncertainty in the sulphur emissions increases as the activation diameter for aqueous phase oxidation increases. It is clear which processes in the model need to be improved to reduce the uncertainty in model estimates of CCN.

The methods here are applicable across a range of global models to identify the important processes. Comparison of the important processes can be used to better understand model diversity. Model complexity will also be considered given information on parameter sensitivities. After individual models are better understood observation data can be introduced to the study and the sensitive parameters better constrained; this is not part of this initial work but is a wider aim of the project to reduce uncertainty and understand diversity in computer models.

Measured and modelled aerosol radiative forcing over an urban location

Rohit Srivastava and S. Ramachandran

Space and Atmospheric Sciences Division, Physical Research Laboratory, Navranpura, Ahmedabad, India
Keywords: Aerosol radiative forcing, AOD, SSA, Columnar properties.
Presenting author email: rohits@prl.res.in

Introduction: Atmospheric aerosols play an important role in earth – atmosphere radiation balance. They scatter and absorb the incoming solar radiation, and outgoing terrestrial radiation. The role of aerosols in the radiation budget is one of the largest sources of uncertainty in validating the model prediction of climate change (IPCC, 2007).

In majority of investigations, aerosol optical properties are measured and used in the radiative transfer models to estimate aerosol radiative forcing. Assumptions associated with the aerosol optical properties and vertical structure can cause uncertainties in the estimation of aerosol radiative forcing using the radiative transfer models (e.g., IPCC, 2007). However, aerosol radiative forcing estimated from the direct flux measurements which are highly sensitive and accurate can have less uncertainty than that estimated by model.

Measurements: Ahmedabad is an urban densely populated (5.8 million) city in western India having large/small scale industries and variety of vehicles. They contribute several types of aerosols comprises sulfate, black carbon, organic carbon and nitrates. The Arabian Sea and Thar desert and are located in the southwest and northwest of Ahmedabad respectively and serve as the major sources of sea salt and mineral dust during monsoon (June - September) and pre-monsoon (March-May) respectively.

Aerosol radiative forcing for different seasons of 2008 are estimated from the simultaneously measured downwelling global fluxes and aerosol optical depths. Downwelling global fluxes were measured using a set of Pyranometers (wavelength range 0.31 to 2.8 μm) and AODs were measured using a Microtops II sunphotometer in the wavelength range of 0.38 to 0.87 μm. Single scattering albedo (SSA) is obtained from aethalometer and nephelometer measured absorption and scattering coefficients and from remote sensing Ozone Monitoring Instrument (OMI). Forcing calculated from the measured fluxes are compared with model estimated aerosol radiative forcing.

Results and Discussion: The observed surface forcing shows large differences when compared to the model estimated forcing when SSA derived from aethalometer and nephelometer are used (Figure 1). It should be noted that these differences are larger than the uncertainties as well as seasonal variations in aerosol radiative forcing. However, when OMI derived SSA is used in model, radiative forcing is in accordance with the observations during winter (December-January-February), pre-monsoon and post-monsoon (October-November), while it shows large deviation during monsoon season. During monsoon model estimated forcing for aethalometer and nephelometer derived SSA deviates less (15% of observed forcing) from observation while forcing in cases of OMI SSA is about a factor of two higher (less negative) than the observed (Figure 1).

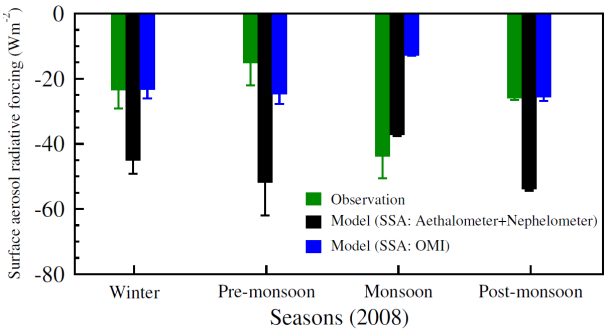

Figure 1. Seasonal aerosol radiative forcing at surface from observation and model in which Aethalometer and Nephelometer, and OMI (Aura) single scattering albedo are used. Vertical bars represent ± 1σ deviation from the mean.

During monsoon forcing estimated using the near surface SSA is closer to the observed forcing, while during other seasons forcing estimated with OMI SSA agree well (Figure 1). The OMI derived SSA during monsoon are even higher than the in situ measurements. OMI derived SSA during monsoon is ≥ 0.99 which could occur due to the assumption that all the aerosols present in the atmosphere are scatterers. Such a high SSA obtained from OMI can lead to lower forcing than that estimated using measured flux.

The details will be presented and discussed.

Columnar ozone from OMI are downloaded from GES-DISC, NASA. Thanks are due to T. A. Rajesh for the prompt maintenance of the instruments.

The alteration of the Earth's radiative balance by atmospheric aerosol is a major uncertainty in assessments and predictions of climate change on both global and regional scales (Forster *et al.*, 2007). Black carbon aerosol (BC), a by-product of incomplete combustion of fossil fuels, biofuel and biomass, is a strong absorber of solar radiation and is considered to make important contributions to the radiative forcing of the atmosphere. The radiative impact of BC is governed by the physical and chemical properties of the particles and their abundance in the atmosphere. The mixing state of BC (the degree to which hydrophobic BC particles are coated with other aerosol components) in particular governs its hygroscopicity, thereby influencing the ability of BC particles to act as cloud condensation nuclei (CCN) and the lifetime of BC in the atmosphere. It is essential to accurately represent these quantities in aerosol models to quantify the impact of BC on climate.

Here, we evaluate the GLObal Model of Aerosol Processes (GLOMAP; Spracklen *et al.*, 2005) against aircraft observations of sub-micron BC aerosol concentrations and physical properties over Europe during the EUCAARI-LONGREX field campaign in May 2008 (McMeeking *et al.*, 2010). Measurements of the mass and number size distribution of BC (in the diameter size range ~60–1000 nm) and some information on the mixing state of BC-containing particles were obtained using a single particle soot photometer (SP2) onboard the FAAM BAe-146 research aircraft.

The GLOMAP model simulates the evolution of size and composition resolved aerosols, including their interaction with trace gases and clouds. The aerosol size distribution is described using a two-moment sectional bin scheme with 20 bins spanning 3nm to 25μm. In the model we include emissions of BC and primary organic matter from anthropogenic sources (fossil fuel (FF) and biofuel (BF) burning), following Bond et al. (2004); and biomass burning following van der Werf et al. (2003). BC is emitted in the model assuming a lognormal mass size distribution with prescribed mass median diameters (D) and geometric standard deviation (σ). To address uncertainties associated with BC emissions (mainly associated to the size at which BC should be emitted in large-scale models); we test two different BC emission schemes (keeping the mass fixed). The first scheme (Dentener *et al.*, 2006; AEROCOM prescribed), assumes small emission sizes for FF and BF: D_{BF}=80 nm and D_{FF}=30 nm (σ=1.8 nm). The second scheme (AEROCOM modified by Stier *et al.* (2005)), emission sizes are a factor of ~2 larger: D_{BF}=150 nm and D_{FF}=60 nm (σ=1.59 nm). The choice of the emission scheme is a crucial point because many aerosol processes are size-dependent. We also implement a new carbonaceous aerosol emission inventory for Europe from EUCAARI (Denier van der Gon et al., 2010); based on emitted particle number concentrations and size rather than mass.

Comparisons between modelled and measured BC mass and number size distribution in the diameter (D_p) size range ~60–400 nm, show reasonably good agreement with both emission schemes, particularly at sizes larger than 100 nm. We find that, although the different emission schemes in the model predict fairly similar BC number and mass concentrations for D_p>100 nm; the transport, ageing and removal of BC are highly influenced by the prescribed emission sizes. Differences between the two emission schemes are more marked in regions far from the sources. This can play an important role for the transport of BC over the Arctic. Differences in BC mass concentrations between the two schemes can be explained in terms of ageing and then removal. For this reason, the BC particles which can act as CCN could be also affected. These results will be presented in more detail along with results from model experiments with the carbonaceous particle number emission inventory included.

Implementation of coagulation into a Lagrangian deposition model

R. Winkler-Heil and W. Hofmann

Department of Materials Research and Physics, University of Salzburg, 5020 Salzburg, Austria
Keywords: stochastic model, particle deposition, coagulation, hygroscopic growth,
Presenting author email: Renate.Winkler-Heil@sbg.ac.at

The stochastic, asymmetric deposition model IDEAL (Koblinger and Hofmann, 1990) allows the calculation of deposition fractions for defined particle diameters and breathing conditions. The smallest geometric airway unit for which deposition fractions are calculated are Y-shaped bifurcations, consisting of half of the parent plus half of the successive daughter airway.

In case of inhalation of aerosols with high particle concentrations, coagulation changes initial particle sizes and concentrations. To implement coagulation processes into the IDEAL deposition model, it was necessary to modify the currently existing code: (1) calculation of deposition probabilities for segments of a bifurcation, including size changes due to hygroscopic growth, and (2) calculation of concentration changes caused by deposition as well as by the coagulation process itself in each segment. These two processes are treated independently in a consecutive fashion.

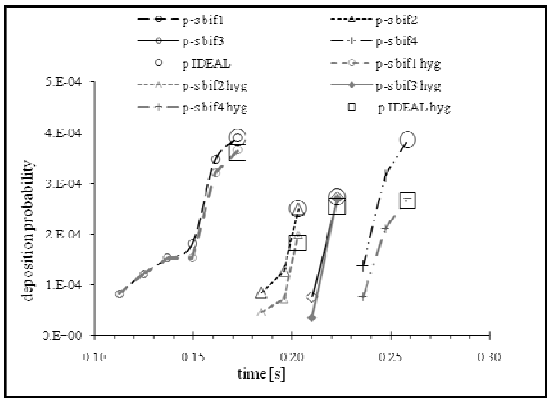

Figure 1. Segmental deposition probabilities (p-s) for bifurcation 1 to 4 for particles with a geometric diameter of 0.206 µm and a density of 2.165 g cm^{-3} and a flow rate of 500 cm^3 s^{-1}. Hygroscopic growth factors (hyg) are based on the work of Ferron et al. (1988). (p = deposition probabilities for each total bifurcation calculated with the original IDEAL code).

For segmental deposition calculations, the bifurcations were divided into a number of time intervals. The length of a given individual time interval is determined by a maximum change of the concentration by 1% in all diameter intervals (Table 1). The deposition probabilities were then calculated segment by segment until the whole bifurcation has been passed. In Figure 1, the obtained cumulative deposition probabilities for the first four bifurcations of one arbitrarily chosen path of the bronchial tree are compared with the deposition probabilities for that bifurcation obtained by the original IDEAL code for (1) assuming no particle growth, and (2) for a hygroscopic particle.

Table 1. Length of time intervals for the first four bifurcations (bif11 denotes the parent and bif21 the daughter airway of bifurcation 1, and so on) for the calculation of the segmental deposition fractions (flow rate = 500 cm^3 s^{-1}).

bif	length of interval [s]	total time t in half bif [s]	number of intervals
bif 11	0.0124	0.0494	
bif 12	0.0116	0.0233	6
bif 21	0.0116	0.0233

Particle mass flux deposition in ventilation ducts of food factories

Mourad BEN OTHMANE[1], Michel HAVET[1], Evelyne GEHIN[2],Camille SOLLIEC[3], Gorges ARROYO[4]

Keywords: deposition velocity, air quality, modeling, ventilation
mourad.ben-othmane@oniris-nantes.fr

The French project CleanAirNet concerns the hygienic design of ventilation ducts in food factories. In the frame of this project, we predict the particle deposition velocity in ventilation ducts of three different food factories. At these locations, during several days, aerosol particle number and mass size distribution were measured using optical particle counter and cascade impactor, respectively. The concentration of particulate matter of aerodynamic diameters in the size range 0.3-20 µm varied from 0.2 to 1.7 µg/ m^3. The measured mass concentration and the predicted particle deposition velocity were used to calculate the deposited particle mass flux (DMF) in the ventilation ducts of each site.

For fully developed flow, Ben Othmane et al (2010) proposed their Eulerian particle deposition model by considering five particle transport mechanisms: Brownian diffusion, turbulent diffusion, turbophoresis, thermophoresis and gravitational settling

$$v_d^+ = \left(\frac{D_B + \nu_t}{\nu} \right) \frac{dC^+}{dy^+} - \left(v_{th}^+ - i v_g^+ + v_{tp}^+ \right) C^+$$

where v_d^+ is the dimensionless deposition velocity. v_{th}^+, v_g^+ and v_{tp}^+ are the dimensionless deposition velocities of thermophoresis, sedimentation and turbophoresis, respectively. D_B is the Brownian diffusivity, ν is the fluid kinematic viscosity ν_t is the turbulent diffusivity, y^+ is the dimensionless normal distance from the wall, C^+ is the time-averaged particle concentration, and i is used to characterize the orientation of the surface.

The results indicate that the DMF at the floor is about 2-20 times larger than that at vertical walls (Table 1). Thus, the deposited particle mass on the floor is sufficient to check if a ventilation duct should be cleaned (Figure 1). According to the chosen cleaning initiation criteria for ducts (400 mg/m², ASPEC, 2004), ventilation systems would take approximately 1 to 9 years to meet the cleaning time.

Table 1. The predicted results of total deposited particle mass in supply ducts

Total deposited particle mass flux (mg/m^2 .year)			
Orientation	Site A11	Site C11	Site U12
Vertical	9.5±3	53±5	3±1
Horizontal	141±10	340±15	45±7

So, cleaning procedures and maintenance intervals are strongly influenced by several parameters, such as flow conditions, particle concentration, characteristics of the ventilation duct and the filter efficiency. The modelling approach combined with mass concentration measurements permits to analyse and quantify the influence of these parameters. Findings of this work may help to identify the specific parameters for cleaning procedures.

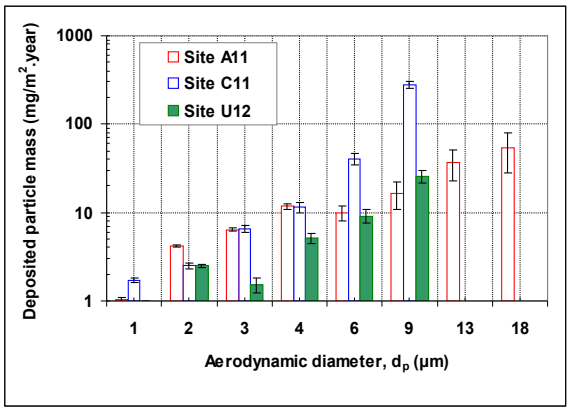

Figure 1: Comparison of deposited particle mass flux at horizontal surfaces in ventilation air supply ducts for the three industrial sites.

To improve the models, knowledge on roughness structure, temperature gradient, flow characteristics need to be further investigated. That will be performed in laboratory at real scale with HVAC materials. Findings of this work may help to identify the specific parameters for cleaning procedures.

Assessing Long-term Oil Mist Exposures to Workers in a Fastener Manufacturing Industry by Using the Bayesian Decision Analysis Technique

H.I. Hsu[1], P.J. Tsai[1,2] and J.C. Soo[1]

[1]Department of Environmental and Occupational Health, National Cheng Kung University, Tainan, 70428, Taiwan
[2] Sustainable Environment Research Center, National Cheng Kung University, Tainan, 70101, Taiwan
Keywords: Oil mist, Fastener manufacturing industry, Bayesian decision analysis, exposure assessment.
Presenting author email: scenicii@gmail.com

This study was set out to assess long-term average oil mist exposure to workers in a fastener manufacturing industry by using Bayesian decision analysis technique. In the present study, inhalable oil mist concentrations (C_{inh}) were measured from 12 fastener manufacturing workers on different working days with different production rates of fasteners. In addition, particle size segregating samplings were simultaneously conducted to 3 workers and the resultant mean size distributions of oil mists, together with the measured inhalable oil mist concentrations, were used to further estimate exposure concentrations of respirable oil mists of workers (C_{res}) (Table 1). The relationship between the estimated oil mist concentrations and their corresponding production rates of fasteners was used to estimate the long term exposure profile of workers in both C_{inh} and C_{res}.

In this study, the measured C_{inh} and the estimated C_{res} were served as the likelihoods for conducting Bayesian decision analysis. On the other hand, the corresponding estimated long term exposure profiles in both C_{inh} and C_{res} were served as the priors. The Bayesian decision analysis results show that only ~21% C_{inh} exceeded the permissible exposure limit value (PEL-TWA= 5mg/m^3) promulgated by OSHA and Taiwan government, but ~77.6% C_{inh} were above the action level (i.e., 2.5mg/m^3) (Fig. 1). On the other hand, almost 100% C_{res} were above the level known for increased risk associated with the pulmonary injury (0.2mg/m^3).

Our results indicate that long-term oil mist exposures to fastener manufacturing workers were quite severe, in particular for those exposures associated with the fine oil mist fractions. Therefore, it is suggested that management measures should be taken, including both conducting periodical worker's exposure monitoring and medical examination. In addition, the installation of local ventilation systems and the use of personal protection equipments are also advised for protecting workers from excessive oil mist exposures.

Table 1. Mean inhalable (C_{inh}) and respirable(C_{res}) concentrations and their 95% confidence intervals for fastener manufacturing workers (n=12)

Types of exposure	Exposure concentrations (mg/m^3)
C_{inh}	2.11(1.89-2.40)
C_{res}	1.40(1.25-1.59)

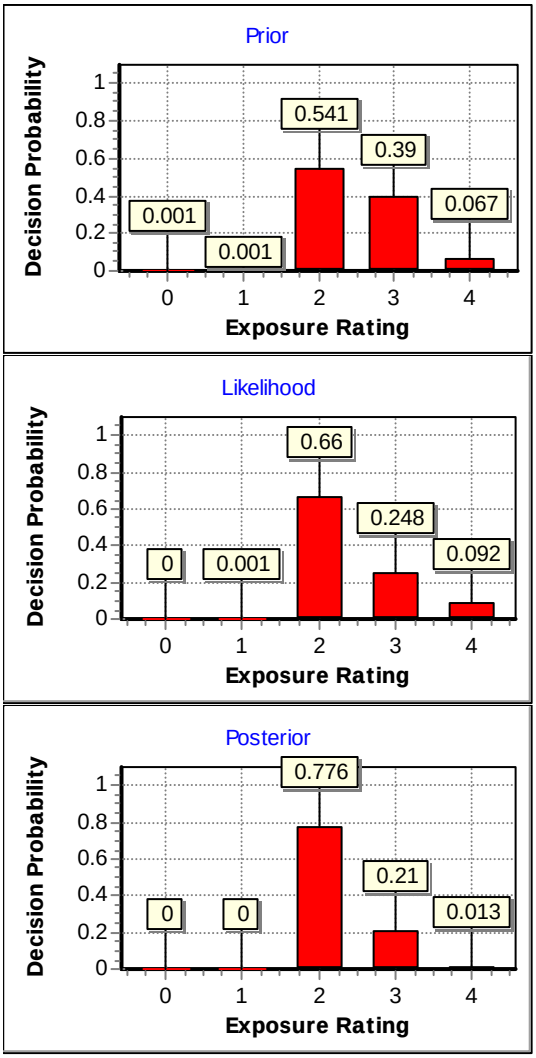

Figure 1. Exposure ratings (0, 1, 2, 3, and 4 represent the exposure levels of 0.1, 0.2, 0.5, 1.0, and 10.0 PEL-TWA, respectively) associated with long term C_{inh} by using the Bayesian decision analysis technique

Secondary atmospheric aerosol number formation has been studied intensively since it became apparent that it is a significant process adding to the tropospheric aerosol loading (e.g. Kulmala et al. 2004). Recent studies have made use of estimations of the logarithm of the nanoparticle formation rate as a function of the logarithm of vapour concentration to gain insight into the formation mechanism; however, there are suggestions that such analysis is inaccurate and the effect of this on the power-law fits is unknown (Vuollekoski *et al.*, 2010).

We use a model that simulates the early stages of growing atmospheric nanoparticles on a resolution of a single molecule, similarly to the model described in Lehtinen and Kulmala, (2003). In practise, the model is given a formation rate and size of a stable condensation nuclei (CN); these nuclei then grow by colliding with either vapour monomers or other CN. This results in a size distribution of small CN. In our model simulations, the vapour properties are assumed to be those of sulphuric acid, and we also assume that the CN equilibriate with respect to available water vapour immediately. The coagulation coefficient for CN collisions and CN-monomer -collisions are calculated using the Fuchs coagulation kernel for the wet aerosol sizes assuming spherical particles. No evaporation or break-up of CN is assumed. Losses to particles larger than the model upper size (ca. 5-20 nm depening on the application and available computation resources) are parameterized by the condensation sink and the coagulation sink parameterization for it (Lehtinen *et al.*, 2007).

There are several phenomena affecting the detection of atmospheric particle formation rates. One of them is the loss of fresh particles due to coagulation to background, and also apparent losses due to change in the size distribution shape. This has been extensively studied theoretically (Lehtinen *et al.*, 2007, Anttila *et al.*, 2010).

Another process affecting the determination of the apparent particle formation rate is the intermodal coagulation affecting the shape of the just-formed particle mode. Our model simulations show that the new particle population shape quickly changes shape, starting to resemble a log-normal size distribution due to collisions between young clusters. This, in turn, affects the time derivative of CN measured at larger sizes than the nucleation size, as the edge of the fresh mode passes the detection threshold of the measuring instrument.

We discuss the effect of these processes as well as the effect of different temporal behaviour of the temporal profile of the condensing vapour production rate.

Air Quality Modelling with CAMx: a case study of PM distribution in Tuscany (Italy)

S.Verrilli[1], G. Curci[2], M.Mazzini[1], I.Ciucci[1], L.Tognotti[3]
1 Department of Mechanical, Nuclear and Production Engineering, University of Pisa, 56126 Pisa
2 Dipartimento di Fisica – CETEMPS University of L'Aquila, 67010 Coppito - L'Aquila
3 Department of Chemical Engineering, Industrial Chemistry and Materials Science, University of Pisa, 56126 Pisa

Within the PaTOS II project of Tuscany Region a study is in development focused on the characterization and source apportionment of atmospheric aerosol in the Tuscany territory.

Applications of air pollution dispersion model CAMx, a multi-scale three dimensional photochemical grid model [Environ2004], have been performed to the Tuscany emission scenario. The study aims at evaluating transport of coarse and fine particulates and formation of secondary fine particulates, with special attention to nitrates and sulphates. Regional emission inventory data were elaborated for defining the distribution of pollutants sources; detailed VOC and PM2.5 speciation was applied [Passant, 2002, SCC2004]. The meteorological input fields were elaborated from MM5 prognostic meteorological model data [Cetemps]. The IC and BC concentrations were provided by the chemistry transport model CHIMERE [Cetemps].

The simulations were performed to reconstruct the PM10 pollution in the Tuscany region during the year 2006, and daily values were compared with observed data by the Tuscany air quality network.

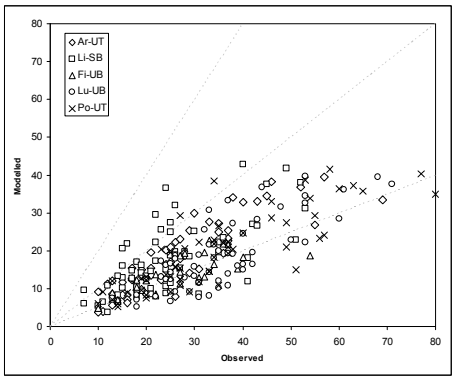

Figure 1. Comparison between PM_{10} modelled and observed data (June and July 2006) [$\mu g/m^3$]

The predicted average values of PM concentration were found to be in good agreement to observed ones. Actually, the calculations for the two summer months already simulated (see Fig. 1) tend to slightly underestimate the measured data. Besides, with respect to the PM composition the percentages of inorganic components are underestimated, especially sulfates, while the organic parts are overestimated (Fig. 2); the primary component percentages are similar to the corresponding values observed for the majority of the areas.The calculations for the full year are being carried out.

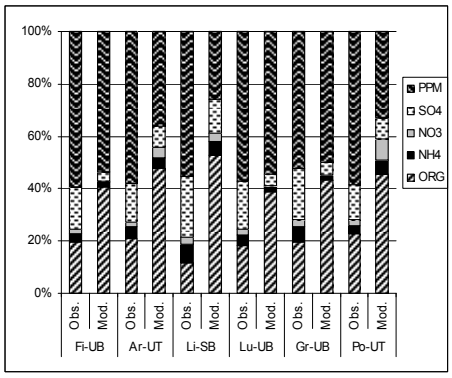

Figure 2. Comparison between experimental and modelled PM_{10} composition (June and July 2006)

The result of the simulations allow the description of the concentration levels of pollutants, especially PM_{10} and NO_2, for the whole region. The results obtained can provide useful information for Tuscany's PM10-emission control and abatement. They can also be used for establishing further pollution-mitigation plans and for providing a solid support for sound air quality management. The CAMx code is therefore proposed as a tool for air quality management in relation to the evaluation of acute episodes of pollution and to plan actions to reduce emissions into the ambient air. However the set-up model needs further improvements in detail and data management input.

Keywords: Ambient aerosols, Source apportionment
Presenting author email: csamara@chem.auth.gr

Suspended particulate matter (PM) is a major environmental problem in several countries in the E.U., while new evidence regarding its detrimental impact on human health has emerged. Implementation of the Thematic strategy on Air Pollution by the E.C., through the most recent Directive 2008/50/EC, will require lower limit values for PM in air. In this framework, the identification of PM sources, as well as the quantification of their contribution to the observed concentration levels, acquires increased interest since it may assist towards the development of source-specific control measures and mitigation policies. Greece is a European country, where a great deal of improvement with respect to emission control strategies can be made. The aim of this work is to review the source apportionment studies conducted so far in Greek urban centres in an attempt to summarize the main anthropogenic and natural sources influencing the ambient PM levels.

Figure 1 summarizes the available data on PM_{10} and $PM_{2.5}$ yearly ambient concentrations measured at two major Greek cities, Athens and Thessaloniki, during the last two decades.

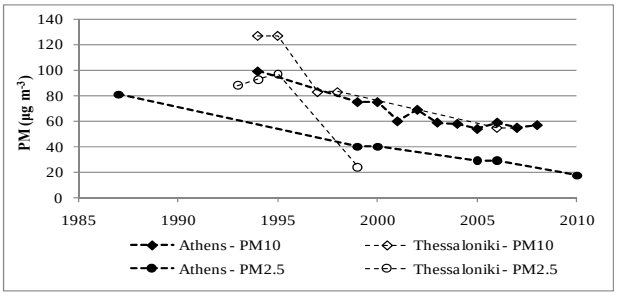

Figure 1. Long term trend of PM_{10} and $PM_{2.5}$ yearly concentration levels in Athens and Thessaloniki

Source apportionment of ambient PM has been carried out at three urban areas (Athens, Thessaloniki and Volos). Different receptor modelling approaches were employed for this purpose, based on the ambient concentration levels of particles and their chemical speciation. Chemical source profiles were constructed for the Chemical Mass Balance (CMB) receptor modelling. The different sources identified and their relative contributions (%) are listed, along with the source apportionment models used in Table 1.

In the studies where PMF was employed (Athens, Volos), the generated factors provided information on chemical source profiles and source contribution. For the CMB modelling (Thessaloniki, Volos) the chemical source profiles from the receptors were successfully reconstructed by local source profiles. In the cases were simple statistical procedures were used (PCA and FA/MR), unidentified sources were resolved.

Modelling SOA formed in a chamber from a mixture of organic gases

Marta G. Vivanco[1], Manuel Santiago[1] and Ariel Stein[2]

[1]Department of Envrionment, CIEMAT, Madrid. Spain
[2]Earth Resources and Technology on assigment to NOAA's Air Resources Laboratory. Silver Spring, MD. USA
Keywords: secondary organic aerosols, modelling

Models are being extensively used for diferent purposes in air quality management. Normally, the evaluation of model performance is carried out using information obtained at monitoring sites, and thus all the physical and chemical procesess involved in air pollutant concentration are evaluated in a global way. This means that errors in a certain process can be compensated with errors in another one, making difficult to decide on how the model is suceeding to represent individual procesess. Moreover, secondary organic aerosols have an additional uncertainty, as normally measurements at monitoring sites are not directly measured, but obtained from OC/EC relations.

Six experiments with biogenic organic precursors were carried out in the EUPHORE facility located in CEAM (Valencia, Spain) (Becker, 1996). Figure 1 illustrates de chamber when it is closed (left), being opened (center) and opened to sunlight (right).

Figure 1. EUPHORE facility: closed (left side of the figure), while opening (middle of the figure), and opened to sunlight (right side of the figure).

Experimental conditions are summarized in Table 1. Different mixtures of volatile organic compounds and HONO were introduced into the chamber at different relative-humidity values. Other experiments with anthropogenic precursors were also performed in 2008 (Vivanco and Santiago, 2010, Vivanco et al., 2011)

Multiple measurement techniques, such as Gas Chromatography coupled with Mass Spectrometer (GC-MS), Fourier Transform Infrared Spectrometry (FTIR), High Pressure Liquid Chromatography (HPLC), Gas Chromatography (GC-ECD and GC-FID/PID), Absorptive Sampling Solid Phase Microextraction (SPME) were used to monitor the gas concentration of reactants and products. Regarding the particle phase, aerosol concentration was monitored in an on-line way with a TEOM (Tappered Element Oscillating Monitor) and a SMPS (Scanning Mobility Particle Sizer).

Two models (CMAQ and CHIMERE) were applied in order to simulate the six experiments. Both models were modified to reproduce EUPHORE conditions. SOA formation is described in both models by the gas-particle partitioning theory, by which the formation of these aerosols is governed by the formation of a group of semivolatile compounds from the photochemical oxidation of certain biogenic and anthropogenic volatile organic compounds. Modeling results indicate that a general overestimation is found for both models. An example of how CMAQ and CHIMERE overestimates SOA recorded in the chamber is shown in Figure 2.

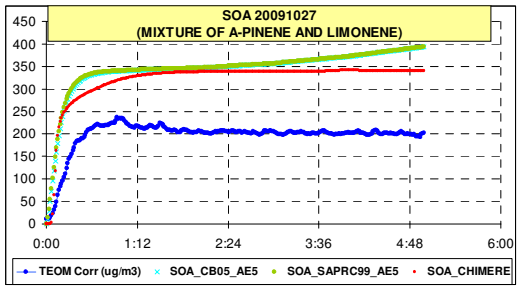

Figure 2. Observed and modelled SOA concentration for the experiment on 27102009. No isoprene was introduced that day into the chamber. CMAQ and CHIMERE results are presented in green and red, respectively. Blue line shows TEOM SOA concentration

Electrical Effects

Charged Particles from Laser Printers

Rohan Jayaratne, Xuan Ling, Congrong He and Lidia Morawska

International Laboratory for Air Quality and Health, Institute of Health and Biomedical Innovation
Queensland University of Technology, Brisbane, Australia
Keywords: Indoor Air Quality, Laser Printer, Respiratory Health
Presenting author email: r.jayaratne@qut.edu.au

It is now well known that most laser printers emit large numbers of ultrafine particles during their operation (He et al., 2007). Continued exposure in office environments has led to serious concern on their effect on human health. Moreover, the deposition rate of particles in the human respiratory system is enhanced when they are electrically charged (Cohen et al., 1998). Since the basic principle of operation of a laser printer involves static electricity, this study was aimed at investigating whether the emitted particles were charged and, if so, to quantify the emission rates of charged particles and cluster ions from a typical printer. Cluster ions are molecular ions smaller than about 1.6 nm.

An HP1320N laser printer was placed within a closed 1m^3 cubic chamber and commanded to print 150 monochrome A4 sheets with a toner coverage of 5% at 22 ppm. The particle number concentration (PNC), charged particle concentration (CPC) and cluster ion concentration (CIC) in the chamber were monitored in real time with a TSI 3022A condensation particle counter, a TSI 3068A aerosol electrometer and an Alphalab air ion counter, respectively, and logged at 1s intervals. Four separate tests were carried out.

Fig 1 shows a typical test result. The PNC in the chamber increased steadily and peaked at 6.35 x 10^4 cm^{-3} at the end of the print run. Positively charged particles were detected around 4 min into the run and the CPC peaked at about +7000 ions cm^{-3} at the end of the run. The charged particles were accompanied by positive CIC. The PNC and CPC remained high after the print job, decaying exponentially to background, while the CIC fell to zero as soon as the printing had ceased. This is not unexpected, as cluster ions readily attach to aerosols in the air. Thus, from these results alone, although we can conclude that the printer emitted cluster ions, we cannot confirm that the printer emitted any charged particles or whether the emitted cluster ions attached to neutral particles after emission.

Assuming no particle and charge losses in the chamber during the print runs, we estimate that the printer emitted at least 4 x 10^8 ultrafine particles and 4 x 10^7 ions per sheet printed.

This is a preliminary study and, while establishing that particle emission from laser printers may be accompanied by electrical charge, it raises several questions such as do all laser printers emit charges, what is the mechanism of charge generation and what are the potential exposure and associated health effects of the charged particles? A full understanding of these processes awaits further investigations.

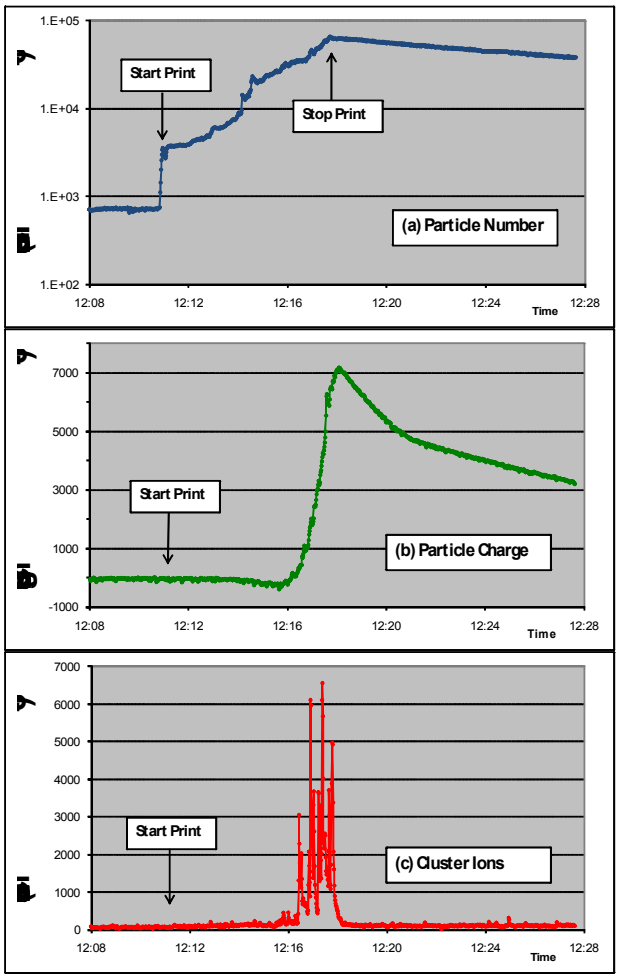

Figure 1: Time series of (a) PNC (b) CPC and (c) CIC in the chamber during a typical print run of 150 sheets.

Presenting author email : d93841001@ntu.edu.tw

Several experimental studies investigated the charge effect on the deposition of inhaled aerosol particles in either cast replica or human subjects (Balachandran et al., 1997; Melandri et al., 1983; Ali et al., 2009; Bailey, 1997; Bailey et al., 1998). Since human respiratory tract is conductive in nature, the increase in aerosol deposition in human airway was assumed due to image force. In general, the experimental data focused on image force for particles deposition efficiency were rather limited. Moreover, the amount of charges carried by the particles was only about hundreds of elementary charges for micro-meter sized particles. The low electrical mobility was apparently due to the limitations of aerosol generation methods employed in these studies. In the present study, we adopted an induction method to generate aerosol particles with the amount of charges close to the Rayleigh limit. In addition to the experimental work, a closed-form theoretical model was developed and validated by using the experimental data produced.

A vibrating orifice monodisperse aerosol generator was modified to generate monodisperse aerosols with uniform charge. A small amount of nitric acid was added to the Di-2-ethylhexyl sebacate (DEHS)-ethanol solution to increase the conductivity and, thus, make the aerosol charge control achievable. An Aerodynamic Particle Sizer was used to monitor the aerosol size distributions and particle number concentrations upstream and downstream of the tubes. The total aerosol charge was measured using an aerosol electrometer. The particle loss in the sampling train of the electrometer could affect the particle charge calculation and needed to be characterized.

Six metallic tubes were used in this study. Three with the same length of 40 cm but different inner diameter (0.78 ~ 2.11 cm); while another three with the same inner diameter of 1.66 cm, but different length of 10 ~ 30 cm. The sampling flow rates through the metallic tube were adjusted to the corresponding face velocities of 3.9 ~ 38.5 cm/sec. All the air flow were controlled and monitored by mass flow controllers. All the aerosol penetration tests were repeated for at least 5 times.

The aerosol electrical mobility in this work was, up to 24,000 elementary charges on a 1-μm particle, at least 100 times higher than that used in previous studies. The modeled data agreed well with the experimental data, especially for aerosol carried low charges and long tubes in which air flow was well developed. The aerosol deposition efficiency increased with increasing aerosol charge and tube length, due to stronger image force and longer retention time, respectively. The deposition efficiency decreased with increasing face velocity because of shorter retention time. Under the same face velocity, the deposition loss decreased with increasing tube diameter. This is because, for small diameter tube, the fraction of aerosols near the inner wall was higher than that of large diameter tube.

The theoretical model based on parabolic flow had a good agreement with most of the experimental data, except for data of highly charged particles. This discrepancy was likely due to space charge force, which was not taken into account in this work.

High-throughput multi-jet mode electrospray for two fluids using a coaxial grooved nozzle

Inyong Park[1], Woojin kim[1] and Sang Soo Kim[1]

Aerosol and Particle Technology Laboratory, School of Mechanical, Aerospace & Systems Engineering, Korea Advanced Institute of Science and Technology, Guseong-dong, Yuseong-gu, Republic of Korea
Keywords: Electrospray, Multi-jet mode, Coaxial grooved nozzle, High-throughput
Presenting author email: inyongpark@kaist.ac.kr

Despite the promising features of liquid atomization, the electrospray technique currently has few practical applications, mainly because it is restricted to electrical conducting liquids and hampered by low throughput. To overcome these limitations, there are many modifications have been proposed. Electrospray for non-conducting liquids was reported by Loscertales et al. (2002) who showed that a double-layered cone-jet formation occurs when two immiscible liquids are fed coaxially. To achieve high-throughput, the multi-jet electrospray mode was proposed by Duby et al. (2006).

To overcome these drawbacks simultaneously, we introduced a coaxial grooved nozzle.

In this study, in order to obtain stable multi-jet operation, a grooved coaxial nozzle was employed to enhance the exterior electrical field. The outer nozzle had an outer diameter of 6.350 mm and inner diameter of 4.064 mm. The inner nozzle had an outer diameter of 3.175 mm and inner diameter of 2.032 mm. The six grooves in the inner nozzle were made by wire electro discharge machining (WEDM). Each groove had a width of 0.4 mm and height of 0.5 mm.

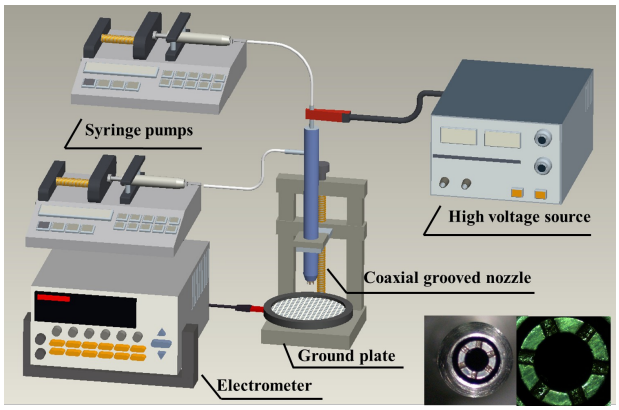

Figure 1. Schematics of the experimental set-up and the nozzle geometry.

Multi-jet formation appeared at larger applied voltage than the cone-jet mode. With a smooth nozzle, the jet formation is unstable, and the origins of the jets move along the circumference of the nozzle. This makes it hard to control multi-jet operation. However, when a grooved nozzle was used, each jet was anchored at a groove, and stable operation was achieved. The jets were electrically balanced with each other, and six stable jets were observed. Images showing multi-jet operation are presented in Figure 2.

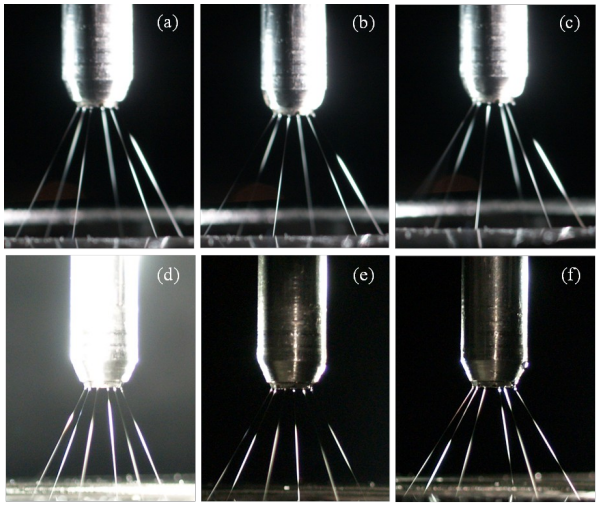

Figure 2. Spray visualization.

Investigation of charge conditioning of aerosols by means of soft X-ray and AC corona discharge devices

P. Kallinger[1], G. Steiner[1] and W.W. Szymanski[1]
[1]Faculty of Physics, University of Vienna, Boltzmanngasse 5, Vienna, 1090, Austria
Keywords: Nanoparticles, Charging efficiency, Soft X-ray, Corona discharge.
Presenting author email: peter.kallinger@univie.ac.at

Electrical measurement techniques for the experimental determination of nanoparticles' properties, rely on a well-defined particle charging process. Radioactivity based chargers are widely-used because of their simple application and the well-known equilibrium charge distribution, but there is also a safety risk connected with this method.

In this work the performance of two alternative possibilities for charge conditioning of aerosols are investigated – soft X-ray and bipolar corona discharge. For the latter one a commercial instrument is used (Electrical Ionizer, Model 1090, MSP Corporation, USA). The soft X-ray charging unit is a homemade device consisting of two photoionizers (L9491, Hamamatsu Photonics, Japan; 9.5 kV) which are mounted at an aluminum ionization/charging chamber. For comparison, a radioactive source (^{241}Am, ^{210}Po) in a chamber with identical geometric dimensions is used. First, a high resolution DMA (Steiner *et al*, 2010) operated at about 500 lpm connected to an aerosol electrometer (Faraday Cup) is used to measure the distribution of ions produced by each charging device. Preliminary measurements indicate similarities in the morphology of the ion distributions curves (Kallinger *et al*, 2010).

To investigate the charge conditioning performance of the aerosol charging devices test particles where routed through the charger, into a scanning DMA and detected with a CPC.

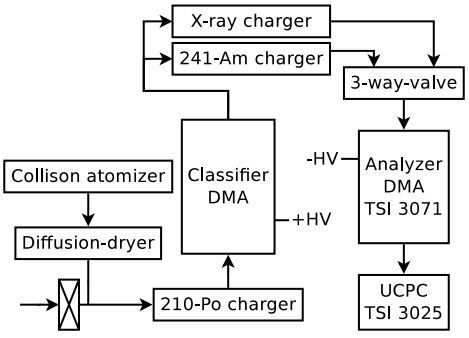

Figure 1: Schematic diagram of the experimental setup.

Monodisperse aerosols of polystyrol-latex (PSL) particles as well as DEHS droplets in the size range of 20–200 nm are used, generated by means of atomization and subsequent classification with a DMA. A schematic diagram of the experimental setup is shown in Fig. 1. It has to be mentioned that the particles leaving the first DMA are negatively charged whereas the second DMA measures positively charged particles. In the size range below 30 nm silver and gold nanoaerosols generated by means of an electrospray (Mod. 3480, TSI Inc.) are used before the DMA classification.

Results for monodisperse DEHS droplets (Fig. 2) show comparable performance of both, the soft X-ray device and the radioactive charger, however the yield from the X-ray charger seems to increase with increasing particle size, which is in contrast to previous reports (Shimada *et al*, 2002, Yun *et al*, 2009). Further measurements are in progress and will be reported.

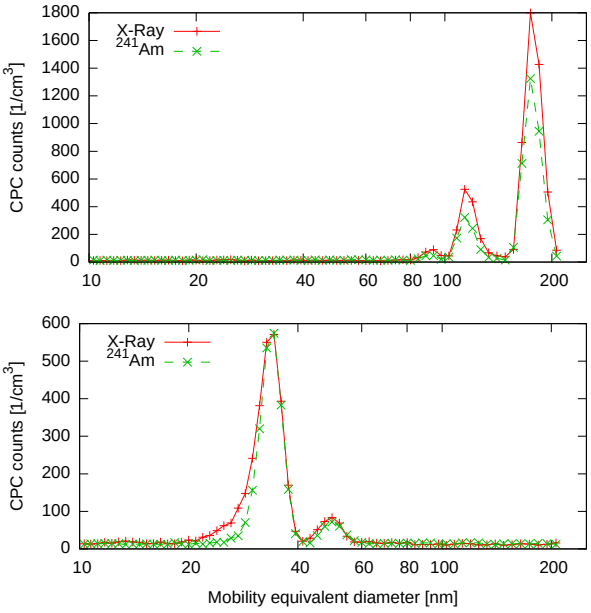

Figure 2: Efficiency of the soft X-ray charger compared with a radioactive ^{241}Am charger using monodisperse DEHS particles.

OPTIMUM CONDITIONS OF TWO-STAGE ESP SYSTEM FOR OIL MIST CONTROL

K.S.HWANG[1] and D.N.Shin[2]

[1,2]Environmental and Energy Research Center, Research Institute of Industrial Science & Technology
Pohang P. O. Box 135, 790-330, Republic of Korea

Keywords: Oil Mist, Pre-ionizer, Electrostatic Precipitator, Collection Efficiency

INTRODUCTION

There are a number of sources emitting fine oil mist and fume. One of them comes from metal working fluids which act as coolant, lubricator and flushing material of metal chips during the metal working process. The particle size of oil mist and fume produced by such process is so fine, such as 0.03-1.0 μm in diameter, that oil mist and fume pose a serious hazard, for example, causing respiratory problems. Among the control technologies of such oil mist and fume, electrostatic precipitator (ESP) is known to the most effective way of the control of them. This paper presents the optimum conditions of two-stage ESP system for collecting oil mist and fume.

METHODS

The pilot scale experimental system was made for the control of oil mist and fume, and the available capacity of the system was about 15 m^3/min of the flow rate. It is composed of an oil mist and fume generation section, pre-ionization section, collection section and measuring section. The schematic diagram of the experimental system has been represented in Figure 1. The pre-ionizer consists in metal wires having small diameters and operates with a positively direct current high voltage in the range of 0 - 15 kV. Such high voltage on the wire creates an electric field to charge the oil mists. The initially produced electrons in the pre-ionizer flow across the oil stream and in turn collide with or adhere to the particles, imparting a charge on them. The collection section is a series of parallel metal plates which are spaced apart with alternate plates charged and grounded. The metal working fluids oil investigated in this study was insoluble cutting oil in water.

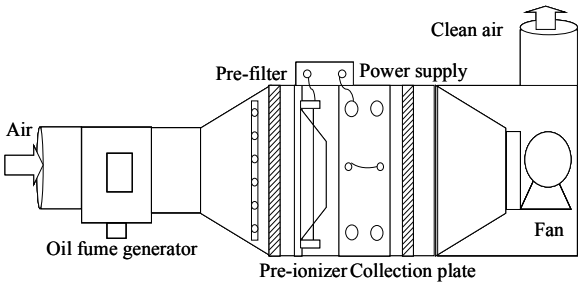

Figure1. Schematic diagram of the pilot scale ESP system

RESULTS

In this study, the performance of the two-stage ESP system has been investigated as a function of applied voltage to pre-ionizer, gas velocity, and plate-plate distance of collecting plate etc. Figure 2 has illustrated the collection efficiency as functions of applied voltage to pre-ionizer by using wire-plate type. In Figure 2 the inlet velocity was 1.5 m/sec. It has been observed that the collection efficiency of oil mist was rapidly increased with applied voltage at 7~11 kV ranges, and then thereafter very slightly increased with applied voltage. This implies that there is a optimum value of applied voltage governing the degree of charging the oil mist.

Also, we have also investigated the effect of the distance between the collecting plates, which are evenly placed, on the collecting efficiencies of oil mist. As shown in Figure 3, it is found that the collecting efficiencies are nearly steady with increasing the distance of plates from 15 to 18mm. Further increasing to 21 mm gives the reduction in the collecting efficiencies from about 92 to 85%. Based on our experimental results, there may be optimum value of the distance between plates greatly affecting the collecting efficiencies.

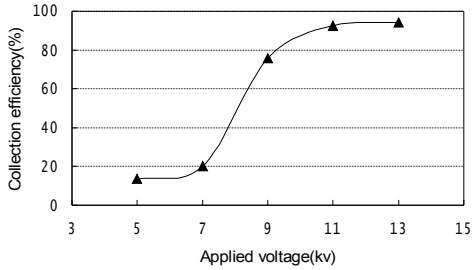

Figure2. Effect of applied voltage on collection efficiency.

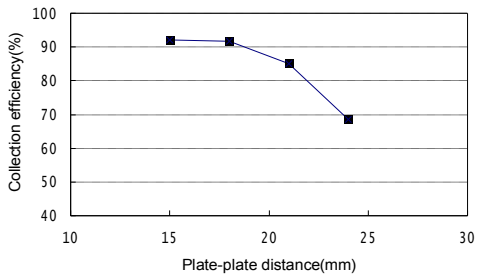

Figure3. Effect of plate-plate distance on collection efficiency.

Comparison of charging characteristics between particle chargers using different discharging materials

B. Han, H.-J. Kim, D.-K. Song, W.-S. Hong, W.-H. Shin and Y.J. Kim

Environmental Systems Research Division, Korea Institute of Machinery and Materials, Daejoen, 305-343, Korea

Keywords: Ion, Ozone, Carbon fiber, Stainless steel, Corona

Presenting author email: bhan@kimm.re.kr

Charging of fine and ultrafine particles is very important for the control of the particle transport in appropriate external electric fields, for example, such as DMAs (differential mobility analyzers). Corona dischargers which use metallic wires or needle tips have been commonly used for the charging of the particles. However, they possibly generate considerable amount of ozone and other small nanoparticles near the discharging electrodes. Recently, new unipolar and bipolar chargers using carbon fiber electrodes which generate nearly negligible ozone but charge fine and ultrafine particles with high efficiency have been developed (Han et al., 2008, 2009). However, the ion generation, ozone emission and charging performance of the charger using a carbon fiber electrode have not been compared to the conventional corona chargers using metal tips in detail. In this study, a carbon fiber charger has been compared to a conventional corona charger in the same charging chamber by replacing a stainless steel tip to a carbon fiber electrode. The carbon fiber electrode comprised of a bundle of carbon fibers with a diameter of about 5-10 μm and a number of about 300 ea. For comparison, a negative high voltage was applied to the carbon fiber and stainless steel chargers and their voltage-current curves were measured and compared. Ion and ozone concentrations were also measured for different supplied voltages to the chargers by an ion counter and an ozone detector at the outlet of the chargers in which filtered clean air was introduced. For a given supplied voltage, current of the carbon fiber charger where a ground electrode was connected was a little higher than that of stainless steel charger and thus, ion concentration of the carbon fiber charger was also higher than that of the stainless steel charger. However, ozone emission of carbon fiber charger was about a half of that of stainless steel corona charger. For the carbon fiber charger where a ground is not connected to the ground electrode of the charger, current of the carbon fiber charger was nearly zero, and however, the concentration of the generated ions was comparable to both the conventional corona charger and carbon fiber charger where a ground is connected, even though ozone emission of the carbon fiber charger without a ground was nearly zero.

For particle charging measurements, KCl particles were generated by a constant output generator and they were introduced into both a diffusion dryer and Kr-85 neutralizer to remove humidity and initial electric charges. The neutralized particles were introduced into the carbon fiber charger and stainless steel corona charger. Particle loss, intrinsic charging efficiency and extrinsic charging efficiency were compared for both chargers. Particle loss in the charger was the highest for the stainless steel corona charger. Most charged particles were lost by the strong electric field formed in the stainless steel corona charger. For the case of carbon fiber charger, ions were generated at a relatively low voltage and thus particles loss was also relatively low compared to the stainless steel charger, because a little low electric field was formed in the carbon fiber charger. Particle loss for the carbon fiber charger without a ground was the lowest. The loss was mostly less than 20% for the particle size range between 30 and 300 nm while the loss for the stainless steel corona charger was mostly more than 40% at the same size range. Figure 1 showed extrinsic charging efficiency with particle diameter for carbon fiber charger without a ground and stainless steel corona charger with a ground. For about 20 nm particles, the extrinsic charging efficiency of the carbon fiber charger was about 60% and however that of the stainless steel corona charger was only about 5%. Therefore, it has been found that carbon fiber charger showed much higher particle charging performance and lower ozone emission compared to the conventional corona charger at the same geometric condition.

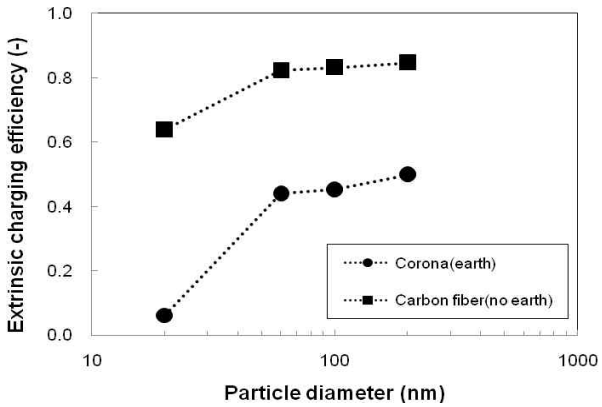

Figure 1. Comparison of extrinsic charging efficiency with particle diameter for carbon fiber and stainless steel corona chargers.

Factors affecting ESP aerosol generation

C.W. Lin, S.H. Huang and C.C. Chen

Institute of Occupational Medicine and Industrial Hygiene, National Taiwan University, Taipei, Taiwan
Keywords: ESP, generation, penetration
Presenting author email: r92841013@ntu.edu.tw

The Electrostatic precipitators (ESP) have been used for over a century to control industrial particle emissions. The mass collection efficiency of the ESP is in the order of 90-99 percent. It is also ESP's characteristic of low pressure drop and low electric power consumption. However, several studies reported that ESPs could generate nanoparticles by itself in some specific operational conditions (Romay et al., 1994). These particles might collisions between ions and discharge wire (Biris et al., 2004). The particle generated by ESP could decrease ESP performance and contaminate environment. The ESP may not be a good particle collector when it generates particles. The main objective of the present study was to characterize the phenomenon of ESP aerosol generation in the present of challenge particles under different environmental conditions.

A lab-scale wire-plate ESP was designed and built for the particle generation test. The discharge wire was made of 0.1 mm stainless steel and the collections were made of aluminum. Particle number concentration and size distribution were monitored by a scanning mobility particle sizer. The challenge particles were generated by a TSI constant output generator. The air temperature before and after ESP were monitored by using k-type thermal couples. Particle number concentration and size distribution data obtained in the power-on and power-off modes were used to characterize the particle generation of the ESP. The major operating parameters included air flow rate, field strength, type of carrier gas and challenge particle number concentration.

The results showed that the ESP penetration could be affected by changing carrier gas, electric field strength and air flow. The challenge particle concentration did not affect ESP collection efficiency. However, the ESP generated nanoparticles resulted in the particle penetration exceeded 100%. As shown in Figure 1, the particle size distribution of the particles generated from ESP was between 5 to 50 nm, with the mode around 10 nm. After the test, the stainless steel wire became brown and the erosion on the surface of discharge wire was observed from SEM pictures. The particle generated by the ESP might be the result of sputtering.

The field strength range operated in this work is from 4.0-4.3 kv/cm and the flow rate is from 3-9 L/min. The ESP had the highest particle generation rate at the flow rate of 6 L/min and the electric field strength of 4.3 kV/cm. That is because the ESP removed particles more efficiently when the electric field strength was higher than 4.3 kV/cm. The sputtering was suppressed when the electric field strength was lower than 4.3 kV/cm. Particles had shorter retention time when the flow rate was less than 6 L/min and sputtering was suppressed when the flow rate exceed 6 L/min, probably due to the heat loss. The challenge particle concentration range operated was from 10^5 to 10^8 #/cm^3. The particle generation rate decreased with increasing challenge particle concentration because the challenge particles might absorb the ions, and therefore, protect discharge wire from sputtering. The particle penetration and particle generation both increased when carrier gas was changed from air to nitrogen. The mechanism of this phenomenon is not well understood and need to be explored further.

As a result, the way to suppress the particle generation from ESP and increase the overall performance is to increase electric field strength, decrease flow rate and increase challenge particle concentration.

Calculation of the electrical field and charge density in a corona unipolar charger with a complex geometry

M. Domat[1], M.A. Rodríguez-Braña[1], E. Kruis[2], J.M. Fernández-Díaz[1]
[1]Department of Physics, University of Oviedo, C/Calvo Sotelo, s/n, E-33007 Oviedo, SPAIN

Keywords: Corona effect, charging
Presenting author email: maida.dro@gmail.com

The use of unipolar particle chargers, such as based on corona discharge, is increasingly spreading because they have not the obvious restrictions that radioactive chargers have.

However, the data for corona chargers are determined for each specific design, based on experimental procedures or simple theories, and can differ greatly from different device configurations. This leads to errors in further processing the data of charged aerosol.

Moreover, it has the disadvantage that its behaviour changes with time (since the electrode gets worn out and can change its geometry) and are less stable than radioactive chargers, which have a well defined charge distribution.

Therefore, there is a need to study corona chargers from a theoretical point of view, leading to precise knowledge of the charge density and electric field at every point of the device, and thereby to the Nt product calculation, necessary to determine the charging efficiency by particle sizes.

We present a method for obtaining the electrical parameters of a corona particle charger at any point inside it. Since the electrical current within the generator is very small, magnetic effects are negligible and the problem can be solved by means of:

- The Poisson's equation for the electric potential, V:

$$\nabla^2 V = -\frac{\rho}{\varepsilon_0},$$

  where ρ is the free charge density and ε_0 is the electrical permitivity of the vacuum.

- The continuity equation for the charge density:

$$\frac{\partial \rho}{\partial t} + \vec{\nabla} \cdot \vec{j} = 0,$$

  where $\vec{j}$ is the electrical current density, which is in our case:

$$\vec{j} = -b\rho\vec{\nabla}V - \mathscr{D}\vec{\nabla}\rho,$$

  where b is the generated ion mobility and $\mathscr{D}$ its diffusion coefficient.

- Proper boundary conditions, including an injection charging law compatible with the Kaptzov condition.

In this model we have neglected some effects not relevant (see Dumitran et al., 2006). Likewise, during normal usage of the charger can be assumed that the system is stationary (and hence charge density, potential and electric field do not change with time).

The resolution of the previous set of equations for not simple geometries is quite difficult. The Poisson's equation is an elliptic one, which can be properly solved by finite element method (FEM) when the geometry is complex. On the other hand, the equation of continuity is a parabolic-hyperbolic one and therefore, the direct FEM is inadequate since produces a great numerical dispersion and unreal results. However, numerical corrections which add a controlled artificial viscosity along the current lines, make possible the use of FEM with the same mesh used for solving Poisson's equation.

As the use of three dimensions would be too complicated to address the problem in this first approach, FEM has been applied to cases reducibles to two dimensions. In this way, all cases of interest are virtually covered: sheet corona generators and needle corona ones with cylindrical symmetry around the needle.

To solve the system of equations, FreeFEM++ (Pironneau et al., 2010) has been used. It is a comprehensive package of finite element with its own language (similar to C++) that can solve very general problems.

Results are not shown for lack of space in this document. Nevertheless, results for simple geometry cases, as the plate-plain configuration, compare well with the ones of Dumitran et al. (2010), which have been obtained using a different numerical method.

FreeFEM++ will be used to solve together the electric and the fluid flux problems in the corona charger in the future. Also, other electric aerosol devices, as electrometers, can be modelled to improve their behaviour.

We thank the MEC of Spain for support under grant BES-2006-12469.

Keywords: aerosol charging, diffusion charging, charge distribution, corona discharge

Numerous aerosol processes are based on aerosol charging by ions (filtration, size measurement, electrostatic agglomeration …). This work focuses on the comparison of charge distributions estimated from mobility spectra measurements and calculations assuming a constant ion density. The main objective is to investigate the homogeneity of the charging conditions in other words to prove that most of the particles encounter similar charging conditions (mean Ni.τ product, the time integration of ion density Ni on the particle trajectory).

Diffusion charging takes place in post-negative corona discharge with air at atmospheric pressure. The charger has been designed to limit ion and aerosol losses. The discharge occurs around a needle of 50 µm radius. The discharge current is typical of the negative corona regime [1].

Ni.τ products are first evaluated by current measurement. The decrease of ion density along the charging zone has been characterized by current measurements at different locations.

Then average particle charge levels and aerosol charge distributions are measured and compared with those predicted by Fuchs' theory [2] in the transition regime. In that respect, aerosols of controlled size (related to DMA voltage) and concentration (controlled by the furnace temperature and maturation time after furnace) are injected in post-discharge as described on figure 1. The first DMA is used to select a given electrical mobility. The fraction of multi charged aerosol never exceeds 10 %.

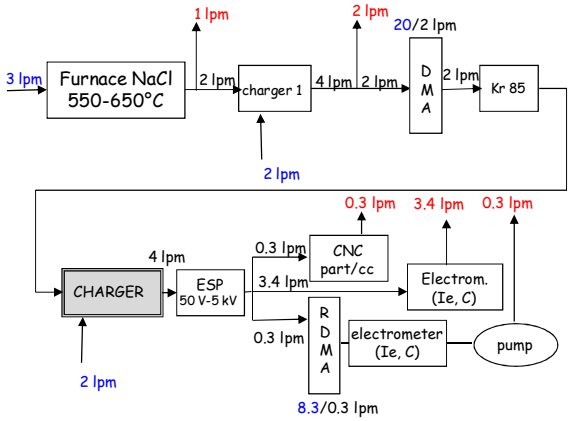

Figure 1. Setup for monodisperse aerosol generation and charge distribution measurements

The charger operates with ion and aerosol flow rates of 2 and 2 lpm. The average discharge current is of -40 µA. The mean charge per particle is calculated from CPC and electrometer measurements after an electrostatic precipitator (ESP) to remove all ions at low voltage (50 Volt). The comparison with Fuchs theory allows another estimation of the mean Ni.τ product to be performed. The two estimations of the mean Ni.τ product are around $6 \cdot 10^{12}$ s.m^{-3}.

Aerosol losses through the charger are determined with the CPC. Maximal aerosol losses are reached for smallest particle size tested (10 nm) and remains below 10 % for a charge fraction of 40 %.

The neutral fraction is determined using the CPC and the same ESP at higher voltage (5 kV) to collect all charged aerosol. Aerosol charge distributions are obtained from mobility spectrum measured with a Radial Differential Mobility Analyser (RDMA).

For instance, charge distributions are represented on figure 2 for particle of 11 and 51 nm. The dots represent the measurements, whereas the histograms represent the results of the calculations using the birth and death theory [3].

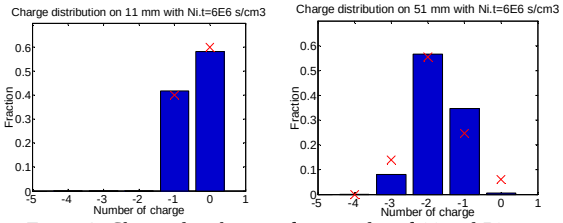

Figure 2. Charge distributions for particles of 11 and 51 nm

The zone of mixing is axi-symmetric. Radial and axial profiles of ion density are stationary but asymmetrical. Simple estimations of these profiles have been done, but angular profile depends on gas velocity and possible surface or space charge effects. Measured charge distributions are broader than calculated ones proving that particles encounter different charging conditions.

A model developed for aerosol and ion mixing in this arrangement [4] will be used for the evaluations of Ni profile, mean Ni.τ product and charge distributions in realistic conditions.

Aerosol is one of the most important elements of atmosphere and it is closely connected with variations of actinometric, electric, radiation and meterorological parametres of atmosphere. In this paper the authors study dynamics of light ions concentrations, electric field intensity, volume charge density, radioactivity and turbulence in the surface layer of atmosphere during storms over a period of 2006-2010.

The study of connections of the above mentioned parameters has a special importance under conditions of atmosphere reconstruction in the process of its transition from the conditions of fair to disturbed weather, which includes pre-thunderstorm reconstruction of atmosphere. The latter is closely connected with dynamics of the medium, changing of its aerosol and ion composition and generation of electric energy in zones of low pressure and cold fronts. In pre-storm situations the development of convective and turbulent upward and downward flows at cold fronts results in the interaction of neutral and charged particles in the moving low-ionized plasma, rapid evolution of aerosol dimension spectrum and effective transformation of heat and mechanical energy into electrical energy. The analysis has shown, that in this case one can observe coordinated changes of polar conductivities, during which the number of light ions can both sharply increase and decrease practically to zero. It is shown, that in storm atmosphere the transport of air ions, along with turbulent air flows, is carried out by electric forces, and the latter have the dominant role. One revealed the dynamics of electrode layer width changing depending on field intensity variations and it is shown, that the dynamics can increase to one hundred metres and more.

The characteristic feature of electrode layer behaviour in storm atmosphere is quasiperiodical change of volume charge sign of light ions under the changing of electric field direction. The coordinated level variations of gamma-background, standard meteorological values and turbulence characteristics during storms are revealed. Typical variations of atmosphere values during storm are represented in the figure.

To describe the properties of nonstationary electrode layer of surface atmosphere during storms basing on the approach, suggested in (Morozov, 2007), a nonstationary model has been developed. This model is used to determine the changes of positive and negative air ion concentrations and electric field intensity.

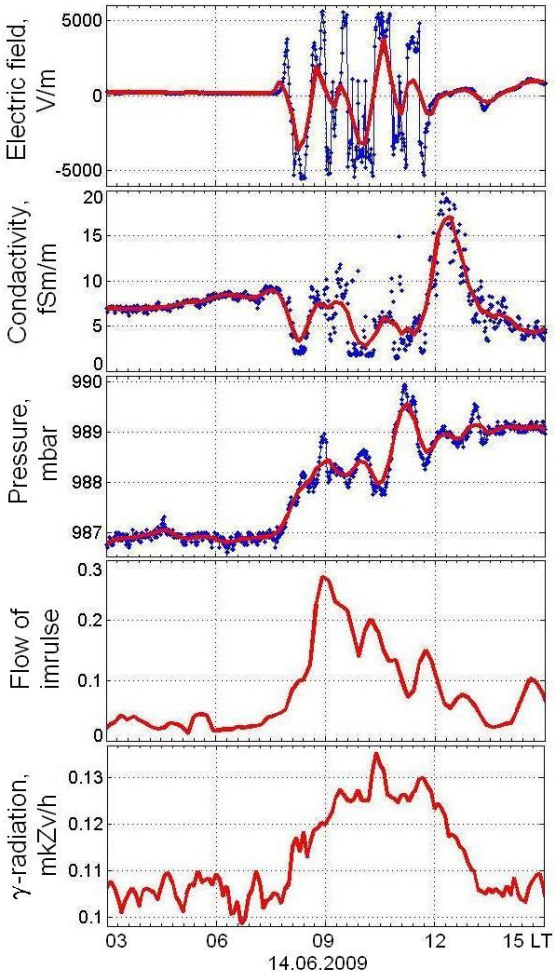

Figure. Coordinated variations of atmospheric electrical, meteorological values and gamma-background in storm atmosphere.

Atmospheric aerosols – Specific Aerosol Types

Dispersion and deposition pathways of combustion aerosols over tropical evergreens

A. Mukherjee[1], J. R. Picardo[1] and S. Ghosh[1,2]
[1]School of Mechanical and Building Sciences, VIT University, Vellore, India
[2]ICAS Associate, School of Earth and Environment, University of Leeds, U.K.

Presenting author email: picardo21@gmail.com

The Neyveli Lignite Corporation (NLC), located in southern India, is a large lignite based power plant which caters to the energy needs of the world's second fastest growing economy. Two thermal power stations continuously emit gaseous and particulate matter via 13 elevated stacks (particulates source strength: 12-20 g s^{-1}). High efficiency electrostatic precipitators (99.5%) are in operation and the fine particulates (mainly PM10) which are emitted remain suspended over considerable distances. Precise measurements and characterization of the size spectrum of the emitted particulates is in progress. The founding fathers of NLC initiated a massive afforestation program which has resulted in a green canopy of 17 million trees. The ability of this ever-green tropical expanse to counter emissions from NLC seems intuitive and demands detailed quantification.

In this work we aim to trace the path of suspended particulate matter (SPM) as it is dispersed in a tropical boundary layer, whilst accounting for the green carpet below. We employ a tailor-made atmospheric particulate dispersion-deposition model developed as part of an ongoing consultancy work with VIT University and NLC (Fig. 1 depicts SPM contours for Feb'10).

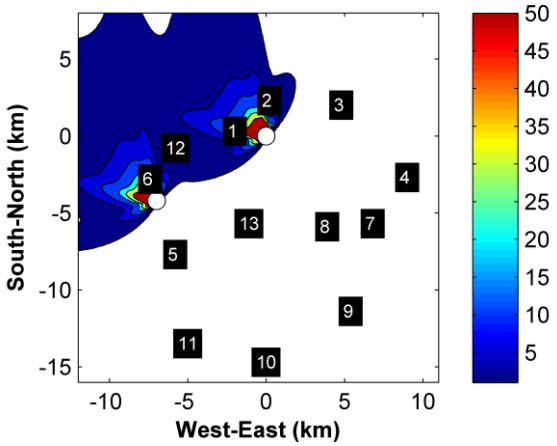

Fig. 1: Contours of ground level SPM - February 2010, 14:30 IST (μg m^{-3}). The text markers denote measurement sites and large white markers the power stations.

Since ultrafine particulates (dia. <1μm) do not settle under gravity, they would remain suspended if it were not for deposition onto the extensive vegetative canopy. This is evidenced by the SEM image (Fig. 2) of a leaf from a monitoring station (station [2] in Fig 1.).

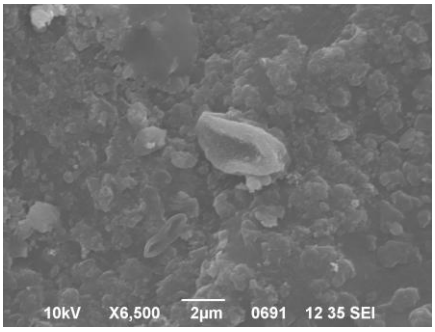

Fig. 2: Scanning Electron Microscopy (SEM) of a leaf sample from a monitoring station at NLC showing particle aggregates from power plant emissions.

The seasonal variation in green cover over southern India is very different from that over mid-latitude regions, both in the pattern of variation and intensity. Satellite derived, leaf area index (LAI) data from MODIS (available from the web) as displayed in Fig.3, along with daily meteorological inputs from NLC allow the model to capture unique characteristics of this tropical region.

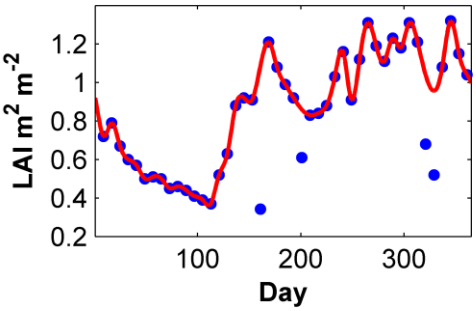

Fig. 3: LAI data for NLC as obtained from MODIS for the year 2010

With high source strengths and sprawling urban vegetation, NLC offers a unique opportunity to model aerosol transport over intermediate length scales. Hence, this analysis will aid modelers in bridging the gap between micro-scale aerosol process studies and global circulation models.

This work is supported by the Neyveli Lignite Corporation, Tamil Nadu, India under grant no. CARD/ENVT/MAP/Project 1218/2009.

Source emission studies and biomass burning assessments in Venice Lagoon area

A.M. Stortini[1], R. Zangrando[1], E. Barbaro[2], F. Bonetto[2], N. Kerward[1], C. Barbante[1,2] and A. Gambaro[1, 2]

Keywords: trace elements, Levoglucosan, ionic composition, PCA, PMF
Presenting author email: stortini@unive.it

Venice is located at the northern end of the Adriatic sea at the north-eastern most part of the Po river plain, and from the climatic point of view it is characterised by atmospheric stability and thermal inversion inducing cold masses at the ground level during the winter time. Humidity is high causing foggy events in winter and intermediate seasons, with low pollutants dispersion. Temperature increase is coupled with an increase of the Planetary Boundary Layer, consequently both pollutants mixing and dispersion increase in summer time.

From the chemical point of view, sources of particulate matter (PM) in Venice have been identified by different studies (Stortini et al, 2009; Rossini et al., 2010; Masiol et al., 2010). For heavy metals in PM10 the thermoelectric power plant and the glass factories are considered the most important emission sources. Data from the national environmental agency (ARPAV, 2006) for ships in the two principal berthing areas of Venice has shown that 69% of the emissions come from the petrochemical industry deliveries, while the 31% from the tourism and local activities. Venice area and its hinterland are characterised by industrial and agricultural activities, and urban agglomerates together with rural background areas are widely represented there. This scenario lets account a number of different sources and the use of further chemical methods is necessary for their identification.

A preliminary study was performed on particulate matter samples (PM10 and PM2.5) randomly collected in 2007 and 2008, and trace elements, ions and Levoglucosan have been measured. The aim of this study is to verify how biomass burning is recognizable, and how well could be identifiable in emission sources studies, taking into account the complexity above described for the area here considered.

Trace elements were measured by Inductively Coupled Plasma-Quadrupole Mass Spectrometry (ICP-QMS Agilent 7500I). Elements concentrations in samples have been obtained after subtraction of their field blank values. Details about sample treatment and accuracy are reported elsewhere (Stortini et al., 2009).

Ions where measure by an ionic cromatograph Metrohm 761 Compact IC, with a Metrosep A Supp 4 – 250 column for the anionic analysis, and nitrates, nitrites, chlorides, sulphates and oxalates were measured (Bonetto, 2009). Their measurement represent an useful tools for the assessment of secondary aerosol.

Levoglucosan (1,6-anhydro-β-D-glucopyranose) was measured for aerosol samples (Zangrando, 2007), and this is a product of cellulose combustion, that take place when cellulose is heated to over 300°C causing by various pyrolytic processes that cause the Levoglucosan production in large quantities. This chemical marker is useful as molecular tracer for biomass burning in the atmosphere because Levoglucosan it cannot be generated by noncombustive processes or by nonwood combustion. Sample analysis was performed by using liquid chromatography/negative ion electrospray ionization tandem mass spectrometry (HPLC/(-)ESI-MS/MS). An Agilent 1100 series HPLC system (Agilent, Waldbronn, Germany) coupled to an API 4000 triple quadrupole mass spectrometer (Applied Biosystems/MDS SCIEX, Toronto, Ontario, Canada) were used to determine Levoglucosan.

First results evidenced a seasonal trend in terms of PM concentration and in terms of measured analytics. PCA and PMF statistic tools are applied on all the parameters considered in this preliminary study evidenced the complexity of the studied area.

Particulate matter in the European urban areas has been increasing due to increased anthropogenic emissions, and levels of PM have become high with respect to the Air Quality Standards (AQS) specified by EC directives and by local regulations. In Western Europe emission sources (natural and anthropogenic) have a different influence depending on the local scenario and climatic areas (e.g. Iberian Peninsula and north Europe), evidenced the importance of the source recognition (Putaud et al., 2010; Querol et al.; 2007). In the Balkan area efforts for introduce and establish standard operating procedures and quality assurance procedures in all stages of aerosol management and analysis were performed (Joksić et al.; 2009), and some physical and chemical characterization of PM have been assessed in some past projects (Joksić et al.; 2009), as well as chemical and toxic approach for organic pollutants (Škarek et al.; 2007), but of course the collection of information about emission sources and their influence is still in progress.

In the frame of the project "Scientific cooperation between research Institutions for the study of airborne fine particles in IMportant Cities of the Adriatic area" (SIMCA - INTERREG/CARDS-PHARE Adriatic New Neighbourhood Programme), aerosol samples were collected in two urban sites located in Belgrade (Serbia) and in Sarajevo (Bosnia-Herzegovina) respectively. Samplings were performed in a 48-hours time interval from June to December 2008, and aerosol samples were collected by high-volume cascade impactor, fitted with PM10 size selective inlets. Particles with aerodynamic diameters <10µm were collected into six size intervals (cut-off aerodynamic diameters of 7.2, 3, 1.5, 0.95, 0.49 and <0.49 µm). Assessments on Ionic composition and trace elements (this poster) were performed.

Each filter was cut in two parts and one of them was microwave digested according the procedure described by Buccolieri et al. (2005). The digestion programs and the microwave operations are elsewhere described (Stortini et al.; 2009).

Trace elements were measured by Inductively Coupled Plasma-Quadrupole Mass Spectrometry (ICP-QMS Agilent 7500I), the accuracy and precision of the method was controlled using the standard reference material (Urban Particulate Matter NIST 1684a). Elements concentrations in samples have been obtained after subtraction of their field blank values.

Results evidence a consistent amount for elements typically from anthropogenic sources, and in particular from combustion process. PCA and PMF analysis are applied in both data sets with the aims of better describe all the emissions contributions in both urban areas.

Continuous time resolved measurements of environmental aerosols especially during New Year 2011 with a new fine dust monitoring system

M. Weiss, J. Spielvogel

Palas GmbH, Karlsruhe, 76229, Germany
Keywords: aerosol instrumentation, air quality network, fine particulate matter, particulate mass, particle size
Presenting author email: weiss@palas.de

Real time continuous and accurate measurements of atmospheric particles are important when complying with regulation or in the context of source apportionment; e.g in determining how much is contributed by traffic, industry or residential heating. If the time resolution is high enough it allows reliable transport modelling based on actual data. A lack of this information was causing the closure of the European air space when the Iceland volcano Eyjafjallajökull erupted in April 2010.

We will present the Fidas®, a new fine dust monitoring system based on optical light scattering. The Fidas® is equipped with a white light LED as stable light source with long lifetime and an integrated filter holder. The Fidas® allows the continuous recording of the particle number and particulate mass (simultaneously PM1, PM2.5, PM4, and PM10) with a time resolution of down to one second providing the opportunity to monitor dynamic changes. If desired the user can also obtain the particle size distribution with this instrument.

We will report on a one year measurement campaign where a Sigma-2 sampling head (described in detail in VDI 2119-4) was used to ensure representative sampling even in strong wind conditions. Specific events such as new year's fireworks will be highlighted and analysed in detail and also compared to another continuous fine dust measurement device and the data from a reference filter sampler.

We will also discuss implications for the reporting of particulate matter under these circumstances.

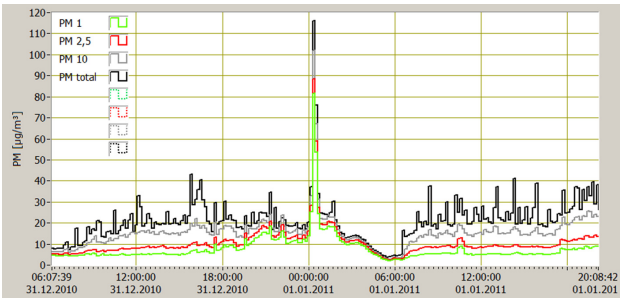

Figure 1. Simultaneous PM_1, $PM_{2.5}$, PM_{10} and TSP concentrations from before to after new year 2011

Figure 1 shows the concentration time line for the PM-fractions from before to after new year 2011 measured outdoors in a big German city. The particle emissions caused by the fireworks that accompany the new year celebrations lead to a significant increase of all PM-values for a short time. Figures 2 and 3 show the particulate mass and particle number distributions corresponding to before, during and after the fireworks, respectively.

As can be seen in figure 2 the mass concentration of small particles increases significantly and is caused by a factor of 10 increase in particle number (Figure 3). These small particles (< 400 nm) are primarily caused by the combustion process of the rockets and explosives.

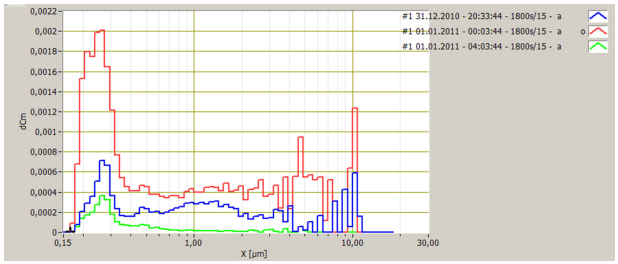

Figure 2. Particle mass distributions in mg/cm^3 before (blue), during (red) and after (green) new year 2011

Due to the implemented filter holder, a gravimetric filter can be used to analyse the sample further, e.g. by chemical analysis, and to verify the optically measured data.

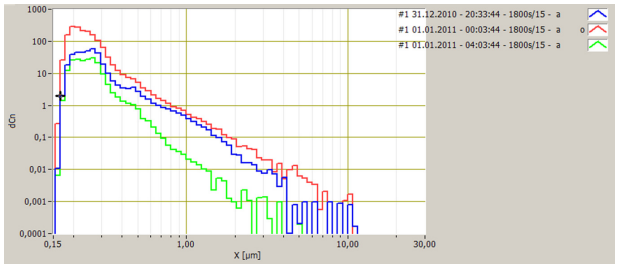

Figure 3. Particle number distributions corresponding to the mass distributions in figure 2

The high time resolution of the data of the Fidas® system facilitates the comparison between theoretical model and actual measured data. It measures continuously with no consumables and very little maintenance and the high resolution of particle sizes can be used for transport modelling and source apportionment.

Influence of the road traffic intensity on air pollution in the Prague

J. Ondráček[1], V. Ždímal[1], J. Schwarz[1], V. Bízek[2] and J. Smolík[1]

Keywords: traffic emissions, particle size distribution, chemical composition.
Presenting author email: ondracek@icpf.cas.cz

Aerosol particles belong to major air pollution sources. Moreover, it is generally known that aerosol particles have chronical and acute adverse health effects, they damage cultural heritage, reduce visibility and cause a climate change. A special type of environment, when taking into account the human health, is the urban area. Aerosol particles emitted from the road traffic in the city significantly contribute to high levels of air pollution and, at the same time, the population exposed to these particles is very large. Today, these particles represent one of the main sources of air pollution in the urban environment.

The particles emitted from road traffic can be divided into two categories – direct and indirect emissions. Direct emissions are for example emissions from vehicle exhausts, abrasion of car breaks, tyres and pavement and particle resuspension. The indirect emissions include secondary aerosol particles originated by chemical reactions from the gas phase. Apportionment of road traffic particles according to their size can be made taking into account the processes of particle formation and transformation. Nanoparticles (< 50 nm) and ultrafine particles (< 100 nm) are produced by high temperature and chemical processes and thus represent exhaust emissions and secondary aerosol particles. The coarse particles (> 1 μm) are usually formed by mechanical processes, which include the abrasion and the resuspension mechanisms.

Two measurement campaigns near a busy freeway and a suburban crossroad (different traffic intensity) were carried out in Prague during this work. Both of the two traffic related campaigns were supported by simultaneous measurements at suburban background site to compare measured values with corresponding city background. Extensive set of aerosol instrumentation was used during both campaigns at both measurement sites. Two pairs of aerosol spectrometers (SMPS and APS) were used to monitor aerosol particle number size distributions. Two BLPIs provided information about mass size distribution and chemical composition of collected size resolved aerosol samples. The crossroad campaign was also supported by two EC/OC field analysers providing information about elemental and organic carbon concentrations. Consequent chemical analysis of collected size resolved samples comprised of ion chromatography (water soluble ions), PIXE (elements) and RBS (carbon).

Results obtained from aerosol spectrometers and BLPIs showed that the main contribution of traffic in ultrafine size range can be attributed to direct exhaust emissions, while the coarse fraction was dominated mainly by regional background aerosol with small traces of brake and tyre abrasion as well as the resuspension of the road dust. Chemical analysis demonstrated that most of the water soluble ions (see e.g. Fig. 1) can be found in fine fraction of mass distribution and mostly comes from regional background and long range transport. Most of major elements (see e.g. Fig. 2) were found in coarse fraction of mass size distribution. It can be attributed to three different sources: abrasion of different vehicle parts (Fe, Cu, Mn and Zn), the road dust resuspension (Si, Al, Ca) and long range transport or regional background (Ca and K). Elemental carbon concentration (diesel engine emissions) was found to be proportional to traffic intensity.

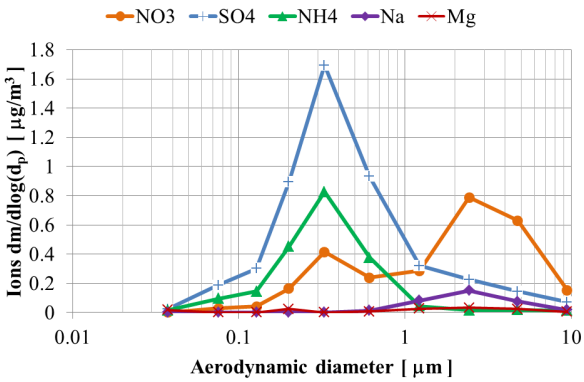

Figure 1. The mass size distribution of main ions from BLPI measured next to the freeway (Sep 2008).

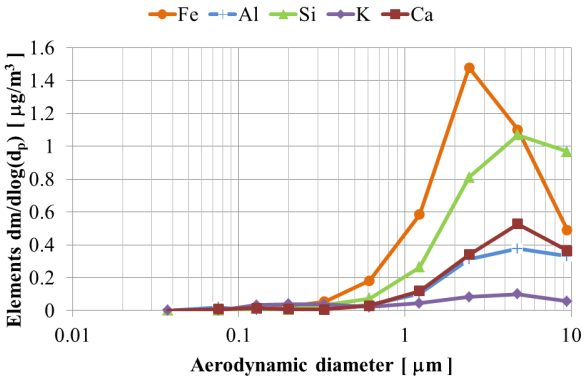

Figure 2. The mass size distribution of main elements from BLPI measured next to the freeway (Sep 2008).

Airborne particulate matters (PM) have been studied intensively for their environmental effects on the public health, the reducing visibility and solar radiation balance (Yatkin and Bayram, 2008). The aim of this study is to characterize and compare the PM and their composition fractions at urban of central Taiwan and provide the input data for air quality model. The sampling site is located at National Chung Hsing University campus, influenced by local sources. Thirty-six of 24-hour daily samples were collected at Taichung from April to December 2009 using a Dichotomous sampler (Andersen Instruments, Model 241, USA). Water-soluble ions (Na^+, Mg^{2+}, K^+, Ca^{2+}, NH_4^+, Cl^-, NO_3^-, SO_4^{2-}) in aerosols collected with quartz-fibers filters were determined using an ion chromatography (DX-100, Dionex, USA). Total carbon (TC) and element carbon (EC) were measured using an element analyzer (W.C. Heraeus elemental analyzer CHN-O-Rapid, EA).

The mass concentrations and the fractions of $PM_{2.5}$ and $PM_{2.5-10}$ chemical compositions sampling in diurnal and night time are presented in Figure 1 and Table 1, respectively. The average concentration of diurnal $PM_{2.5}$ is 31.1μg m^{-3} including SO_4^{2-} (25.3%), Organics (13.8%), EC (10.9%), NH_4^+ (10.6%), NO_3^- (6.0%), Mg^{2+} (3.5 %) and sea salt (1.9%). The percentage of other compositions is 26.6%. In the other hand, the average concentration of diurnal $PM_{2.5-10}$ is 23.4μg m^{-3}. The percentage of other compositions in coarse particle is up to 47.1%. The major fractions of $PM_{2.5-10}$ compositions are EC (16.7%), Organics (12.4%), NO_3^- (10.3%) and then sea salt (4.8%) in daytime. The results of daytime particle composition in $PM_{2.5}$ and $PM_{2.5-10}$ are shown that the hygroscopic aerosols including sulphate, nitrate, Organics and EC mainly exist in the fine particle (Tsai and Chen, 2006; Pope et al., 2010).

The average concentration of nighttime $PM_{2.5}$ is 35.7μg m^{-3}. Like the main $PM_{2.5}$ compositions sequence in daytime, that of main $PM_{2.5}$ compositions in nighttime is SO_4^{2-} (23.4%), Organics (14.1%), EC (10.5%), NH_4^+ (9.8%), NO_3^- (7.4%), Mg^{2+} (3.6 %) and sea salt (1.3%). The average concentration of nighttime $PM_{2.5-10}$ is 20.8μg m^{-3}. The fraction of other compositions in fine and coarse particle at nighttime is 28.4% and 39.7%, respectively. The major fractions of $PM_{2.5-10}$ compositions in nighttime are EC (18.0%), NO_3^- (13.9%), Organics (13.8%) and then sea salt (5.5%). Comparing the particle compositions at night between the fine and coarse particulate matters, the hygroscopic particles grow up in $PM_{2.5}$ mainly in theory and can be observed from Figure 1. Basically, there is no obvious difference for the composition proportions among the $PM_{2.5}$ and $PM_{2.5-10}$ aerosols sampling in daytime and night time.

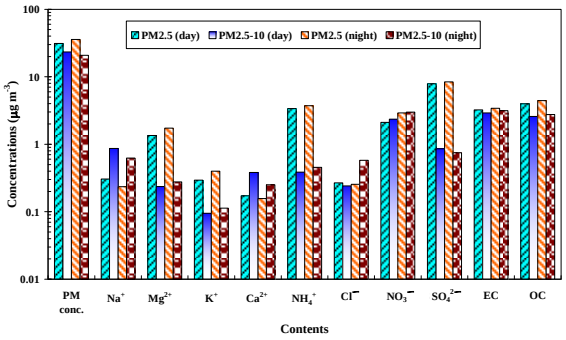

Figure 1. Mass concentrations of fine and coarse particulate matter compositions at Taichung, Taiwan in April – December 2009.

Table 1. Fractions of fine and coarse particulate matter at Taichung, Taiwan in April – December 2009.

Category	Fractions (%)										
	Na^+	Mg^{2+}	K^+	Ca^{2+}	NH_4^+	Cl^-	NO_3^-	SO_4^{2-}	EC	OC	others
$PM_{2.5}$ (day)	1.0	3.5	0.9	0.6	10.6	0.9	6.0	25.3	10.9	13.8	26.6
$PM_{2.5-10}$ (day)	3.6	0.9	0.4	1.8	.7	1.2	10.3	4.0	16.7	12.4	47.1
$PM_{2.5}$ (night)	0.6	3.6	1.0	0.5	9.8	0.6	7.4	23.4	10.5	14.1	28.4

Estimation of direct aerosol radiative forcing at Pune

G. V. Pawar[1], G. R. Aher[1] and P. C. S Devara[2]
[1]Physics Dept., Nowrosjee Wadia College, Pune (India), 411 001
[2]Indian Institute of Tropical Meteorology, Pashan, Pune (India), 411 008
[1]Physics Dept., Nowrosjee Wadia College, Pune (India), 411 001, +91(020) 26162944, +91(020) 26163108,
Keywords: Climate forcing, Aerosol direct radiative forcing, Aerosol optical depth.
Presenting author: aher.g.r@gmail.com.

Atmospheric aerosols are significant source of direct and indirect climate forcing hence are of primary concern due to their role in perturbing the Earth-atmospheric radiation balance. Hence there is considerable interest in quantifying and reducing uncertainties in the calculations of aerosol direct radiative forcing (ARDF), which is defined as the change in the global radiation balance attributable to changes in the amount of light scattered and absorbed by particles suspended in the atmosphere. In spite of how atmospheric aerosols affect the Earth's radiation budget, the ARDF has larger uncertainties than those of greenhouse gases due to the relative short life time, nonuniform composition, size, spatial and temporal distributions of aerosols in the troposphere (Chalson et al., 1992; Schwartz and Andrea, 1996).

Direct radiative forcing is estimated by modeling and experimental techniques. In the experimental technique, sunphotometer and radiation sensors play major role in the measurement of aerosol optical properties and the global solar flux respectively.

These data are employed to estimate aerosol direct radiative forcing (ARDF). MICROTOPS-II sunphotometer at 440, 500, 675, 870 and 1020 nm wavelengths and Eppley make Precision Spectral Pyranometer (PSP) in the spectral band 280-2800 nm are being simultaneously operated on clear sky days from Nowrosjee Wadia College, Pune to measure aerosol optical depth (AOD) and global solar flux respectively. Instantaneous AOD values normalized for air mass factor (m = sec Z, $Z \leq 70^0$, Z being solar zenith angle) at λ = 440, 500, 675 nm are correlated with global solar flux by using linear regression technique by following Jayaraman et al. (1998).

Slope of the linear regression fit yields a change in ground reaching global solar flux (ΔF) in W/m^2 per unit 0.1 increase in AOD at each wavelength. The zero AOD intercept gives surface reaching global solar flux for no aerosol. Fig.(1) illustrates an example on the day of January 2011. It is seen that the ARDF is – 163.37 $\pm$6.4 per unit 0.1 increase in AOD. Analysis of the data indicates that there is a significant day- to-day variation in ARDF values. This may be correlated with meteorological conditions at the observing site. In the present paper, seasonal variation of ARDF will be discussed. ARDF data obtained will be validated using model calculations.

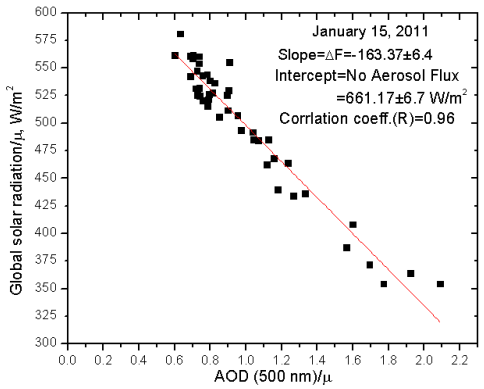

Fig.(1): Corrlation between measured Global solar flux and columanar aerosol optical depth values normalized for the air mass term 1/μ

Seasonal and statistical features of aerosol optical properties over different Indian sites

S. D. More[1], G. R. Aher[2] and P. Pradeep Kumar[1]

[1]Dept. of Atmospheric and Space Sciences, University of Pune, Pune 411 007, India
[2]Dept. of Physics, Nowrosjee Wadia College, Pune 411 001, India
Keywords: MODIS, Angstrom wavelength exponent, Atmospheric aerosol, Cloud Optical Depth
Presenting author email: aher.g.r@gmail.com.

Atmospheric aerosols are one of the most variable components of the Earth's atmospheric environment. They can affect and change the Earth-atmosphere system's radiation budget through direct effects, semi direct effects, the cloud albedo effect and the cloud lifetime effects (IPCC, 2007). Aerosol optical, physical and chemical properties have been studied in many regions of the globe; however the large spatio-temporal variability, short lifetimes and mixing processes lead to uncertainties on the effect of aerosols on climate system (Bouya et al., 2010). Understanding how aerosol properties vary locally would improve the current knowledge of aerosols around the world and would be useful in integrating global datasets. Satellite based remote sensing provides systematic retrieval of aerosol optical properties on regional and global scale.

In the present study, we employed multi-year MODIS/Aqua and Terra Data sets of column integrated aerosol and cloud optical properties over Western Himalayas [29.5^0 – 33.5^0 N, 76.5^0 – 80.5^0 E], Pune [19.5^0 – 17.5^0 N, 72.5^0 – 74.5^0 E] and Kolhapur [17.5^0 – 15.5^0 N, 73^0 – 75^0 E] to delineate the aerosol and cloud properties on monthly, seasonal and inter – annual scale and their statistical characteristics. Analysis of multi-year aerosol cloud optical data revealed strong seasonal and monthly cycles of atmospheric aerosol loading over all the sites. Monthly variation of both aerosol optical depth (AOD) and cloud optical depth (COD) show that, in general, both are low during Jan- March period. From April onwards, AOD/COD rise steadily to a high value in July which is a summer high for these regions. A gradual fall is noticed till September with small secondary peak in Oct-Nov months. Variation in Angstrom wavelength exponent (α) showed an opposite pattern. A linear least-squares fit can express the relationship between AOD and α [Fig.(1)]. The frequency distribution of AOD, COD and α follow a lognormal frequency distribution. Study indicates that the Gaussian model of the form:

$$y = y_0 + \frac{A}{w\sqrt{\frac{\pi}{2}}} \exp\left[-2\left(\frac{X-X_C}{w}\right)^2\right]$$

can be fitted to the entire data sets during 2000-2009 at all the observing sites.

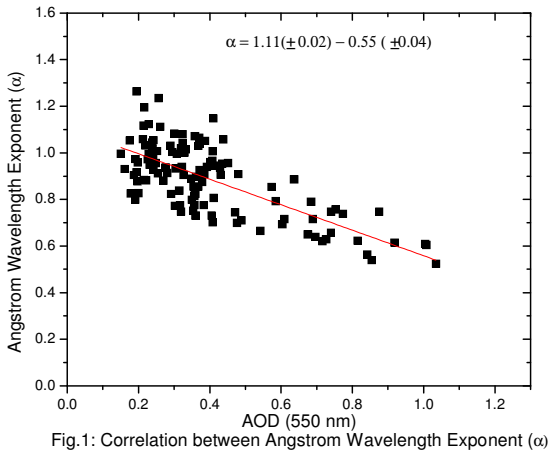

Fig.1: Correlation between Angstrom Wavelength Exponent (α) and AOD

Personal exposure to urban aerosol in terms of mobile particle number and surface area concentrations measurements

J. Gauweiler[1], K. Kordowski[1] and S. Weber[1]

[1]Climatology and Environmental Meteorology, Institute of Geoecology, Technische Universität Braunschweig, 38106, Braunschweig, Germany
Keywords: urban, surface area, particle number, mobile measurement.
Presenting author email: s.weber@tu-braunschweig.de

Introduction

Recent health related research indicated not particle mass, but number and surface area concentrations as particle metrics with best association to health impacts. It holds especially for the fraction of lung deposited aerosol, i.e. the alveolar lung deposited aerosol surface area concentration (ALDSA). This metric is of particular interest within cities due to the abundance of ultrafine particles (< 100 nm) in urban atmospheres (Morawska et al., 2008). Recently, mobile devices became available which are able to determine the fraction of ALDSA at a high temporal resolution.

The assessment of spatio-temporal variation in exposure of people towards urban particle number and surface area concentrations in different environments is an important topic in health related research.

Material and methods

The mobile measurements of particle number and surface area concentrations were performed in Braunschweig, Germany. A handheld miniature diffusion size classifier (miniDisc, Fierz et al, 2011) was used. The minidisc is capable of measuring particles at a 1Hz resolution in a size range of 10 nm < D_p < 300 nm. The alveolar lung deposited surface area is calculated from the charge distribution of the measured aerosol.

A number of 15 mobile measurements were performed in the time frame from 05 January to 09 February 2011. A 6 km measurement route was subdivided into 42 route sections representing common classes of land use in Braunschweig. The land use comprises of traffic sections (high density and main roads), residential areas, downtown pedestrian areas, urban parks and indoor passages (shopping malls). Each measurement took about 1 hour to minimise overlying trends of particle concentrations on the diurnal course.

Results

The urban particle number concentrations and ALDSA are clearly related to the different land use classes (Fig. 1). Highest concentrations are observed at the high density traffic sections (e.g. route sections 6, 7) with a mean ALDSA of about factor 1.8 above the average level of the measurement route. This corresponds to an absolute lung deposited surface area concentration of about 60.5 µm^2 cm^{-3} and a median particle number concentration of about 29,000 cm^{-3}.

The spatial pattern of particle number and surface area concentrations was consistently recurring during the 15 mobile measurements. More detailed results (e.g. dependence on meteorological conditions) will be provided during the poster presentation.

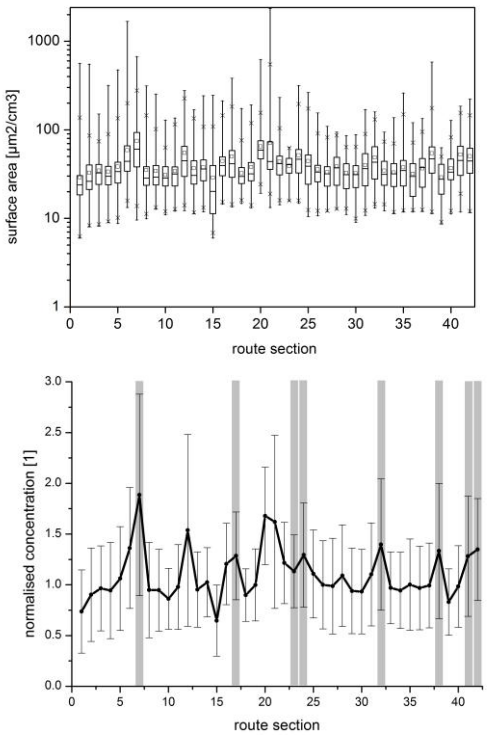

Fig 1 Top: Alveolar lung deposited surface area concentrations along 42 route section in Braunschweig, Germany. The plot indicates the mean (circles), median, 25 and 75 percentile (box), 1 and 99 percentile (asterisks) and absolute minimum and maximum (whiskers). Bottom: Mean normalised ALDSA during 15 measurements at the route sections. The high density traffic sections are indicated by grey shadings.

Large urban agglomerates are a significant source of aerosols and trace gases, with potential effects to the hydrological cycle (Lohmann and Feichter, 2005) and climate patterns. Atmospheric aerosols and trace gases are tightly connected via physical, chemical and meteorological processes. New ethanol based fuels for the worlds' vehicular fleet have been developed to reduce the dependence on fossil fuel, as well as to reduce carbon dioxide emissions. However, little is still known about their impacts on human health, air quality and climate. The metropolitan area of São Paulo, Brazil (MASP) is a unique laboratory for studying the complex physical and chemical processes associated with the use of bio-fuels. The MASP is special in the sense that bio-ethanol is the main fuel used along with its vast vehicular fleet counting 7.2 million and rising. At MASP, it has been estimated that out of the 7.2 million passenger and commercial vehicles 55 % of the burnt fuel is alcohol (CETESB, 2007)

The site locates roughly 10 km from the city centre, at the western edge of the most densely populated area. São Paulo city is surrounded by vast suburban areas populated by 20 million people, resulting in the world 7th biggest metropolitan area. The city of São Paulo is located on a plateau 860 meters above sea level (a.s.l.) surrounded by hills rising up to 1200 meters a.s.l.

Total particle concentrations are measured with a CPC and the aerosol size distributions are measured from 2 to 800 nm with a differential mobility particle sizer (DMPS) and a Neutral cluster and Air Ion Spectrometer (NAIS). In addition light scattering and light absorption coefficients are measured using a three wavelength TSI nephelometer and a Multi Angle Absorption Photometer (MAAP).

Table 1. Comparison between theoretical predictions and experimental measurements.

Day	$GR_{6\text{-}20}$ (nm h^{-1})	J_6 ($cm^{-3}s^{-1}$)
10 Oct	25.1	11.2
2 Nov	9.3	11.4
7 Nov	16.1	18.5
15 Nov	10.7	4.5

New particle formation events were observed with growth rates ranging from 9 to 25 nm h^{-1} (Table 1). The measured total particle concentration typically varies between 10 and $30 \cdot 10^3$ cm^{-3} being the lowest late in the night and highest around noon and frequently exceeding $50 \cdot 10^3$ cm^{-3}. The median modal peak of the size distribution was 24 nm. Clear diurnal patterns in aerosol optical properties were observed ranging between 21 and 64 Mm^{-1} for light scattering coefficients (σ_{SP}) and between 12 and 33 Mm^{-1} for light absorption coefficients (σ_{AP}).

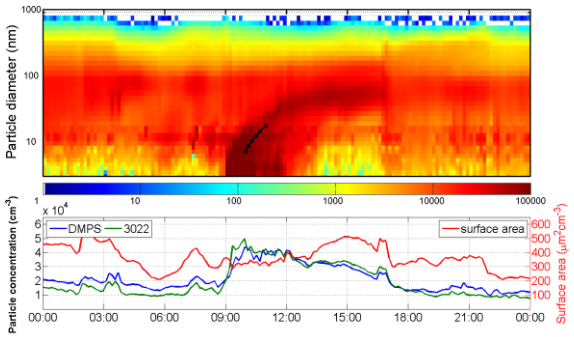

Figure 1. *The first nucleation event measured on the 2nd of November 2010. The growth rate of 9.3 nm h^{-1} was calculated using DMPS data from 6 to 20 nm indicated by black circles.*

The effects of intensive BIO-Fuel production and USE on regional air quality and global climate (BIOFUSE) was supported by the Academy of Finland's Sustainable Energy Research Programme (SusEn) and by the Brazilian National Council for Scientific and Technological Development (CNPq)

Comparison of a New Optical Particle Sizer to Reference Sizing Instruments for Urban Aerosol Monitoring

A.F. Zerrath[1], O.F. Bischof[1], H.-G. Horn[1], T. Krinke[1], T. Johnson[2] and K. Erickson[2]

[1]TSI GmbH, Neukoellner Str. 4, 52068 Aachen, Germany
[2]TSI Inc., 500 Cardigan Road, 55126 Shoreview, MN, USA
Keywords: optical counter, number size distribution, environmental particles, monitoring
Presenting author email: axel.zerrath@tsi.com

Optical Particle Counters are in widespread use for measuring various aerosols including environmental monitoring.

Since almost all optical particle counters and spectrometers are factory-calibrated with polystyrene latex (PSL) particles, sizing errors could be significant if the refractive indices of the aerosol are significantly different from the refractive index of PSL of 1.59.

Hand and Kreidenweiß (2002) have shown how to determine unknown aerosol properties like refractive index and effective density by using the combination of sizing by the particles' electrical mobility, aerodynamic and optical properties.

TSI has developed a new Optical Particle Sizer (OPS), the Model 3330. It is a lightweight, portable unit that provides fast and accurate measurement of particle concentration and size distribution using optical single particle counting technology. It is a new instrument with various technical improvements, which allows high resolution monitoring of aerosols in the range from 0.3 to 10 µm, with user-adjustable size classes, size resolution of up to 16 channels and measurement time down to 1 second.

In order to address the issue of the material dependence of optical sizing, the OPS features real-time Mie scattering calculation capability to adjust the PSL calibration curve to a curve that better fits the aerosols of interest. The refractive index value can be adjusted for real and imaginary components for every size class. For non-spherical particles, an additional shape factor can be entered to perform further adjustment of the calibration.

Data processing and analysis software also allows a unique density for every size channel to be entered to improve mass concentration measurement. In addition, humidity and temperature sensors are integrated into the OPS instrument.

The OPS was launched in late fall of 2010 and first results will be explained. A sample data set is shown in figure 1. This presentation focuses on the results obtained from monitoring urban aerosol in the city of Aachen (Germany), with the OPS in comparison to reference particle sizing instruments like the Scanning Mobility Particle Sizer (SMPS) for ultrafine and the Aerodynamic Particle Sizer (APS) for coarse particles.

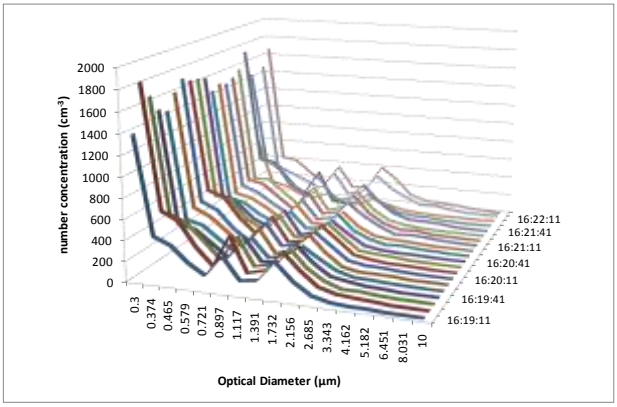

Figure 1: Atmospheric aerosol measured with the OPS 3330 in January 2011.

In the spring of 2011 a measurement campaign monitoring urban aerosol using OPS, APS and SMPS in parallel was conducted in the city of Aachen. The SMPS provided high-resolution submicrometer size data in the range of up to 1 µm. The APS was used as high-resolution reference for coarse aerosols in the range from 0.37 µm to 10 µm. One of the OPS' pre-configured, user adjustable size channel configurations uses the same channel width and resolution as the APS Model 3321. The difference between the optical equivalent diameter obtained from the OPS and the aerodynamic diameter from the APS thus includes information on effective density, shape and refractive index. The results presented here evaluate the OPS' performance for real-time environmental monitoring. This study builds on the measurement of urban aerosol in Aachen as reported earlier (Zerrath and Bischof, 2005).

Particle area and number concentrations influenced by local sources at an urban background station in Germany

H. Gerwig[1], W. Pecher[1] and K. Wirtz[1]

[1]Section Air Quality Standards and Monitoring Methods, UBA – Federal Environmental Agency, 63225 Langen, Germany.

Keywords: particle area, car traffic, asphalt grinding, gas-fired CHP, airport

The European Union defined a daily average PM_{10}-limit of 50 µg · m^{-3} for the protection of human health (2008/50/EC). Epidemiological and toxicological studies give evidence that ultrafine particles (< 100 nm, UFP) show negative health effects (Knol *et al.*, 2009).

Reduction limits for diesel cars are fixed (EURO VI). To control the results of reducing emitted particle numbers from cars and especially trucks, governmental agencies in Germany started to measure ultrafine particles on a routine base (Birmili *et al.* 2009 and Löschau *et al.* 2010).

Table 1 1-h av. tracheobronchial particle area and particle conc. 09-09-2009 – 14-06-2010

	NSAM	UCPC	SMPS
	µm²/cm³	p / cm³	p / cm³
nm	10 - 1000	3 - 1000	10 - 500
Median	5.0	9 900	8 600
Std	3.1	6 100	6 000
5 Perc	1.9	4 600	3 700
95 Perc	11.7	22 500	21 000

The urban background station was situated in Langen, Germany: 15 km south of Frankfurt a. M. and 5 km south east of the airport in the Rhine-Main-Area. Three different particle measuring instruments (TSI Inc.) were running continuously (09-09 – 06-11, 1 min av. and SMPS 6 min av.) on a rooftop at 14 m above ground with cut of at 1 µm. NSAM measures the deposited tracheobronchial (= tb) particle area within particle diameter of 10 - 1000 nm. With UCPC 3776 particle number concentration from 3 - 1000 nm was measured. With SMPS 3936 and CPC 3010 particle number size distributions between 10 – 500 nm were detected. 6 size classes were calculated from SPMS data (10 |30 |50 |70 |100 |200 |500). The difference of UCPC and total SMPS was expected to be size class 3 – 10 nm Offsets between both instruments cannot be excluded.

Temperature, humidity, wind speed, wind direction, precipitation was collected by WS600 (LUFFT GmbH). Only complete datasets of 1 h av. were used for evaluation (85 % of time period). For diurnal Mo-Fr variations data from official holidays and from 23-12-09 until 03-01-10 were excluded.

During the measuring period the median of the tb particle area concentration was 5 µm²/cm³, particle number concentration from 10 to 500 nm was about 8 600 p · cm^{-3}. 1 300 p · cm^{-3} more particles were found from 3 to 1 000 nm range (s. Tab. 1). The temperature was between -15 and +30°C, wind speed up to 14 m · s^{-1}.

For diurnal variations from Monday to Friday 2 different shapes were detected (Fig 1). Shape A: Tb particle area and particles 30 – 500 nm showed a 1st min. around 4:00, max. at 9:00 and 2nd min. at 15:00, similar to previous observations at an urban background during UFIPOLNET (Wehner *et al.*, 2008). Shape B: Particles 3 – 10 nm showed 1st max between 13 – 15:00 probably caused by particle nucleation events and a 2nd max at 7:00. Particles 10 – 30 nm show almost the same diurnal variation as shape A except for afternoon, were the second min. looks as if overlayed by effects responsible for shape B.

Grinding up asphalt and other road construction work in 10 to 100 m distance caused raised particle area and number concentrations. Elevated particle concentration occurred with winds from a nearby combined heat and power gas-fired power plant (CHP). The influence of the airport will be evaluated. The influence of fireworks is described elsewhere (Gerwig *et al.*, 2011).

Personal exposure to fine PM in Milan: a comparison of different travel modes

G. Lonati[1], S. Ozgen[1] and G. Ripamonti[1]

[1]Department of Environmental, Hydraulic, Infrastructures and Surveying Engineering
Politecnico di Milano, Milano, 20133, Italia
Keywords: exposure, PM2.5, PM1, number concentration.
Presenting author email: giovanni.lonati@polimi.it

Emerging evidence suggests that short events of high exposure to particulate matter (PM) occur while travelling in urban areas, depending on the transport mode (Briggs *et al*., 2008; Knibbs and de Dear 2010).

This study compares the personal exposure to fine PM while travelling with different means of transport along a city-centre trafficked road, about 2 km long. For this purpose, 1-min average concentrations were measured with portable instruments during 2 weeks in July 2010, for 3-times a week, on workdays between 3 p.m. and 5 p.m.. The measurements relate to three surface transport modes (i.e., on foot, by bike, by car) and to the underground train (subway). Travel by each mode lasted about 30 minutes, allowing 1 round trip for the walking mode and 2 round trips for the other modes.

Particle number concentrations in the 0.3-2.5 µm size range were measured by means of an optical particle counter (Contec Personal DustMonit, Italy); mass concentrations (PM0.3-1, PM0.3-2.5) were subsequently estimated based on size-resolved density factors for Milan urban area. Particle number concentrations (PNC) in the size range 0.02-1 µm were measured by means of P-Trak UFP Counter (TSI Model 8525, USA). Both instruments were held in a backpack during the travels. During the car trips, the backpack was on the front passenger seat, car windows were closed and the cabin filtered air recirculation was turned on.

Table 1. Concentration levels (avg.±st.dev.) measured in the travel modes.

Travel mode	PM 0.3-1 (µg m^{-3})	PM 0.3-2.5 (µg m^{-3})	PNC 0.02-1 (10^4 cm^{-3})
Car	2.3±1.8	3.2±2.4	1.2±1.2
Walk	10.7±2.0	19.5±3.1	2.2±1.7
Bike	11.4±2.6	21.0±3.9	2.7±1.4
Subway	20.0±7.5	57.3±30.3	1.5±0.2

Results

The comparison between the average mass concentration levels observed for the different travel modes (Table 1) shows the benefit of the filtered cabin air recirculation inside the car. The outside air ambient concentrations, measured during the walking and biking modes, were about 80% reduced in the car cabin. Comparable levels were observed for the walking and biking modes, with slightly higher levels for this latter. The subway mode line concentrations were, on the other hand, the highest (from two to three times compared to outside ambient air) and the most dispersed measured in this study.

Larger differences between travel modes were observed for the PM0.3-2.5 size range (Figure 1). The benefit of the car cabin air filtration is more evident: in fact, supermicron particles (dp > 1µm) strongly affected the mass concentration levels for all the other travel modes. Their average contribution to the PM2.5 mass was about 50% for the walking and biking modes and up to about 65% for the subway mode.

PNC average levels were in the 1-3·10^4 cm^{-3} range, displaying large variability for all the surface travel modes (Figure 2). Conversely from the mass, the average PNC levels for the subway mode were similar to the cabin car levels and the highest concentration were measured for the biking mode.

Atmospheric aerosols - Aerosol Processes and Properties

Ground-based Aerosol Optical Properties and radiative forcing over Karachi Pakistan

K. Alam[1], T. Trautmann[2], T. Blaschke[1,3]

Key words: Aerosol; Radiative forcing, Karachi, AERONET
Khanalamso@gmail.com

Aerosol optical properties have been analyzed through the ground-based Aerosol Robotic Network (AERONET) over the mega city Karachi during August 2006-July 2007. The aerosol optical depth (AOD) is strongly dependent on wavelength; for shorter wavelengths AOD values are higher than at longer wavelengths. The results reveal that the monthly average AOD at 500 nm ranges from 0.38 to 0.98 with an annual mean of 0.56±0.18 and monthly averaged angstrom exponent (Alpha) ranges from 0.17 to 1.05 with an annual mean of 0.55±0.31. The maximum monthly average AOD value of 0.98±0.30 with the corresponding Alpha value of 0.17±07 is found for July 2007, while the minimum monthly average AOD value of 0.38±0.09 with the corresponding Alpha value of 0.28±0.13 is recorded for May 2007 (Figure 1).

The volume size distribution in the coarse mode is higher in summer and lower in winter, whereas in the accumulation mode the volume size distribution is higher in winter than in other seasons due to the hygroscopic growth of aerosol particles (Figure 2). The single scattering albedo (SSA) during spring, autumn and summer seasons shows a slight increase with the wavelength and ranges from 0.88±0.02 to 0.97±0.01. The asymmetry parameter (ASY) is also wavelength

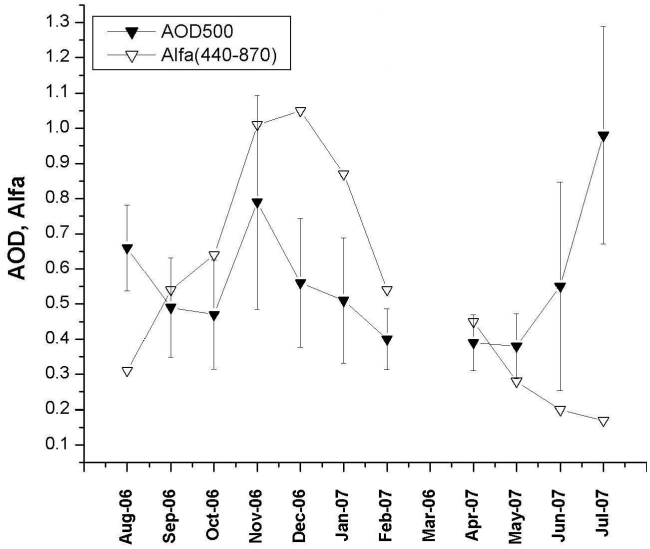

Figure 1. Monthly average variation of AOD at 500 nm and corresponding Alpha (440-870) during August 2006-July 2007.

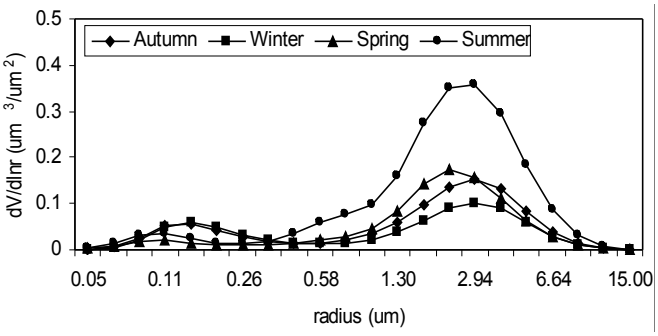

Figure 2. Seasonal variations in AERONET retrieved aerosol size distributions during August 2006 to July 2007.

dependent and varies from 0.61±0.03 to 0.74±0.02 during the year. The aerosol radiative forcing (ARF) for the whole observation period at the top of the atmosphere (TOA) is in the range of -7 to -32 Wm^{-2} (average -19±6 Wm^{-2}), at the surface from -56 to -95 Wm^{-2} (average -74±12 Wm^{-2}), increasing the atmospheric forcing from +37 to +85 Wm^{-2}(average +55±13 Wm^{-2}).

We would like to acknowledge the Higher Education Commission (HEC), Pakistan, and the Austrian Exchange Service (ÖAD) for providing a three year Ph.D. scholarship 2008-2012 to Khan Alam.

Carbonaceous particles and their influence on spectral optical properties and humidification response

S. Lee[1], S.-C. Yoon[1], Y.-P. Kim[2] and S.-W. Kim[1]

[1]School of Earth and Environmental Sciences, Seoul National University, Seoul, 151-742, Korea
[2]Environmental Engineering and Science, Ewha Womans University, Seoul, 120-750, Korea
Keywords: black carbon, organic carbon, humidification, mass absorption cross section.
Presenting author email: ryra78@hanmail.net

Black carbon (BC) particles are freshly emitted into the atmosphere through the incomplete combustion of fossil fuel and biomass burning. Although BC particles are initially hydrophobic, these particles gradually become mixed with soluble components through condensation, coagulation, and photochemical oxidation processes in the atmosphere (Zhang *et al*., 2008). If BC particles have a humidification response from the aging process, it is very important phenomenon for the climate change since aged BC can act as cloud condensation nuclei. The aim of this study is to investigate the optical properties and humidification of carbonaceous particles for the different airmass in East Asia.

Aerosol chemical composition and fine mode fraction (FMF) are used for the criteria of case selection. Pollution cases of period 1 and 2 (P1 and P2) are determined by relatively high $PM_{2.5}$ with large mass concentrations of organic carbon and sulfate during three days in May and June, which is above the upper 10 percentile of all dataset during May to November 2009. Polluted dust (PD) case is selected in the conditions of relatively high PM_{10} with high mass concentration of coarse–mode calcium and low FMF from 21st to 23rd October, which are above upper 10 percentile and below lower 10 percentile of all dataset, respectively.

Figure 1 shows the scattering and absorption coefficients as a function of wavelength for each case. Overall wavelength, scattering coefficient is the highest for P2 since the light scattered aerosols in fine–mode are high, but the scattering coefficient at PD shows the relatively flat slope due to the high concentrations of coarse–mode particles. In Figure 1(b), the difference of absorption coefficient between P1 and P2 is very low, 1.04 Mm^{-1} at 950 nm, but it increases to 5.17 Mm^{-1} at a shortwave of 370 nm. Generally, the absorption by organic species (sometimes called brown carbon) takes place in the UV for the presence of resonant ring structures (Yang *et al.,* 2009). In addition, the mineral aerosols derived from soil could exhibit high absorption in a shortwave (Satheesh *et al.,* 2007). Likewise, aerosol absorptions at P1 and PD are noticeably high in a shortwave as shown in Figure 1(b).

In Figure 2, the relationship between relative humidity (RH) and single scattering albedo (SSA) are compared for each case with considering the mass absorption cross section (MAC). In general, MAC is not only the ability of carbonaceous particles to absorb a photon in a particular wavelength, but it also serves as one convenient proxy for the relationship between radiative transfer and the aerosol mass represented in models (Bond *et al.,* 2006). Figure 2 shows the increase of SSA with increasing RH for all cases. It is because the hygroscopic chemical components, such as sulfate, nitrate and some organic matters can take up water vapor to grow in size and thus enhance the scattering ability. In particular, PD case shows the lower MACs than those of P1 in high RH above 70 %, although the SSAs are similar for both cases.

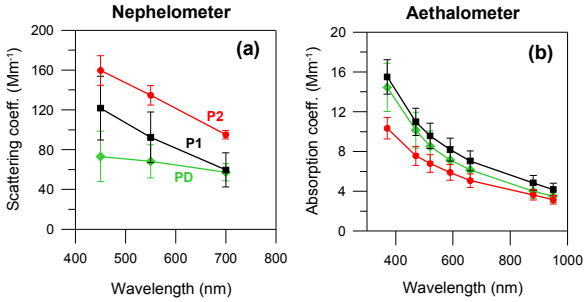

Figure 1. Aerosol scattering and absorption coefficients as a function of wavelength.

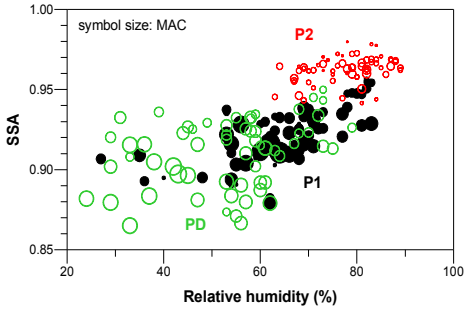

Figure 2. Relationship between RH and SSA for each case. Note, symbol size is described in proportion to the mass absorption cross section.

Presenting author email: xuguang.chi@mpic.de

The Zotino Tall Tower Observatory (ZOTTO) is located in the boreal forest of central Siberia (89.35°E, 60.80°N,114m asl). The tower is 300 meters high and was designed for long-term atmospheric observations at this very remote, continental site. Continuously measurements of comprehensive sets of atmospheric constituents in gas and aerosol phase together with meteorological parameters have been carrying out at ZOTTO since October 2006 (Heintzenberg et al. 2008). Among the others, the particulate scattering is measured by a TSI three-wavelength (450 nm ,550 nm ,700 nm) nephelometer (Model 3653), the particulate absorption is measured by making use of a single wave length Particle Soot Absorption Photometer (PSAP, 574nm, Radiance Research), and the CO mixing ratios are recorded by a fast CO monitor (Model AL5002, aerolaser).

In order to correct for the truncation and illumination non-idealities, the scattering coefficients derived from nephelometer were calculated follow the empirical correction formula of Anderson and Ogren (1998). For PSAP, the resulting absorption coefficients are corrected for the scattering artifact as well as calibration error after Virkkula et al. (2005). For CO measurements, a statistical filtering approach called REBS (Ruckstuhl et al. 2010) is applied for extracting background concentrations.

Particulate absorption shows a smooth seasonal variation with a maximum in later winter and a broad minimum in summer, whereas particulate scattering exhibits a double maximum in winter and summer (Figure 1). We hypothesize that the winter maxima for both parameters are due to northern hemispheric fossil fuel combustion, while the elevated scattering coefficient in summer may be results of enhancement of both biogenic emission and the formation of secondary species by photo-oxidation. Furthermore, for both scattering and absorption, the highest daily average values are found in April and May, which seems caused by the spring agriculture fires (which are often spread to forest) in upwind areas. The CO exhibits a similar seasonal variation (Table 2) as for particulate absorption. By applying REBS approach, 21% of observed hourly CO values are classified as polluted. For these CO polluted periods, the ratio between particulate absorption (σap) and increased CO (ΔCO) are calculated, where ΔCO is the difference between observed CO and the estimated background CO by REBS. Higher ratios are found in spring and winter than in the other two seasons, which may be indication of different combustion sources.

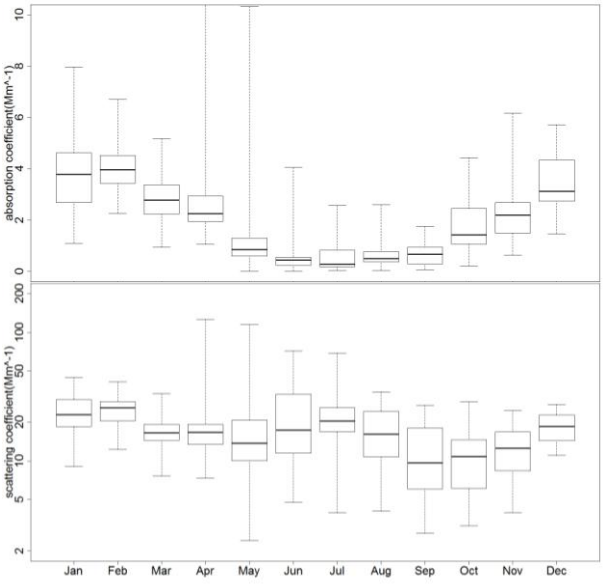

Figure 1. A standard box plot of monthly aerosol absorption coefficient (top) and scattering coefficient (bottom) at 574 nm as derived from daily average for 50m height level taken over the time period October 2006 through April 2010.

Table 1. CO mixing ratios and Bap to ΔCO ratios (only for CO polluted episode) for 50m height level as derived from hourly average since October 2006 to April 2010.

Season	CO (ppb) Median (min-max)	σap/ΔCO (Mm^-1/ppb)
Spring	162 (117-472)	0.183±0.092
Summer	100 (85-889)	0.083±0.069
Fall	116 (93-175)	0.130±0.096
Winter	179 (116-300)	0.192±0.086

Light Scattering by airborne Saharan Dust particles.

D S McCall, E Hesse, Z Ulanowski

Centre for Atmospheric and Instrumentation Research, University of Hertfordshire, AL10 9AB
Keywords: Saharan, scattering, aerosol
Presenting author email: d.s.mccall@herts.ac.uk

The importance of airborne particulates to the Earth-Atmosphere radiation balance is well established. Aerosols such as ice crystals (e.g. those found in cirrus clouds) and Saharan dust particles (Yu et al. 2006) have direct effects on the worlds energy budget by scattering and absorbing solar radiation. The level of influence of atmospheric dust on global energy cycles is unclear, primarily due to large uncertainties regarding the optical properties of the dust particles.

An investigation into the light scattering properties of Saharan dust grains is presented. An electrodynamic trap (Ulanowski et al. 2006) has been used to levitate single dust particles. By adjusting the trap parameters, partial randomisation of the particle orientation has been introduced. While levitated, the particles were illuminated by a laser, and a rotating half-wave retarder enabled selection of vertically or horizontally polarized incident light. A laser diffractometer and linear photodiode array have been used to measure intensity at scattering angles between 0.5° and 177°. Approximating the direct forward scattering region by Fraunhofer diffraction as calculated for a range of appropriately-sized elliptical apertures allows the calculation of the phase function and degree of linear polarization.

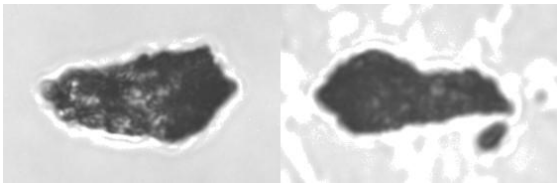

Figure 1. Transmission microscopy images of a dust particle with aspect ratio 2 and size parameter approximately 125. The particle has been rotated 90° about its long axis.

The phase functions and degree of linear polarisation for four case study particles are presented - the phase functions are found to be featureless across most of the scattering region, with none of the halo features or rainbow peaks associated with regularly shaped particles such as hexagonal columns or spheres.

Particle reconstructions comprised of high numbers of facets have been constructed to resemble the levitated particles. Utilizing Gaussian random sphere methods (Muinonen et al. 1996), increasing levels of roughness have been added to the surfaces of these reconstructions.

A Geometric Optics model and a related model, Ray Tracing with Diffraction on Facets (RTDF) (Clarke et al. 2006), have been modified to calculate scattering on these particle reconstructions. Scattering calculations were performed on each of these reconstructions using a range of refractive indices.

Qualitative comparisons are performed on the phase functions and degree of linear polarization, where it is observed that the addition of roughness to the modelled spheroids improves the fit between the computed phase functions and those measured from the levitated particles. The phase functions are quantitatively compared using RMS errors, and further comparison is performed using the asymmetry parameter.

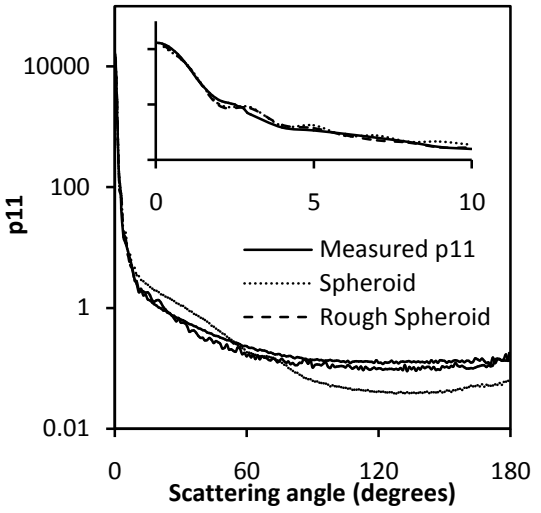

Figure 2. Measured phase function for the particle shown in Figure 1, along with RTDF calculations for a smooth spheroid and a rough spheroid. The refractive index used in the calculations was 1.55 + 0.003i.

AERONET and SKYNET are two well known international networks whose main objective is to provide near real time measurements of columnar aerosol properties for climate research and remote sensing correction. Both networks have their own quality standards and impose homogeneity on the processing of their instruments data.

AERONET is present worldwide, and employs the CIMEL CE318 sun – sky radiometer as the standard instrument for the measurement of sun direct and sky diffuse radiances. Through the use of an inversion algorithm (Duvobik *et al*., 2002) a rather complete set of columnar aerosol optical properties is provided near on real time: aerosol optical depth (AOD), size distribution, phase function, complex refractive index and single scattering albedo.

On the other hand, SKYNET is mostly extended in Eastern Asia. The equivalent standard instrument is the Prede POM radiometer, and the aerosol properties are retrieved by an open source code called SKYRAD (Nakajima *et al*., 1996).

The European Skyrad users network (EuroSkyrad or ESR) is federated with SKYNET and represents a collaboration between users of the SKYRAD algorithm. The main original objective of ESR was the synergistic study of both AERONET and SKYNET networks in Europe. Currently, ten different sites (CE318 and POM instruments) are part of this initiative, mostly in United Kingdom, Italy and Spain.

Although the network is mainly addressed to Prede POM and independent Cimel CE318 users, few ESR sites employ collocated AERONET/Cimel and Prede radiometers, enabling an accurate comparison of the different approaches used by these networks.

In addition to the comparative study of the AERONET and SKYRAD methodologies, ESR has developed its own package of open source code programs. This collection (called ESR.pack) can be directly applied on both instruments, and consists of a selection of AERONET and SKYRAD methods, for the homogeneous elaboration of sun direct and sky diffuse measurements.

In a previous work, the comparison of the ESR.pack direct sun products (AOD) was addressed for a one month database (Estellés et al., 2010). The differences between AERONET and ESR.pack AOD retrievals on CE318 instruments were lower than 0.001 – 0.002 for 440 – 1020 nm channels, and slightly higher for 340 nm channel (~0.005). These values are lower than the expected uncertainty for a master AERONET instrument (0.003) and much lower than the uncertainty stated for an AERONET field instrument (0.01 – 0.02).

When the ESR.pack Cimel and Prede retrievals are compared, the differences were better than 0.003 – 0.006 for the 440 – 1020 nm channels. The comparison of AERONET/Cimel and ESR/Prede showed also a very good agreement (0.004 – 0.007).

Currently, a more complete and improved version of the ESR.pack has been developed, including the retrieval of Ångström exponent and water vapor content. Moreover, the compared database has been extended to a 3 year database obtained in Valencia (Spain). The effect of several assumptions are discussed in this work.

In addition to the direct sun programs, the ESR.pack has been completed with a sky diffuse inversion algorithm (SKYRAD version 4.2). In contrast to AOD retrievals, the inversion of sky radiance is an ill-posed problem whose solution is very sensitive to different assumptions and inputs, as previously shown by Che *et al*. (2008).

In this work we show the comparative analysis of AERONET and ESR inversions for a benchmark of one month sky diffuse data obtained in Valencia (Spain) during 2009 with a Cimel CE318 radiometer, including a preliminary discussion on the different importance of the model assumptions.

Keywords: AOD, Aerosol model, Aerosol characterization, Aerosol radiative forcing
Email: shubhaverm@gmail.com, shubha@iitkgp.ac.in

Aerosols perturb the climate system by scattering and absorbing the solar radiation (direct effect) and by altering the lifetime of clouds (indirect effect). Aerosol measurements carried out during the Indian Ocean experiment (INDOEX) (Ramanathan et al., 2001) showed an enormous amount of aerosol transported to the Indian Ocean originating from Indian subcontinent and adjoining regions (Verma et al., 2007). The Indo-Gangetic basin (IGB) situated in the northern part of the India (comprising of ~ 21% Indian land area), is one of the densely populated regions (supporting ~40% Indian population) and has been identified as one of the regional hotspots in the air pollution scenario. In the present work, we present an analysis of aerosol properties from various surface based measurements in the eastern IGB and their comparison with satellite retrieved data during December (2009) in the winter season and evaluate their chemical constituents, sources of origin, and radiative effects through combination of measurements and modeling tools.

Measurements of aerosol optical depth (AOD) using handheld Microtops II Sun photometer showed a monthly mean value of 0.84±0.13 at 0.5 µm. An aerosol model developed using Mie theory through optical properties of aerosols and clouds (OPAC) software package (Hess *et al.*, 1998) showed that the mineral dust contributed maximum (76%) to total aerosol surface mass concentration. However, water soluble constituents (such as sulphates, nitrates, organics) followed by black carbon contributed 60% and 26% respectively, to the total AOD. The single-scattering albedo (ω) estimated at 0.5 µm was 0.74±0.03, and is lower than the ω value reported for most of the Indian cities.

Moderate Resolution Imaging Spectro-radiometer (MODIS) retrieved AOD showed a good correlation with model estimated AOD at 0.55 µm (correlation coeff. = 0.85) (Figure 1). However MODIS retrieved mean AOD at 0.55 µm (0.61±0.15) is found to underestimate the model estimated AOD at 0.55 µm (0.75±0.11). Aerosol radiative forcing (ARF) estimated using a discrete ordinate radiative transfer model at surface, TOA and atmosphere and atmospheric heating rate calculated are shown in the Figure 2. The average ARF is estimated to be -51.8±6.2 wm^{-2} at surface level while average TOA forcing is -3.3±1.9 wm^{-2}. The atmospheric heating rate due to aerosols is found to vary from 1.0 to 1.6 K per day.

Details on model estimated aerosol optical properties over the east IGB and its comparison with surface based measurements and satellite retrieved aerosol optical properties will be presented.

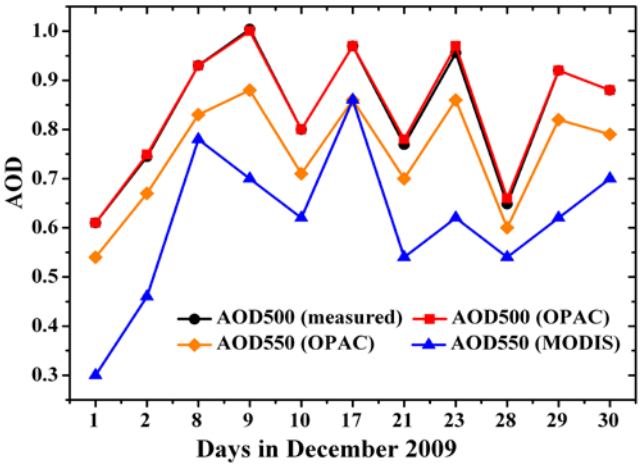

Figure 1. Comparison of measured (0.5 µm), MODIS (0.55 µm) retrieved and model estimated (0.5 and 0.55 µm) AOD values.

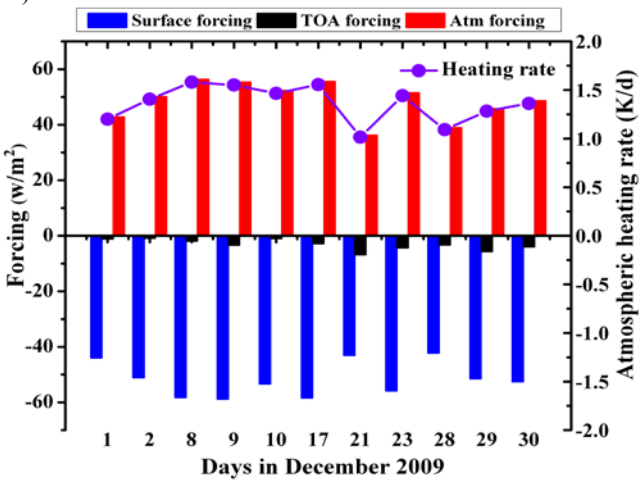

Figure 2. Shortwave direct aerosol radiative forcing (0.25 to 4.00 µm) at the surface, top of the atmosphere and in the atmosphere and atmospheric heating rate.

Particle concentrations in Apulia Region PM natural excedancees

M. Amodio, E. Andriani, P.R. Dambruoso, G. de Gennaro, A. Demarinis Loiotile, A. Di Gilio, L. Trizio

Department of Chemistry, University of Bari, via Orabona, 4, 70126, Bari, Italy
Keywords: optical counter, dust, PM10/PM2.5, natural aerosols.
Presenting author email: eleonora.andriani@chimica.uniba.it

Particulate matter (PM) sources and processes have been deeply investigated in order to provide useful information for air quality management policies. In fact, epidemiologic studies suggested the relevant role of ambient PM in contributing to a range of health effects (Nadadur et al., 2009). These effects have mainly been determined by taking into account data obtained by PM mass-measuring instruments but, recently, it has been suggested that adverse health outcomes depend on the number rather than the mass of fine particles (Sager and Castranova, 2009). Moreover, particle number can be considered an important indicator to characterize the most relevant sources affecting PM concentrations.

In this work, the results obtained by applying an integrated system in PM monitoring campaign are shown. The collected data allowed to determine the different origin of high PM events. In particular, the system allowed to characterize the PM_{10} exceedances due to natural events, such as Saharan dust episodes; this information offers the possibility to discount natural exceedances according to the European Commission regulation (2008/50/EC).

The campaign was performed from October 2007 to December 2009 (data coverage: 79%). The monitoring station was located close to Chemistry Department, University of Bari (urban background), Apulia Region (South of Italy). It was equipped with: SWAM Monitors, dual channel system for automatic sampling of PM_{10} and $PM_{2.5}$; OPC monitor, optical particle counter that allows to perform the real-time dimensional characterization of particles with optical diameter greater than 0.3 µm; PBL Mixing Monitor, a sequential automatic system able to estimate the low PBL layers mixing ratio by means of ß activity related to Radon decay products. Some PM samples (PM_{10} and $PM_{2.5}$) collected in this period were characterized in order to determine inorganic components (Cl^-, NO_3^- , SO_4^{2-}, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}), Polycyclic Aromatic Hydrocarbons (PAHs) and carbonaceous fraction (OC, EC). Finally, daily results of aerosol models (DREAM and NAAPs) and 5-days backward trajectories (HYSPLIT Trajectories) were evaluated to confirm the outbreak from Saharan desert in the Southern regions of Italy.

The PM_{10} excedancees occurred from 28th October to 2nd November are shown in Fig. 1: they were characterized by low $PM_{2.5}/PM_{10}$ ratio and high dispersive atmospheric conditions (Perrino et al., 2009). Information provided by aerosol models and 5-days backward trajectories (data not shown) identified the outbreak from Saharan desert in the Southern regions of Italy. In these days, the OPC data pointed out a significant increase of particles which diameter ranging between 0.94 and 1.54 µm (Fig. 2): this behaviour has been found when African dust contribution occurred at the sampling site and allowed to suggest this range as 'indicator' of Saharan dust intrusion. The chemical characterization of samples (data not shown) allowed to determine that the ionic coarse fraction exceeded the 50% of PM_{10} ionic fraction (its mean contribution is equal to 30%); moreover, a good correlation between PM_{10} calcium and carbonate was observed.

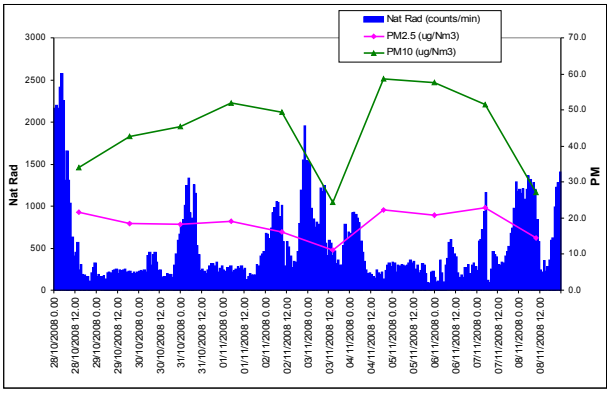

Figure 1. PM_{10}, $PM_{2.5}$ and natural radiation (28 Oct. 2008 - 8 Nov. 2008).

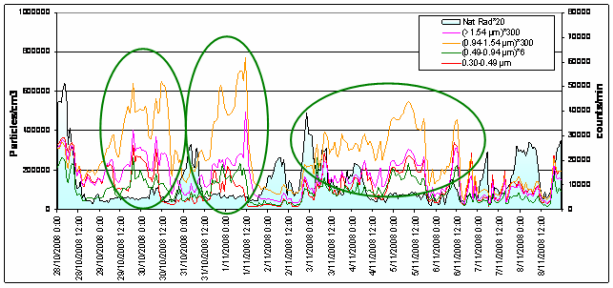

Figure 2. Trends of particles number concentrations and natural radiation counts (28 Oct. 2008 - 8 Nov. 2008).

Aerosol optical properties over East Asia: An integrating CMAQ-simulated and satellite-retrieved aerosol data using a data assimilation technique

C.H. Song, R.S. Park and K.M. Han and M.E. Park

Advanced Environmental Monitoring Research Center (ADEMRC), School of Environmental Science and Engineering, Gwangju Institute of Science and Technology (GIST), 1 Oryong dong, Buk-gu, Gwangju 500-712, Republic of Korea

Keywords: AOD, data assimilation, Direct Radiative Forcing, $PM_{2.5}$.
Presenting author email: chsong@gist.ac.kr

For a better estimation of direct radiative forcing by aerosols and particulate pollution (such as $PM_{2.5}$ or PM_{10}) over East Asia, the production of more accurate aerosol optical properties (e.g., Aerosol Optical Depth (AOD), Single Scattering Albedo (SSA), aerosol extinction coefficient (σ_{ext})) is of primary importance. For the purpose of producing the accurate aerosol optical properties, AOD, SSA and σ_{ext} over East Asia were first investigated in this study, based on US EPA Models-3/CMAQ v4.5.1 modeling. The CMAQ model simulations were improved in several ways, compared to the previous study (Song et al., 2008): (1) the wind fields from MM5 simulations were assimilated with QuikSCAT wind data; (2) the emission inventories of INTEX-B (for China and North Korea), REAS (for Japan) and CAPSS (for South Korea) were used for the year 2006 simulations; (3) for the NH_3 and BVOC (Biogenic BVOs) emissions, EDGAR and MOHYCAN emissions were adopted, respectively; (4) monthly variations for the NO_x, NH_3, NMVOCs and SO_2 were applied; (5) for the dust generation and transport in the domain, the operational ADAM (Asian Dust Aerosol Models) was used (Fig. 1); (6) all the MET/CMAQ simulations and emissions were carried out in a fine grid resolution of 30×30 km^2 for the entire year of 2006; (7) 4-D particulate species concentrations obtained from the CMAQ model simulations were converted into the 4-D AOD products, using Malm and Hand (2007)'s algorithm, which is evolved from the previous Malm (1994, 2000)'s algorithms; and (8) finally, the CMAQ-simulated AOD products were assimilated with MODIS-retrieved AOD.

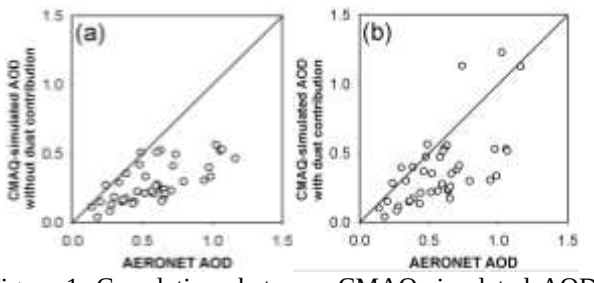

Figure 1. Correlations between CMAQ-simulated AOD and AERONET AOD in spring, 2006: (a) CMAQ-simulated AOD without dust contributions vs. AERONET AOD and (b) CMAQ-simulated AOD with dust contributions vs. AERONET AOD.

The results from the CMAQ model simulations (without assimilation) were improved greatly, compared to the previous study (Song et al., 2008) (e.g., from R=0.48–0.68 to R=0.77–0.89 for four seasons, R is correlation coefficient between CMAQ-simulated and MODIS-retrieved AODs). CMAQ-simulated SSA was also well matched with AERONET SSA, except for those near Honk Kong and Taipei, where biomass burning was strong from Jan. to Apr. It was also found that there were great matches between the vertical profiles of CMAQ-simulated σ_{ext} and LIDAR-derived σ_{ext}. The contributions of sulfate in summer, nitrate in winter, sea-salt in winter and dust in spring were large in East Asia. Especially, the large contribution of nitrate in winter to the AOD distribution over East Asia is remarkable compared to the previous study (Chung et al., 2010). In order to produce more accurate AOD products, the CMAQ-simulated AOD was assimilated with MODIS-retrieved AOD. Both the assimilated and AERONET AODs were better correlated with each other, compared to the correlation between CMAQ-simulated AOD and AERONET AODs (Table. 1). The obvious benefits for this study are that, with the improved aerosol optical properties, particulate pollution or PM forecasting over East Asia (e.g., AOD can be served as a proxy to $PM_{2.5}$) and direct radiative forcing by aerosols can be much better estimated in future.

Table 1. Statistical analysis among CMAQ-simulated and assimilated and AERONET AODs for four seasons, 2006.

AERONET vs.	period	R	RMSE	MNGE	MB	MNB
CMAQ	SPRING	0.59	0.31	45.24	-0.19	-29.88
	SUMMER	0.61	0.30	48.47	-0.13	-22.45

Electrical Effects

Molecular simulation of dynamic phenomena in complex plasmas

C. Durniak[1], D. Samsonov[1], P. Harvey[1], S. Zhdanov[2] and G. Morfill[2]

[1]Department of Electrical Engineering and Electronics, University of Liverpool, L69 3GJ, United Kingdom
[2]Max-Planck Institute for Extraterrestrial Physics, Garching, 85741, Germany
Keywords: dust, charged particles, interparticle forces, laboratory experiments, numerical simulation, crystallization, electromagnetic waves propagation
email:celine.durniak@liv.ac.uk

Complex (or dusty) plasmas are plasmas enriched with microparticles (or dust grains). The microparticles are charged by the interaction with the electrons and ions, predominantly negatively due to higher mobility of the electrons. They interact with each other electrostatically via a Yukawa potential and often form ordered structures. Similar to colloids, complex plasmas can exist in solid, liquid or gaseous states and exhibit phase transitions.

Complex plasmas can be found in space environments. Examples include stellar clouds, comet tails, and planetary rings. Practical applications include satellite protection from charging and dust impacts, as well as removing abrasive dust on Moon and Mars, where it is charged by the solar radiation and poses threat to spacesuits and machinery. Complex plasmas can also be obtained in laboratory by adding grains to a gas discharge. Dust was observed to spontaneously grow in ultra-clean etching reactors and in fusion devices, where it causes contamination. Applications include growth of fine powders for ceramics and catalysts. Knowledge of the complex plasma properties will help optimize production processes and increase yields. Charged dust in the atmosphere can be responsible for pollution.

As the grains are weakly damped by gas friction and traceable individually, a range of dynamic phenomena such as melting, crystallization, diffusion, linear and nonlinear waves can be observed in complex plasmas at the kinetic level in real time. Therefore complex plasmas are valuable tools to answer fundamental questions about physical properties of matter.

We simulate monolayer complex plasmas consisting of negatively-charged microparticles with the help of molecular dynamics simulations in three dimensions (Durniak, 2010). The code can be used to simulate various particle systems which can be characterised by interaction forces or potentials such as colloids, granular media, plasma doping, ion beams, film growth, ion implantation, etc. The equations of grain motion are solved using a 5th order Runge Kutta method taking into account the motion of the microparticles in a global confining potential as well as the interaction of every grain with each other via a Yukawa potential. The ion-electron plasma is not explicitly included in the equations. The grains are confined more strongly in the vertical direction than in the horizontal ones. Their motions are damped by the neutral gas drag. After seeding the grains randomly the code is run until the equilibrium is reached and a monolayer crystal lattice is formed (Figure 1). Then different excitation forces are applied on the lattice. Structural properties and nonlinear waves characteristics are examined as the pulses propagate across the complex plasmas. The numerical results are validated by comparing them to experiments.

The experiments are performed in a capacitively coupled radio-frequency discharge. Monodisperse plastic micro-spheres are levitated in the sheath above the lower electrode. They are confined radially in a bowl shaped potential and form a monolayer hexagonal lattice. A horizontal thin sheet of laser light illuminates the particles, which are imaged by a digital video camera. Wires are stretched above the lower electrode in order to excite waves.

In this study, we report on experimental observations and numerical simulations of dynamic phenomena in complex plasmas: soliton steepening caused by the propagation in an inhomogeneous medium, collision between two counterpropagating solitons, and defects dynamics interacting with compressional waves.

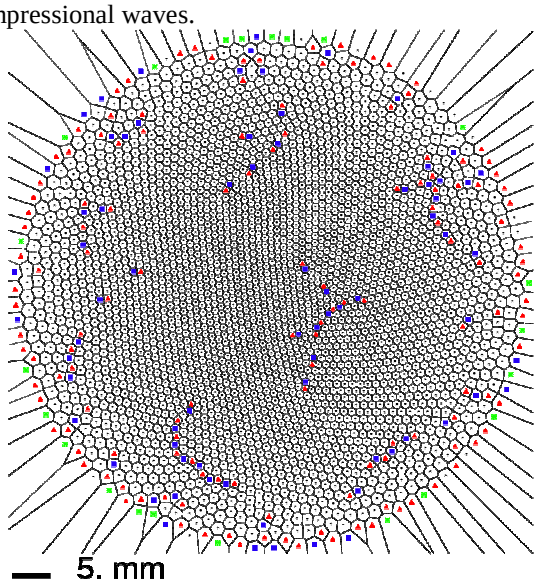

Figure 1. Voronoi map of a lattice obtained numerically with 3000 particles. The crystal defects are marked with ■ (5-fold), ▲ (7-fold), and ✱ (other defects).

Keywords: Filtration, Simulation, Nanoparticles, Deposition, Electrical effects
Presenting author email: kilian.schmidt@mv.uni-kl.de

The demand of nanoobjects with a scale below 100 nm is still rising in industry. It is possible to adjust and improve the physical and chemical properties of a synthetic material for application in nanocomposites, e.g. Such additions are commonly used for all kinds of recent products. Moreover, the filtration of these nanoparticles is an important topic. A special research field is the determination of the nanoparticle filtration efficiency of respiratory protective devices.

An important effect influencing the filtration efficiency is due to electrostatic charges (Rengasamy, 2009). In the field of aerosol filtration, electrostatic effects are decisive in many applications. E.g., electret fibres are used in particle filters for respiratory protection. Measurement and simulation techniques for electrostatic forces respectively charges still need to be investigated.

Measurements and direct numerical simulations of nanoparticle deposition at electret microfibres have been carried out. The general setup for the experiments is shown in figure 1.

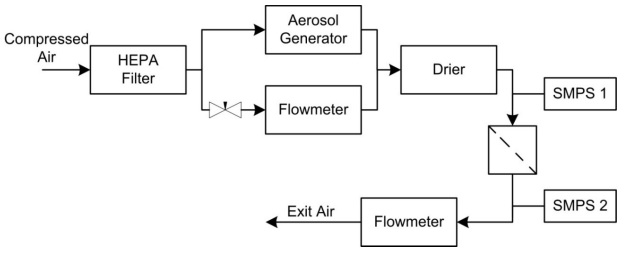

Figure 1. Scheme of the experimental setup.

The measurement and evaluation of the filtration efficiency for nanoparticles is technically extensive, time-consuming and the influence of electrostatic is hard to estimate. Therefore, direct numerical simulation is applied to get deeper insight into the occurring effects. For a 3D model of the distribution of bipolar fibres the airflow and the electric field are computed directly at high resolution as shown in figure 2. The trajectory of each single particle driven by flow, electric field and diffusion is computed, as well as the deposition of the particle at the fibre surface.

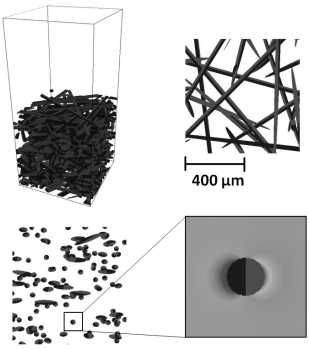

Figure 2 3D model with inflow area (top left), fibres from above (top right), fibres from side (bottom left), electric field computed in the surrounding area of a single bipolar fiber (bottom right).

The results of measurements and simulations will be presented and compared. One of the first results is shown in figure 3.

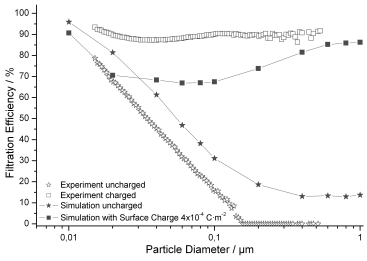

Figure 3 Comparison of measured and simulated fraction filtration efficiencies.

Electrostatic charging of spray droplets by addition of ionic compounds

M. Warren and A. K. Ray

Department of Chemical Engineering, University of Kentucky, Lexington, KY 40506, USA
Keywords: droplet charging, particle capture, respirable dust
Presenting author email: akray@engr.uky.edu

Water sprays are routinely used to control respirable dust particles that arise during mining operations. A neutral water droplet captures particles by Brownian diffusion, interception and inertial impaction. The capture efficiency of the droplet due to all these mechanisms combined is always less than unity, and decreases as the particle size decreases. Airborne particles smaller than 2 μm are difficult to remove by uncharged spray droplets. The capture efficiency, however, is significantly greater than unity when the droplet is charged oppositely to the particles (Dhariwal et al. 1993). The particle capture by Coulombic attraction provides an attractive potential for the removal of small particles. Airborne dust particles carry electrostatic charges that arise from triboelectrification or impact charging (Marra and Coury 2000). Our preliminary experiments on bituminous coal dust samples show that coal particles acquire negative charges during dispersion in air. Therefore, removal of these particles can be significantly enhanced by using positively charged spray droplets. We have examined whether water droplets can be positively (or negatively) charged during the spraying process by adding ionic surfactants or other ionic compounds (e.g., ionophores, and ionic liquids) to water.

Experiments were conducted either on highly monodisperse droplets that were generated using a Vibrating Orifice Aerosol Generator (Devarakonda et al. 1998), or on polydisperse droplets generated by an ultrasonic atomizing sprayer (UAS). Droplets were generated from pure deionized water (resistivity =18.2 Mohm-cm) as well as from water containing an ionic surfactant (e.g., sodium lauryl sulfate or coco amine) or an ionic compound (e.g., tridodecylmethylammonium chloride or tridodecylmethylammonium nitrate) at varying concentration levels. After generation droplets were dispersed by an air stream and allowed to fall downward in a cylindrical chamber. Air samples were continuously withdrawn by an Aerodynamic Particle Sizer (APS) and by an electrometer through two side ports on the chamber. The data from the APS were used to determine the size distribution and the number concentration. For a given sample flow rate through the electrometer current readings were analyzed using the APS data to obtain charge on the spray droplets.

Our results show that a water droplet without any additives acquires about 700 elementary positive charges during the spraying process. Addition of an ionic surfactant or an ionic compound can significantly enhance the charge level on a droplet. For example, sodium lauryl sulfate (SDS) can increase the charge level on a droplet by more than three-fold. The droplet charge depends on the concentration of the additive; the charge level increases to a maximum and then decreases as the concentration increases.

The results of this study suggest that water droplets can charged during the spraying process, and the charge level in sprayed droplets, thus particle removal efficiency, can be maximized by adding optimum levels of ionic surfactants or ionic compounds in water.

High voltage power lines are known to produce ions when the electric field surrounding the cable is sufficiently high to cause corona avalanching. Elevated numbers of these corona ions can be produced if there are protrusions on the cable surface. Predominantly uni-polar clouds of space charge can be detected as changes in the Earth's vertical potential gradient (PG).

Proximity to high voltage power lines has been linked with a higher incidence of childhood leukaemia (Draper 2005). The attachment of corona ions to pollutant aerosols has been hypothesised to increase their deposition in the human lung, leading to adverse health effects (Henshaw, 2002). PG, ion mobility spectra and the charge state of aerosols upwind and downwind of power lines have been measured to assist in testing this hypothesis.

Electric field mills can be used to measure the PG upwind and downwind of HV power lines (Fews *et al* 2002). Long term measurements of PG fluctuations at a fixed site near to two high voltage power lines have shown that the electrical environment several hundred metres downwind can be affected (Matthews *et al* 2010). An increase in the distributions of the mean and standard deviation of PG when the monitoring station was downwind of a power line indicated that there was an elevation of space charge. The conditions found for highest corona emission were overnight, at high humidity, during rainfall and at high wind speeds (Matthews 2010).

Ion mobility spectra near to HV power lines were measured aspirated condenser ion mobility spectrometers (ACIMS) (Fews *et al* 2005). Of 37 measurements upwind and downwind of power lines, only 7 did not show an increase in ion concentration downwind. Though predominantly there was a positive ion excess, bipolar and negative corona were also measured on different occasions (Buckley 2009).

The mean space charge density at ground level from the total small ion concentration recorded by the ACIMS was compared to the mean PG recorded at the same time by electric field mills. 8 upwind and 8 downwind measurements were compared. No consistent relationship was found between space charge density and PG either upwind or downwind of the power lines. At 5 downwind sites, both positive PG and net ion concentration were found. At 2 sites downwind of the same power line, PG measured negative charges overhead while the small ion concentration showed a positive excess. 1 site showed a positive PG but an excess of negative small ions.

Two possible causes of the discrepancy between PG measurements and small ion concentration at ground level are removal of ions by attachment to aerosols and ions being carried at height above the measurement site. Charged aerosols and ions at height would still affect PG as measured by field mills but do not contribute to ground level ion concentrations.

The charge distribution of aerosols downwind of power lines can estimated using the technique described in Buckley *et al* (2008). Figure 1 shows the mean charge per particle downwind of 4 lines.

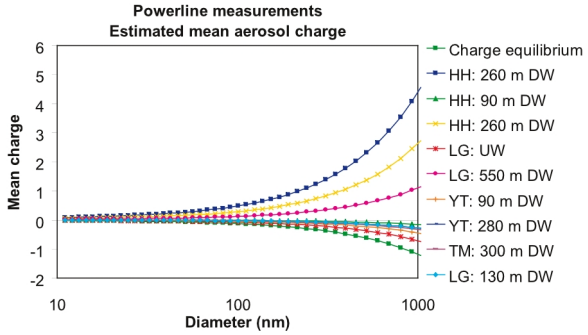

Figure 1. The charging of aerosols in the vicinity of high voltage power lines, from Buckley (2009). Sites investigated were at Ham Hill (HH), Lower Godney (LG), Yatton (YT) and Tormarton (TM) near Bristol, UK.

Measurements of PG, ion concentration and aerosol charge state downwind of high voltage power lines show that there is significant corona production near to some high voltage power lines, which can alter the charge state of aerosol particles.

Keywords: negative air ion concentration, electric field strength, relative humidity, removal efficiency.

Presenting author email: kpyu@ym.edu.tw

Our previous studies showed that negative air ions (NAI) can remove submicron airborne particles efficiently by means of electrostatic force (Wu *et al*, 2006, Yu *et al*, 2008). The cluster ions formed by NAI can attach on particles by means of diffusion charging. The terminal velocity (V_E) of the charged particles within the range of Stokes's Law in an electronic field is (Hinds, 1999):

$$V_E = EZ = \frac{EC_c kT}{6\pi\mu K_E e}\ln\left[1+\frac{\pi K_E d_p c_{i\,mean} e^2 N_i t}{2kT}\right] \quad (1)$$

where, E is the electric field strength; Z is the electric mobility of particles; n is number of charges acquired by a particle; d_p is the particle diameter; k is the Boltzmann constant (1.38×10^{-23} J/K); T is the absolute temperature; K_E is a constant of proportionality (9.0×10^{9} N m^2/C^2); e is the electronic charge (1.6×10^{-19} C); N_i is the NAI concentration; $c_{i\,mean}$ is mean thermal speed of ions (240 m/s at standard conditions); t is the time duration. C_c is the Cunningham slip correction factor, μ is the viscosity of the air. We estimated V_E by measuring the values of E, Ni and d_p. The NAI concentration and the electric field strength generated by the negative air ionizer are distance-dependent [Fig. 1(a) and 1(b)]. The electric field strength is linear proportional to the logarithm of the NAI concentration [Fig. 1(c)]. The net displacement of a particle due to NAI under higher relative humidity (RH) is larger than that under lower RH as demonstrated in Table 1. This may result from that in the presence of water molecules, the air ions can form hydrates (cluster ions) with higher stability (Bracken, 1987). This result agrees with the measurement of NAI concentration and particle (secondary organic aerosol) removal.

Table 1. Comparison of particle net displacement due to NAI, Brownian motion and gravity

d_p (nm)	Net displacement of a particle in one minute (m)				
	NAI (X_{NAI})[a] 25 cm away from air ionizer			Brownian motion[b] (X_{BM})	Gravity[c] (X_{grav})
	RH82%	RH50%	RH18%

Keywords: fog, atmospheric electricity, quasi-periodic variations.
Presenting author email: npm_sta@mail.ru

The purpose of the paper is to study the dynamics and patterns of variations of atmospheric-electrical, meteorological and optical parameters of the atmospheric boundary layer in conditions promoting fog formation.

Basing on the data of field measurements in the spring-autumn period of 2006-2010 the comparative analysis of the temporal variability of the intensity of atmospheric electric field, basic meteorological elements and characteristics of turbulence with tact in 1 minute in conditions of fog occurrence was carried out. We revealed a pronounced positive correlation between variations in the electric field intensity and relative humidity: with the increase in humidity the field intensity increases as well (Phalagov, 2009). A typical example of the electric field dynamics ***E*** and temperature and characteristic of turbulence during fog formation is shown in fig. 1.

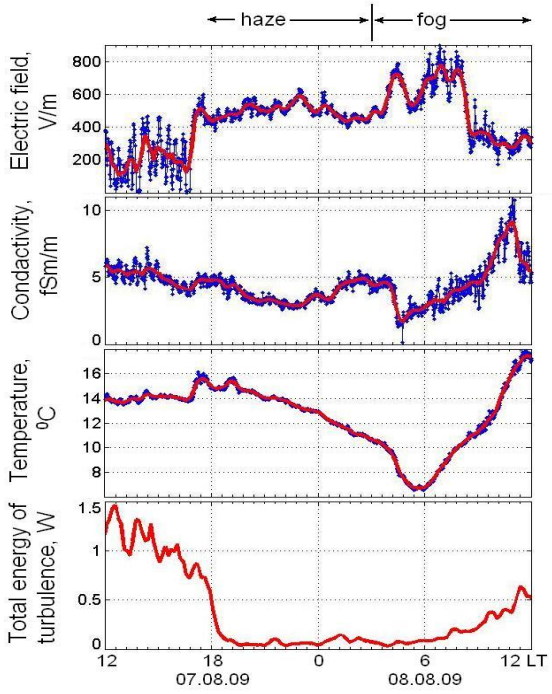

Figure 1. Variations of the meteorological elements during fog.

Since the growth of the electric field is uniquely associated with a decrease in the concentration of light ions in the air, it can be assumed that the formation of fog begins to increase in the concentration of the smallest particles, which still do not participate in the process of light scattering, but already actively serve as a sink for ions.

In turn, the fine particles got charged as a result of ion diffusion actively grow via coagulation processes, and being in the field of the increased humidity they transit to the range of optically active particles. This significantly increases the turbidity of the atmosphere.

It is suggested that the growth of the electric field before formation of fog can be a harbinger of it, which is particularly limited the visibility conditions.

The electric field in the surface atmosphere in the presence of fog undergoes quasi-periodic variations, which amplitude is much greater than the variation of the electric field during «fine weather». Quasi-periodic variations of the electric field appear in the form of oscillation trains in the range of periods.

Wavelet analysis of 17 cases of field *E* registration during summer-autumn fogs allowed to reveal the features of occurrence frequency of quasi-periodic variations depending on the period. In the spectrum of periods T the 4 peaks are distinguished: 10-15 min 60-70 min 110-140 min and 210-300 min. The duration of treatment plots in all cases was 900 minutes. The histogram of registration frequency of *N* variations is represented in figure 2 in depending on the period. Heterogeneous in space can be taken a source of quasi-wave processes the fog density.

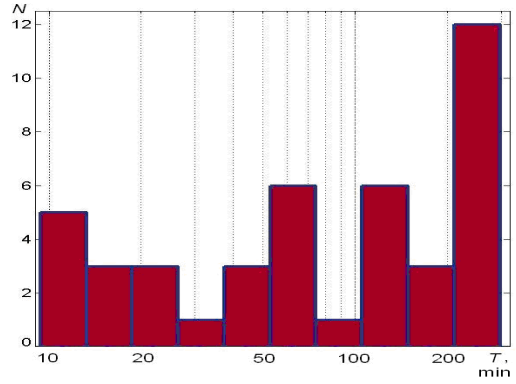

Figure 2. The occurrence frequency of variations of N electric field with period T.

A simplified procedure for particle charge distribution measurements and its application to the characterization of the annual DBD aerosol neutralizer

Wild, Markus[1], Meyer, Jörg[1] and Kasper, Gerhard[1]

[1]Karlsruhe Institute for Technology KIT, IMVM, Strasse am Forum 8, 76139 Karlsruhe, Germany

Keywords: Measurement (characterization), Dielectric Barrier Discharge; charged particles; TDMA.
Presenting author email: markus.wild@kit.edu

The annular dielectric barrier discharge aerosol neutralizer is a device designed to impose a Boltzmann charge distribution to airborne particles by electrostatic means. The device's performance in neutralizing aerosols is compared to a radioactive ^{85}Kr source. Amongst others, the particle charge distributions of sodium chloride particles ranging between 27-200 nm are investigated. The method of choice is a Tandem-DMA setup. The basic task is to determine the number concentration of differently charged particle fractions. Usually a rather complex curve fitting method is applied to evaluate the obtained data, see e.g. Stolzenburg and McMurry (1998). The evaluation process can be vastly simplified if some restrictions concerning the conduct of the experimental procedure are observed.

Therefore, a method to determine the aerosol concentration within a well defined interval of electrical mobilities – such as distinct peaks in a mobility spectrum illustrated in Figure 1– directly from a continuous DMA scan is described.

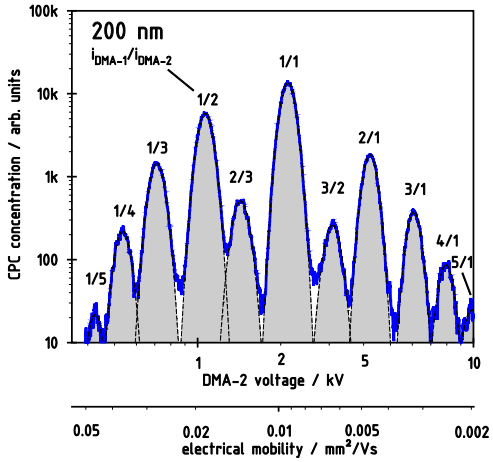

Figure 1. mobility spectrum of a pre-classified (200nm) and neutralized sodium chloride aerosol measured by a CPC after DMA-2 in a TDMA setup. i indicates the state of charge in DMA-1 and DMA-2, respectively.

The method is based essentially on moving the transfer function across the spectrum at such a rate that the time window during which particles of an arbitrary mobility can pass through the DMA remains constant during the scan. This implies a specific ramp function for the scan voltage, which we derive, thereby establishing a direct and simple link between the cumulative number of particles exiting the DMA while scanning across a peak, and the concentration enclosed within that mobility window at the inlet (see Figure 2). The method is an implicit part of the theoretical framework described by Wang and Flagan (1990). However, by relaxing the goal of deriving a complete size distribution in favour of the lesser requirement of measuring only the total concentration within certain, well defined bounds of mobility, one gains accuracy, sensitivity, and last not least convenience because there is no need for extensive post-processing of the data. The method is particularly suitable for measuring aerosol charging probabilities with distinct peaks in the mobility spectrum.

While the charged fractions of laboratory generated aerosols in the range of 27 to 200 nm are investigated with a TDMA set-up and the mentioned data evaluation procedure, the neutral fraction is measured by a separate measurement.

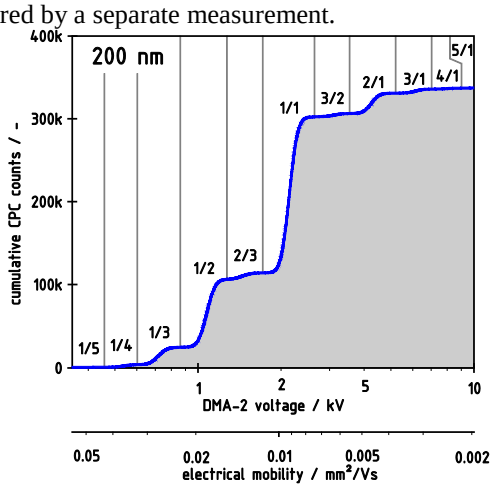

Figure 2. cumulative particle counts of the aerosol introduced in Fig. 1 when performing an up-scan using a logarithmic voltage ramp

The method was used to determine the performance of the annual Dielectric Barrier Discharge (aDBD) aerosol neutralizer in comparison to a common ^{85}Kr β-source. The obtained charge distributions resembled each other very well. The aDBD proofed to provide a promising alternative to the use of radioactive material and its well-known disadvantages in aerosol measurement technology.

Instrumentation

The comparison of bioaerosol disinfection efficiencies of several new commercial air purifiers manufactured in Russia

S.A. Kiselev, A.S. Safatov, Yu.V. Marchenko, A.N. Sergeev, Ar.A. Sergeev, Al.A. Sergeev, E.K. Emelyanova, V.Yu. Marchenko, G.A. Buryak

Keywords: air indoor quality, bioaerosols, bacteria, viruses.
Presenting author email: safatov@vector.nsc.ru

Air purifiers/disinfectors (APDs) are intended for reduction of indoor concentration of aerosol containing microorganisms and, consequently, the probability of aerogenic infection of humans, animals and birds.

Filtration and disinfection efficiencies of APDs functioning in recirculation mode were determined as the ratio of weight-average and biological aerosol concentration at the inlet and outlet of the functioning device. The studies were performed at an aerosol test bench for testing APDs with airflow up to 400 m^3/hour like that described in (Delaby *et al.,* 2008).

Aerosols containing a physical label (uranin) and avian influenza A virus subtype H5N1 (AIV) A/Chicken/Suzdalka/Nov-11/2005 or strain or *Mycobacterium smegmatis* (MS) B-836 strain (imitator of mycobacterium tuberculosis) were generated to test the devices. The mass median diameter of particles was 1 - 2 μm. The experiments were conducted at the temperature of 25 – 34 °C and relative humidity of 30 – 45 %. At fixed airflow (Q), the mean values of efficiencies (E) and their 95 % confidence intervals (I) were determined by the results of Experiments 4 - 6 for different APDs.

The following results can be obtained using the methodology for determining the efficiencies of air filtration and disinfection by devices of recirculation type developed at FSRI SRC VB Vector Rospotrebnadzor:

1. Determination of filtration, disinfection and inactivation efficiencies for bioaerosol with definite parameters of dispersion composition containing a microbiological test object using an APD of recirculation type at a preset airflow in one run. If necessary, the corresponding efficiencies can be determined for individual sections of the APD.

2. Determination of filtration, disinfection and inactivation efficiencies for individual aerosol fractions.

The results of the carried out tests (Table 1) provided an objective evaluation of efficiencies of air purification and disinfection by APDs of recirculation type at a preset airflow in one run, which does not depend on the peculiarities of the rooms where the tests are performed. The work results promote a more efficient and justified application of air purifiers-disinfectors to improve the human environment and to prevent aerogenic infections.

The conducted tests with air disinfectors of different Russian manufacturers demonstrate their high efficiency.

The work was supported by the Federal Target Program (Contract # 02.518.11.7139).

A miniaturised Airborne Particle Classifier (APC)

C. J. Stopford, P. H. Kaye, E. Hirst, Z. Ulanowski, R.S. Greenaway, and W.R. Stanley.

Centre for Atmospheric & Instrumentation Research, University of Hertfordshire, Hatfield, U.K.
Keywords: atmospheric particle, ice crystal, spatial light scattering, in situ measurement.
Presenting author email: c.stopford@herts.ac.uk

The single greatest source of uncertainty in the estimates of climate sensitivity to either natural or man-made changes continues to be clouds (IPCC, 2007). Much of this uncertainty arises from the lack of information relating to the properties of smaller cloud particles (droplets, ice crystals) and aerosol. In the past, the University of Hertfordshire has developed several types of aircraft instrument (Kaye, 1998; Hirst *et al*, 2001; Kaye *et al*, 2008; Cotton *et al, 2010*) based on spatial light scattering technologies (so-called SID probes) that are able to monitor and differentiate between these particle types *in situ*. These probes have been procured by meteorological research organisations in the UK, USA, and Europe.

However, the SID probes require a PMS-canister mounting and this severely restricts the number of aircraft on which they can be flown. We have therefore developed a proof-of-concept laser scattering instrument, the Airborne Particle Classifier (Figure 1), which is, in effect, a miniaturised SID probe, designed to count, size, and classify (on the basis of morphology) micrometer sized particles at rates of several thousand per second. The APC is intended for a Rosemount or similar aircraft fitting and could potentially be carried by a UAV. Beyond this, it could also find wider application in general aerosol monitoring in areas of environmental health, pollution monitoring, source apportionment etc., where knowledge of the aerosol's constituent particle types is essential.

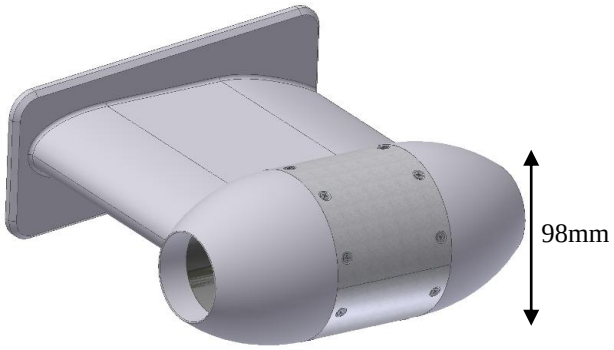

Figure 1. Prototype Airborne Particle Classifier.

A laser orthogonal to the flow of air illuminates individual particles as they pass through a sensing volume defined optically by a combination of custom photodiode and elliptical reflector. This triggers a second, high-power pulsed laser to illuminate each particle, the scattering from which is captured on two parallel linear 512-pixel CMOS detector arrays. The azimuthal distribution light scattered by the particle is compressed in one dimension via a cylindrical lens, such that a greater range of scattering angles is captured by the CMOS arrays. The minimum particle size for measurable scattering pattern recording is approximately 2-3µm. The data from the arrays are saved to an external single board computer for post-flight analysis. Figure 2 illustrates the CMOS array output data recorded for different particle morphologies, from columnar to spherical. For illustration only, the relative positions of the two CMOS arrays, shown in red and green, are indicated on 2D SID3 probe scattering pattern images recorded from similar particle types.

Analytical processing methods are currently being developed to determine metrics of particle size, morphological class, and number concentration from the recorded APC data.

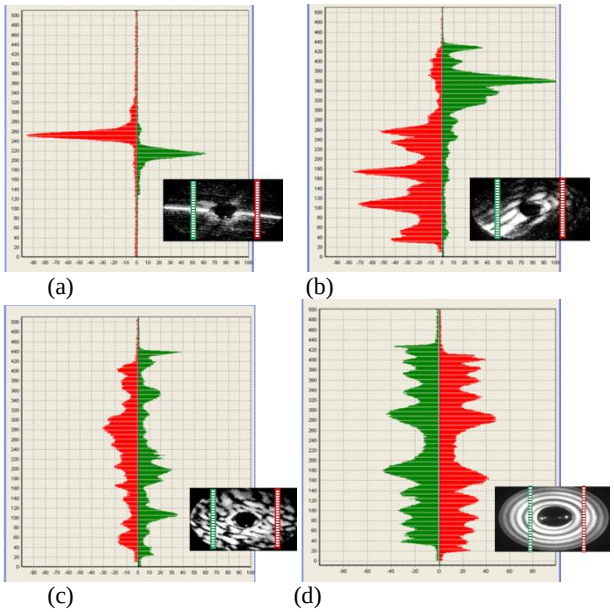

Figure 2. Examples of APC CMOS-array data for various particle morphologies: (a) columnar, (b) plate-like, (c) irregular cubic, (d) droplet. Y-axis represents array 0-512 pixels; x-axis represents light intensity for each array. (Image inserts are from SID3 probe data for similar particle types).

A new analyser for continuous measurement of the concentration and composition of aerosols

Y. Mizuno, M. Fujiwara and H. Kume

[1]HORIBA Ltd., Kyoto, 601-8510, Japan
[2]National Institute for Environmental Studies, Tsukuba, 305-8506, Japan
Keywords: PM2.5, chemical composition
Presenting author email: hkume@nies.go.jp

Aerosols discharged from factories and automobiles are a major cause of air pollution in metropolitan areas as well as in areas along arterial roads. In Japan, the ambient air quality standards apply to suspended particulate matter (SPM: particles with a diameter less than 10 μm). In addition to the SPM regulation, PM2.5 regulation has been started in September 2009. There are more than 1,500 continuous air pollution monitoring stations in Japan. This monitoring alone, however, does not provide us with sufficient information for the identification of the sources of aerosol emissions or an understanding of aerosol dynamics in the environment. Additionally, it is very important to obtain the chemical information in order to determine the source contribution. As a result, there is an urgent need of the equipment which has combined the properties of multifunction analysis and mobility.

In response to this situation, we are currently developing an apparatus that can simultaneously analyse the concentration and composition of aerosols. This apparatus features an original filter, an X-ray tube, and an electron gun to success qualitative or quantitative analysis. The X-ray tube and electron gun are small in size and energy-efficient to operate. The X-ray tube is used for component analysis by the X-ray fluorescence method, and the electron gun is used for measurement of aerosol concentrations by the electron transmission method. While the conventional monitoring stations measure only the aerosol concentrations, this apparatus is intended to identify the sources of aerosol emission

Measuring chemical components of aerosols requires thin high-purity filters. A glass fiber filter commonly used contains various contaminants, making a qualitative or quantitative analysis of the chemical components very difficult.

Recently, we have developed an original membrane filter based on a polytetrafluoroethylene (PTFE) film with new filter structure (HORIBA, Ltd., TFH-01 roll type) . TFH-01 has the following features:

1) The structure consisting mainly of PTFE and non-woven fabric.
2) Less hygroscopicity than glass fiber filters and less electrostatic charge than a filter consisting of only PTFE.
3) Smaller unit weight than that of glass fiber filters. This has improved mass-detection sensitivity by approximately five times compared to β -ray attenuation mass monitors (HORIBA, Ltd., APDA-370).
4) Ultra low chemical background.

XRF spectra of a glass fiber filter and TFH-01 filter obtained by EDX are shown in fig. 1. This result demonstrates that TFH-01 filter is almost free from contamination.

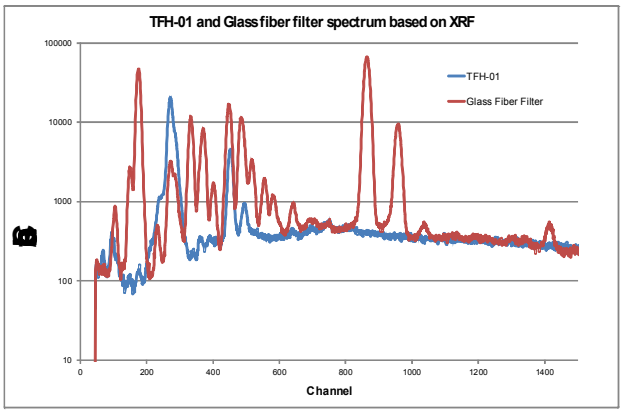

Figure 1. Comparison of XRF spectra between a glass fiber filter and TFH-01.

We have been checking the total performance of the analyser using a test bench shown in fig. 2.

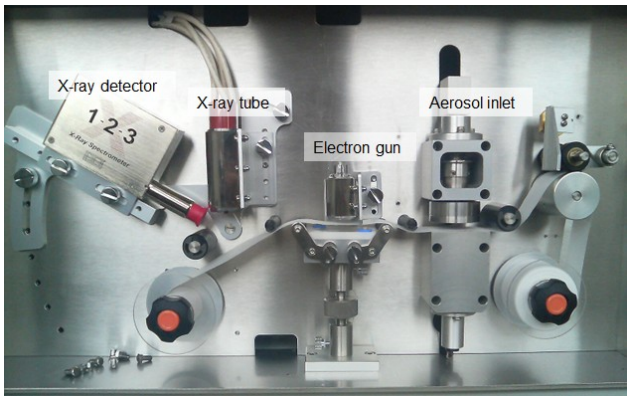

Figure 2. A laboratory bench upon which the performance of the analyser is tested

The calibration of an aerosol dilution system

L. Škrabalová[1, 2] and V. Ždímal[1]

[1]Laboratory of Aerosol Chemistry and Physics, Institute of Chemical Process Fundamentals, Academy of Sciences of the Czech Republic, Rozvojová 135 Prague, 165 02, Czech Republic
[2]Department of Physical Chemistry, Faculty of Science, Charles University in Prague, Hlavova 8 Prague, 128 43, Czech Republic
Keywords: aerosol diluter, dilution ratio, calibration.
Presenting author email: skrabalova@icpf.cas.cz

When sampling aerosols it is often necessary to reduce number concentration of aerosol by dilution. Dilution enables us to suppress condensation of semivolatile gaseous components, quench coagulation of the sample, or bring its concentration to the instrument's range of operation. The choice of a suitable diluter depends on required dilution ratio, sample flow rate, particle losses in the diluter and other parameters. (Baron & Willeke, 2001). A variety of diluters and a description of a diluter designed specially for high dilution and transport of coagulating ultrafine aerosol is described e.g. by Brockmann *et al* (1984).

The aerosol dilution system presented in this paper has been built in the mechanical workshop of the Institute of Chemical Process Fundamentals. It has been designed in order to dilute highly concentrated aerosol samples formed by aerosol generators. The aim was to build a diluter offering a wide range of dilution ratios achieved in one dilution step. Because the diluter was intended for operation in front of the Scanning Mobility Particle Sizer, another requirement was the option to recover the original particle size distribution. In order to do that, the dilution ratio has to be known even as a function of particle size.

The diluter's design is based on a well-known principle. The aerosol flow is divided into two parts. One enters a thin capillary and the other is led through a bypass provided with a high efficiency particulate filter and a flow-controlling valve. Particle concentration of the capillary flow remains unchanged whereas the HEPA filter removes nearly all particles from the bypassing flowrate. The two flows are then merged together in a mixing chamber. The dilution ratio is given by the ratio of the capillary and bypassing flows. When the dividing and mixing parts are properly designed, it is possible to predict the dilution ratio from the pressure drop across the capillary by using Hagen–Poiseuille equation. This paper describes the measurement procedure and consequent data evaluation of dilution ratios.

In order to calibrate the diluter and determine the dilution ratios as a function of particle size, 6 stainless steel capillaries with inner diameters 0.04, 0.03, 0.02, 0.01, 0.007 and 0.005 inches were used. The polydisperse aerosol was generated by nebulizing the ammonium sulphate solution in the aerosol generator AGK-2000 (Palas GmbH, Germany). A monodisperse fraction of the aerosol was selected using an electrostatic classifier provided with a long differential mobility analyzer (EC3080+DMA 3081, TSI Inc., USA).

Concentrations of the aerosol upstream and downstream of the diluter were recorded using two condensation particle counters (UCPC 3025A, TSI Inc., USA). The measurement procedure was designed in such a way that the slight differences in performance of the two counters were taken into account. The dilution ratio was determined for each of the six capillaries, and for 9 size fractions of the aerosol: 20, 35, 50, 70, 100, 140, 200, 280 and 400 nm.

An example of comparison of dilution ratios observed experimentally and predicted by theory is presented in Figure 1 as a function of particle diameter. It is obvious that for capillaries with diameters of 0,02 and 0,04 inches the agreement of the experimental values with theory is excellent. The capillary with the diameter of 0,005 inches shows deviations from theory at larger particle sizes caused probably by particle losses. It has been found that the diluter offers dilution ratios in the overall range between 4:1 and 10^4:1.

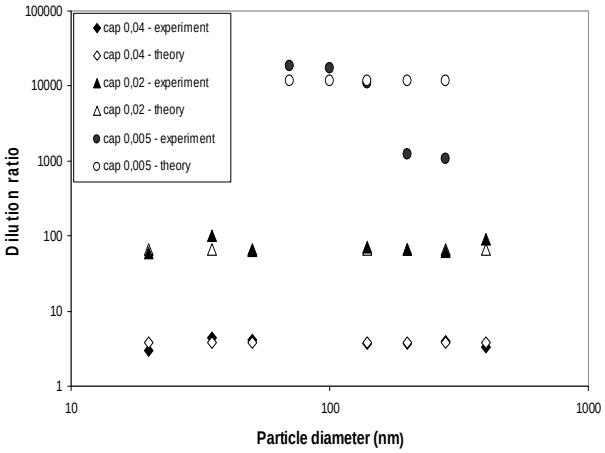

Figure 1. A comparison between dilution ratios determined experimentally and predicted theoretically.

Presenting author email: zagaynov@cc.nifhi.ac.ru

There are some complications in measurements of aerosol particles in nanometer size range. First of all every instrument has threshold sensitivity, and all particles of less size will not be counted. At the same time during particle generation great number of particles may be beyond this threshold. In this case solution may be found by optimal selection of the measuring equipment.

In nanometer particle size range there are two instruments, which may be chosen for such measurements: differential mobility analyzer (DMA) (Hagwood et al, 1999) and diffusion aerosol spectrometer (DAS) (Julanov et al., 2002). Both these instruments have their preferences and shortcomings. Conversion of measured data by DMA into particle size distribution has condition number lower as compared to corresponding number for DAS based measurements. It means that DMA measurements may be considered as more reliable. At the same time aerosol charging efficiency accross the particle size range of several nanometers is very low leading towards increase in measurement errors.

Here we compare measurements made by these two instruments. The measurements were made by DMA and DAS simultaneously for particles, produced by a spark generator. Advantages of this generator are mainly related to stability of particle size distribution and concentration over long time (several hours) if parameters of generation are not changed. Obviously, using air as a gas carrier enables to produce nanoparticles of metal oxides, whilst utilization of inert gases (for example nitrogen) leads towards production of particles containing only metals. In most of cases particles have spherical shape and narrow size distribution.

For our experiments, a molybdenum wire was heated in the air stream flowing around it to produce MoO particles of spherical shape in concentration of up to 10^7 particles per cubic centimeter if the air carrier. Some portion of this stream was diluted to the concentration around 2×10^4 cm^{-1} and sampled simultaneously by DAS and DMA

Fig. 1 shows he results of measurements of particle size spectrum as acquired by DAS and DMA. As is clearly seen in the figure, the results obtained by both instruments are in very close agreement with each other. The averaged particle radius measured by DAS was 14.5 nm and by DMA – 14.75 nm.

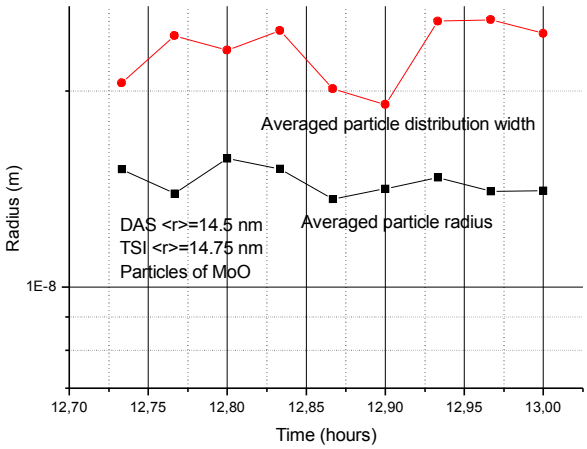

Figure 1. Measurements of particle size distribution made by DAS and DMA.

The source of the discrepancy between readings of DAS and DMA is twofold – low charging efficiency of small aerosol particles and different particle sensitivity of different enlarging vapors. In spite of different measurement methods and reconstruction of particle size distributions from measured data the results of the measurements are in close agreement. The measurements were undertaken at Karpov Institute (DAS and DMA), VNIIFTRI (DMA), and Griffith University (DMA). For all measurements, particles were produced by the same spark generator.

Intercomparison of scatter and backscatter integrating nephelometers Characteristics and angular sensitivity correction

T. Müller[1], M. Laborde[2,3], G. Kassel[2] and A. Wiedensohler[1]

[1] Leibniz Institute for Tropospheric Research, Leipzig, Germany

Integrating nephelometers measure a value close to the light scattering coefficient of airborne particles. Different models of nephelometers have been used for many years for monitoring and research applications. We present here an intercomparison of two nephelometers and corrections for the angular non-idealities. The instruments are the Aurora3000 (Ecotech Pty, Ltd, Knoxfield, Australia) and the TSI3563 (TSI Inc, St. Paul, MN, USA), which are the only commercially available three-wavelength scatter and backscatter integrating nephelometers.

Main differences between these nephelometers are the size of the sensing volumes, the light sources and the design of the backscatter shutter. The sensing volume of Aurora is about 30% smaller compared to TSI3565. The light source of TSI 3565 is an incandescent lamp, whereas the light source of Aurora 3000 is based on LEDs. The backscatter shutters of TSI 3565 and the Aurora3000 are a continuously rotating and a periodically moving shutter blade, repectively.

The illumination function of light sources and the design of cell, backscatter shutter and the detection optics deviate from ideal nephelometers leading to a non-ideal angular sensitivity function. Angular intensity distributions of the light source were measured with a goniometer setup. Results are given in Müller et al. (2010). To correct for the angular non-idealities, a particle size and refractive index dependent correction factor has to be considered. Correction factors for a log-normal particle number size distribution with a refractive index of 1.53-0.01i were calculated with Mie-theory. Correction factors for total scattering and backscattering are shown in Figure 1.

Another correcting method was found by Anderson and Ogren (1998). They found a parameterization of correction factors as function of the Ångström exponent α with $\alpha=\ln(\sigma(\lambda_1)/\sigma(\lambda_1))/\ln(\lambda_2/\lambda_1)$, where $\sigma(\lambda)$ is the uncorrected scattering coefficient.. Parameterizations were developed for sub- und supermicrometer particles with real parts of refractive indices between 1.40 and 1.52. The imaginary part of refractive index is between 0 and 0.001. Following the approach of Anderson and Ogren (1998), parameterization for sub-micrometer particles were derived. E.g. for the green wavelengths of the nephelometers the parameterization for TSI3563 was found to be $C_{ts}=1.152-0.044\cdot\alpha$, what is close to the parameterization given in Anderson and Ogren (1998). For the Aurora3000, the parameterization was determined to be $C_{ts}=1.2065-0.0788\cdot\alpha$.

Scattering coefficients of ambient air were measurements with TSI3563 and Aurora3000 for a period of 46 days. A correlation between TSI3565 and Aurora3000 adjusted to the wavelength 525 nm using the Ångström-equation are shown in Figure 2. The slope for total scattering is about 1.01 with and 0.98 without angular sensitivity correction. For backscattering, the slopes with and without correction are 1.05 and 1.03, respectively.

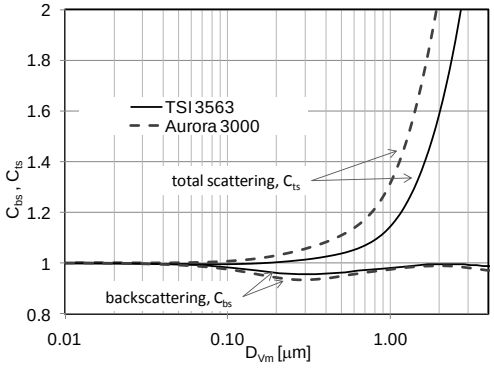

Figure 1. Correction factors for total (C_{ts}) and backscattering (C_{bs}) versus the volume median diameter.

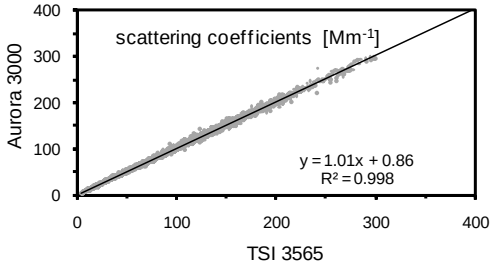

Figure 2. Correlation of total scattering coefficients between with the TSI3565 and Aurora 3000.

Keywords: Cascade Impactor, Collection Efficiency
Presenting author email: estibaliz.garcia@ehu.es

Multi-nozzle cascade impactors are used instead of single-nozzle impactors in order to get the desired air flowrate and cutpoint at a reasonable Reynolds number through each nozzle.

Careful analysis of deposits from multiple–nozzle impactors shows particle collection directly underneath the nozzles where the jets directly impinge upon the impaction plate (i.e. primary deposits). However, secondary deposits are also commonly seen as straight lines directly between adjacent nozzles, both on the impaction plate and on the backside of the nozzle plate, or as a "halo" around the primary deposits (Rocklage J.M., 2007)

The objective of this work was to determine the mechanisms that cause secondary deposits in multiple-nozzle impactors, and to evaluate the effect of these deposits on the collection efficiency curves. With this information it is intended to establish design criteria for the optimum distance between nozzles to minimize the negative effects of the secondary deposits.

Experimental work was conducted on a cluster of three equally-spaced round nozzles (tapered inlet), with four different nozzle spacings: 2.5X, 4X, 6X and 8X (where X is the nozzle diameter), and at three Reynolds numbers: 500, 1500 and 2400. The jet-to-plate distance to nozzle-diameter ratio was one (i.e. S/W=1).

For the experimental tests, perfectly monodisperse oleic acid particles tagged with a fluorescent uranine tracer were used as the challenge aerosol. These particles were generated by a TSI 3450 Vibrating Orifice Aerosol Generator (VOAG), diluted with clean, dry air to prevent coagulation, neutralized by a Kr-85 source, and followed by a sharp-cut, multiplet reduction impactor (Siegford et al., 1994).

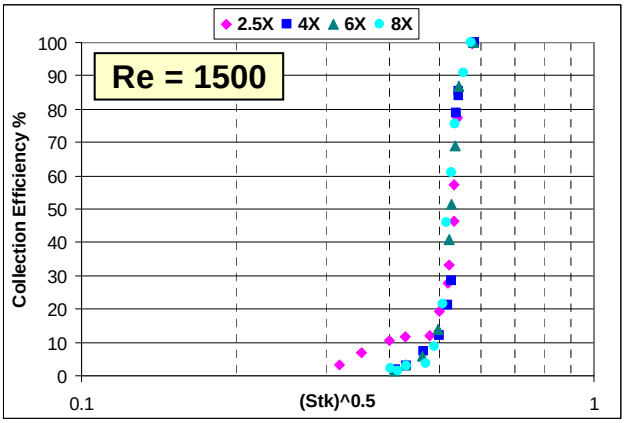

Figure 1: Collection efficiency curves Re = 1500

Figures 1 and 2 show the experimentally determined collection efficiency curves at Reynolds numbers of 1500 and 2400, and for all the nozzle spacings tested.

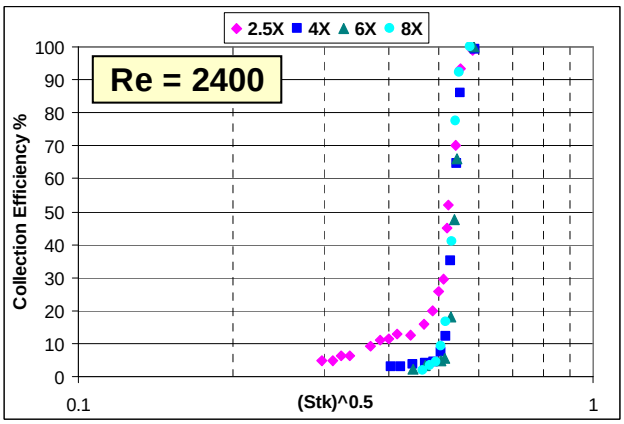

Figure 2: Collection efficiency curves Re = 2400

The experimental results at the lowest nozzle spacing (i.e. 2.5X) show that significant secondary deposits (visible as straight lines) start to appear before the primary deposits are seen. These secondary deposits are responsible for the long tail at low particle diameters of the collection efficiency curve shown both in Figures 1 and 2. These deposits are formed due the fluid flow-particle interaction between the nozzle jets as they approach the impaction plate. Secondary deposits were not observed at Re = 500.

The collections efficiency curves at nozzle spacings of 4X, 6X and 8X are nearly identical and show no effect of the secondary deposits on the typical sigmoidal curves, even though these deposits were visible up to 6X at Reynolds number of 1500 and up to 8X at Reynolds number of 2400.

Level of light absorption coefficient at an engineering classroom

Jeonghoon Lee[1]
[1]School of Mechanical Engineering, Korea University of Technology and Education, Cheonan, South Korea
Keywords: absorption, maap, aerosol.
Presenting author email: jlee@kut.ac.kr

In the atmospheric science community, light absorption is a very important parameter that can affect the estimation of radiative forcing by changing the single scattering albedo. Especially, black carbon increases the level of light absorption. Methane, tropospheric ozone and black carbon aerosol are thought to be key contributors to global warming, augmenting the radiative forcing of carbon dioxide by 65% (Penner *et al.*, 2010). Black carbon is generated from various sources: Exhaust manifold of transportation vehicles, power plant, biomass burning and so forth (Bond *et al.*, 2004). The measurement of absorption coefficient in ambient aerosol has been performed for a long time. However, the absorption coefficient at a classroom has not been measured. In this study, we investigated the light absorption at an engineering classroom and compared the relevant values to the absorption coefficient presented in literatures.

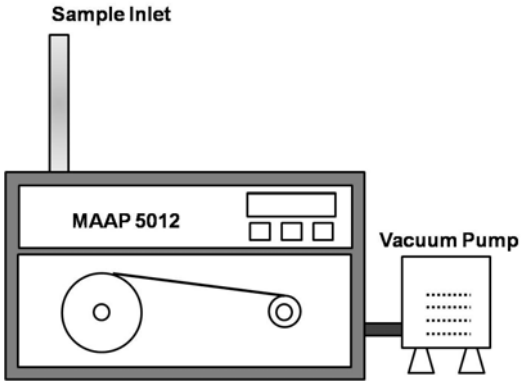

Figure 1. The schematic of Multi Angle Absorption Photometer (MAAP)

Figure 1 shows the experimental apparatus used in the present study. A Multi Angle Absorption Photometer (MAAP) was used to measure light absorption coefficient inside an engineering classroom where students intermittently operates several instruments and facilities such as a thermal radiation experiment, heat exchanger and small wind tunnel. MAAP (Thermo Scientific 5012) is a typical filter based absorption measurement instrument similar to a Particle Soot Absorption Photometer (PSAP) which measures light transmittance through a filter after depositing particle aerosols. The PSAP and the MAAP can be operated unmanned. During the last five years, PSAP has an issue associated with the scattering effect from the filter substrates. However, MAAP is known to show better performance than PSAP in that MAAP corrects the artifacts of scattering effect arisen from the filter substrates.

Shown in Figure 2 are aerosol absorption coefficients measured for 24 hours at the engineering classroom. There was no class and no operation of instruments/facilities for 20 hours during the absorption measurement period. Surprisingly, absorption was measured to be larger than 1 g/m^3, which was somewhat larger than we expected. As far as the authors know, it is for the first time that we measured the absorption coefficient at a classroom where engineering practices are periodically exercised. We will discuss the implication of the absorption coefficients that were detected at a classroom as opposed to in ambient environment.

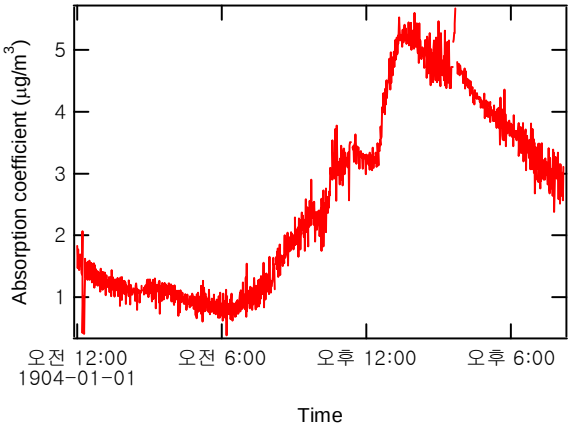

Figure 2. Absorption data for 20 hours measured at a classroom.

Determining the transfer function of a Very Long DMA using polymer size standards

J. Uin and E. Tamm
Laboratory of Environmental Physics, Institute of Physics, University of Tartu, Tartu, Estonia
Keywords: DMA, Transfer function, Aerosol spectrometry, Aerosol instrumentation.
Presenting author email: janek.uin@ut.ee

The aim of this work is to measure experimentally the transfer function (TF) of a Very Long DMA (working length 1.2 m) (Peil and Tamm, 1984). It is an experimental continuation of the previous theoretical work where possible distortions to the DMA TF were examined (Tamm and Uin, 2009).

There are different ways for measuring the TF of a DMA. One well-known method uses a setup where two identical unknown DMAs or a known DMA and a different unknown DMA are used in tandem (Stratmann *et al.*, 1997). Another method uses three different unknown DMAs in pairs (Martinsson *et al.*, 2001). These are proven methods, but in addition to the DMA under investigation, they require the presence of another, identical or at least similarly capable DMA. As the above-mentioned Very Long DMA is rather unique, these methods are not suitable.

A way for determining the DMA TF, which does not require multiple DMAs, is to measure a highly monodisperse aerosol. From the definition of the TF, it can be seen that when scanning over the aerosol distribution with a DMA, the measurement result is a convolution between the aerosol distribution and the DMA TF. If the aerosol distribution is very narrow (much narrower than the DMA TF), then the measurement result can be approximated as a convolution between the TF and a delta function, which is equal to the TF itself (change in the absolute width of the TF is small enough to be ignored). Here, only the half-width of the TF is examined and the height (and area) of the TF are not investigated, as the total aerosol concentration is, in this case, practically impossible to determine.

To experimentally measure the TF half-width of the instrument in question, a suspension of polymer microspheres with a mean diameter of 1 (0.994) µm and standard deviation of 0.010 µm was atomized to produce a monodisperse test aerosol. The obtained aerosol was then dried in a silica gel drier and neutralized using a ^{239}Pu neutralizer. The mobility distribution of the test aerosol was then measured using a Very Long Vienna-type DMA and a CPC. A triangular function (Stolzenburg, 1988) was fitted to the measured distribution of singly charged particles (singly and multiply charged particles were easily distinguished, i.e. there was no overlapping) and the relative half-width β of the function was obtained (Figure 1). Ideally (determined by the DMA airflows) $\beta = 0.100$, but in this case, measurement results gave $\beta = 0.170$.

The wider TF is most likely caused by the less than perfect geometry of the DMA (and also possibly by the non-uniformity of the aerosol flow). Namely, as the DMA electrodes are comprised of several sections, some parts of the electrodes may not be entirely concentric. And according to numerical modelling, this can cause a widening of the DMA TF (Tamm and Uin, 2009).

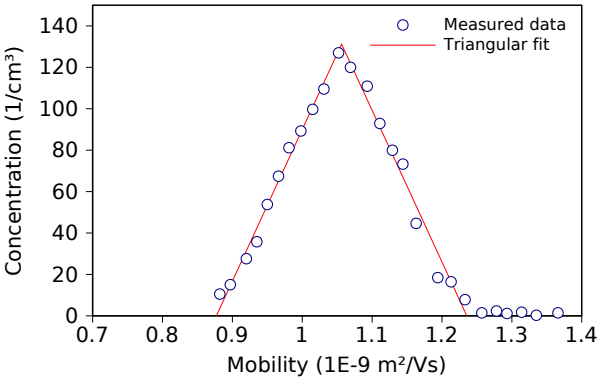

Figure 1: Experimentally found DMA TF and triangular fit ($R^2 = 0.990$).

As stated above, the height of the DMA TF was not investigated, Therefore, the vertical axis in Figure 1 shows the aerosol concentration as measured by the CPC. This is presented to illustrate the relatively low particle concentrations available, which can make the described experiments difficult. Attempts were also made to use aerosols with 7.9 µm mean diameter, as the DMA used is capable of measuring particles with diameter up to 10 µm. However, while the solid content of the 7.9 µm suspension is approximately 10 times higher than that of the 1 µm suspension, the volume of a particle is 10^3 times higher, which gives much lower number concentrations and makes the particle detection/counting even more difficult.

This work was supported by the Estonian Science Foundation under grant no. 8779 and by the Estonian Research Council Targeted Financing Project SF0180043s08.

Cascade impactors are widely used instruments in chemical aerosol characterization. There are several techniques for the chemical analysis of aerosol samples from cascade stages , e.g. EDX, GC-MS, Raman, XRF, etc., but none of them measures particle size and size distributions. Particle size resolved quantitative chemical analysis either requires the additional use of particle classifiers (e.g. SMPS) or the quantitative analysis of the deposits on cascade stages. The latter implies sample strengths above the lower threshold of the respective analytical method. Many environmental indoor or outdoor aerosols are polydisperse and consist of several chemical substances in different quantities. The quantification of one given chemical substance or a given element, hidden in the background of all the other contributions, and its assignment to a particle size class is therefore not always easy to achieve with the methods available.

Here we present a novel approach to use Gracing Incidence X-Ray Fluorescence Analysis (GIXRF) based on fundamental constants in order to determine size, quantity and chemistry of small nanoparticulate aerosol fractions within a poly-disperse aerosol.

The sampling was done with an electrostatic aerosol sampler (TSI 3089), using one square inch clean Si-wafers. We prepared monodisperse $ZnTiO_3$, TiO_2 nanoaerosol by use of an atomizer (Topas ATM 220) either with and without size selection by the Classifier and also a technical produced example of a polydisperse indoor aerosol.

For the experiments we used the PTB/BAM X-ray beamlines at BESSY II in Berlin at different excitation energies. High spectral resolution enables studies of the chemical state of the elements (Reinhardt et al., 2009) while the low divergence of the beam allows for dedicated geometries, such as a grazing incidence setup. Based on total-reflection X-ray fluorescence analysis (TXRF), which offers very low quantitative detection limits in the pg to fg range (Beckhoff et al., 2007), in GIXRF the incident angle of the excitation radiation is tuned between 0° and about threefold the critical angle of total-reflection. Thereby the position and strength of the maxima of the X-ray standing wave field (XSW) above the surface is modified. Particles with a given diameter deposited on a flat substrate will be exposed to excitation radiation of varying intensity depending on the angle of incidence and the particle size.

Hence the measured X-ray fluorescence signal contains information on the atomic composition of the particles and information on the deposited size fraction.

Based on fundamental constants we could use GIXRF measurements at BESSY II beamlines to determine the total amount of deposited nanoparticles of one size on a flat surface. Besides the absolute determination of the deposited nanoparticles, the measurement is independent of small contaminations of the substrate with other materials or polydisperse nanoparticles. This makes the GIXRF method a unique and very promising method for nanoparticle characterization, especially regarding poydisperse and inhomogenic environmental aerosols.

A chamber for aerosol instrument comparisons

P.G.Quincey[1], T.D.Gardiner[1], F.Innocenti[1] , M. Coleman[1] and J.Tompkins[1]

[1] Analytical Science Division, National Physical Laboratory, Teddington, Middlesex, TW11 0LW, UK

Keywords: aerosol instrumentation, measurements.

Methods and facilities for calibrating aerosol instrumentation are not new, but it is only in recent years that systematic efforts have been made to harmonise such measurements, though initiatives such as EUSAAR in the ambient aerosol area (feeding into EMEP) and the Particle Measurement Programme (PMP) for vehicle emissions. International standardisation is currently taking place through CEN and ISO. National Measurement Institutes (NMIs) are starting to provide traceability for number concentration measurements, in the same way as for most other measurements, with the first NMI comparison for aerosols taking place at METAS in Switzerland in 2008 (Schlatter, 2009).

While most calibrations are expected to take place in dedicated rigs using pipework rather than a chamber, there is an important role for chambers in allowing the simultaneous comparison of many instruments presented with a variety of aerosols, possibly changing in time, especially when the instruments have different operating principles such as optical as well as extractive. The primary aim of such a chamber is to provide a controlled homogeneous aerosol volume with many equivalent sampling points.

A chamber has been designed and built specifically for this purpose. The basic design is a cylindrical chamber with great care taken to introduce the aerosol uniformly throughout the central section of the cylinder, with a clean air sheath at the walls. The layout is illustrated in Figure 1.

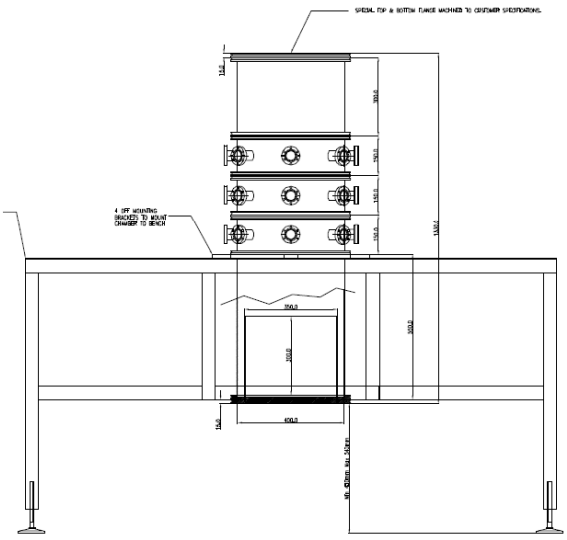

Figure 1. Design of chamber

The basic parameters of the chamber are given in Table 1. Several different aerosol sources can be connected to the chamber. For example, the laboratory includes a CAST soot generator, atomisers, electrospray, and fluidised bed aerosol generators.

Diameter	35 cm
Sampling ports	3 series of 8, at 45° intervals
Aerosol flow rate	40 l/min
Aerosol velocity	0.7 cm/s

Table 1. Basic chamber parameters.

Measurements of aerosol uniformity within the chamber have been made. Measurements from a complete traverse of a diameter are given in Figure 2, showing a variation of around ±1%. Similar variations were found between a set of 8 ports around a circumference. Results from a comparison involving several laboratories will be presented.

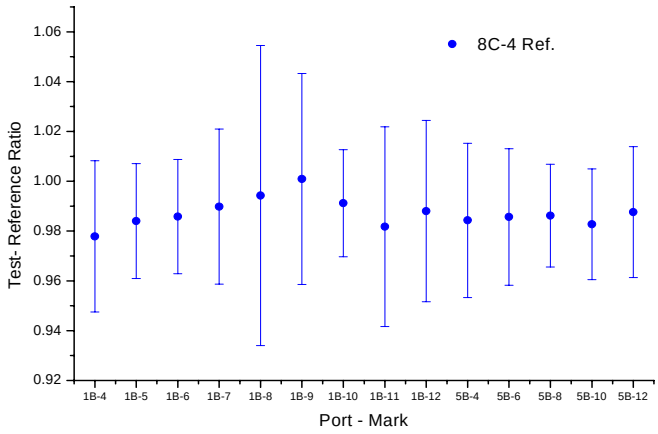

Figure 2. Radial uniformity of 55 nm soot particle concentration. The points span the central 30 cm of the chamber.

This work was supported by the UK's National Measurement Office Chemical and Biological Metrology Programme. The contribution of R.J.J.Gilham to the design and construction of the chamber is gratefully acknowledged.

Introduction

To understand and quantify the impact of a chronic or accidental atmospheric release of pollutant in the form of aerosols in the environment, it's essential to know the transfer velocity of aerosols air at the surface. Dry deposition velocity (V_d) is obtained by the ratio of flux deposited and the aerosol concentration measured in air.
The purpose of this work is to make an intercomparison of dry deposition velocity obtained using an Electrical Low Pressure Impactor (ELPI, Dekati, Inc) and a Condensation Particle Counter (CPC, Grimm 5.403).

Material and method

Dry deposition flux can be calculated from the covariance between fluctuations of the vertical wind velocity and those of the concentration of atmospheric aerosols (Damay *et al.*, 2009). Deposition velocities measurements have been led on a heterogeneous field during unstable and convective atmospheric conditions (Lecce, Italy). The atmospheric stability was deduced from value of 1/L (Monin Obukhov length) and z_0 (Table.1) (Tagliazucca *et al.*, 1983). An ELPI and a CPC both coupled with anemometers were used (Donateo *et al.*, 2006). The post processing procedures were the same for the two devices (streamlines reference system, inlet transfer time and high frequency loss correction). Because the response times of devices are different from 10Hz, a flux correction has been computed (Horst, 1997). In order to validate measurements, a quality test was performed following the method proposed by Foken and Wichura (1996) with a confidence interval of 60 %.

Results

V_d measured with an ELPI is plotted as a function of V_d established using a CPC (Figure 1). There is a good agreement between V_d determined with the ELPI and V_d determined with the CPC. Moreover it can be noticed a similarity in the values of V_d/U^*. The average value of V_d/U^* obtained with the two instruments is of 0.012 for downward fluxes and -0.025 for upward fluxes (Table 1). On a homogeneous field in the same atmospheric stability condition (unstable) V_d/U^* is of 0.010±0.003. (Damay *et al.*, 2009). This result is in agreement with ours and shows that V_d/U^* does not depend significantly on the roughness of the site.

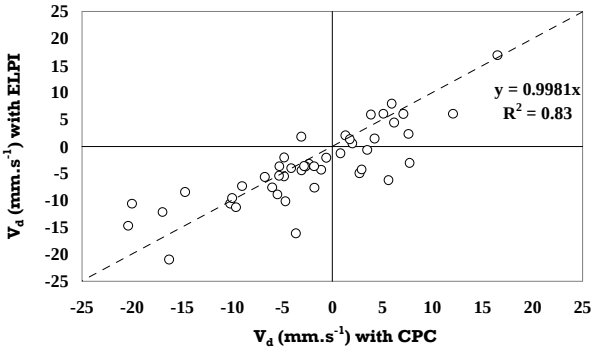

Figure 1. Dry deposition velocity measured with an ELPI and a CPC.

Table 1. Deposition velocity statistics for two cases: only upward fluxes and only downward fluxes selection. (z_0 =0.53±0.02m and d=6.1±0.4m)

	CPC	ELPI	1/L (m^{-1})
Upward fluxes V_d/U^*	-0.0245	-0.0261	-0.025
Downward fluxes V_d/U^*	0.0125	0.0115	-0.0319

Aircrafts offer the opportunity to study specific atmospheric phenomena that can not be studied by any other way, for example, evolution of gases and aerosols meanwhile they are transported in the atmosphere.

An intercomparison campaign between several atmospheric research aircrafts from several countries was carried out under the frame of Quality on Airborne Data (QAD) course organized by EUFAR from October 26 to November 5 last year. Three aircrafts took part in this campaign: ATR 42 from SAFIRE (France), Falcon 20 form DLR (Germany) and Hercules C130 from NCAR (United States).

These aircrafts were instrumented to measure several parameters like gases concentration, temperature, humidity, pressure, aerosols properties, etc. Size distribution measurements were performed by the Optical Parricle Counters (OPC) shown in table 1. The aerosol measured range has been added to the table as a third column.

Aircraft	Instrument	Size range [μm]
Safire ATR42	Grimm 1.109	0.25 - 2.50
Safire ATR42	SPP-200	0.10 - 3.00
DLR Falcon 20	PCASP-100X	0.10 - 3.00
NCAR C130	UHSAS	0.06 - 1.00

Table 1: Instruments used in this work

The PCASP-100X, SPP-200 and UHSAS are mounted on hard points below the wings or on the fuselage, whereas the GRIMM 1.109 is installed inside the ATR42 cabin. The inlet of the GRIMM is connected to an external mobile inlet installed on a window of the aircraft.

Flights developed on October 29th, 30th were carried out by ATR42 and Falcon 20, whereas the aircrafts involved in the flight of November 3rd were ATR42 and C130. The measurements compared correspond to the periods in which the aircrafts flew wing by wing in straight line runs (SLR). A total of seven SLRs were performed during the flights, only five of the latters being considered for the comparison.

The channels of the different instruments have been groupped to cover the same size range and to allow comparing the measurements directly. A total of 13 channel groups or sets, have been considered. A one minute average has been applied to the data before being analyzed. The obtained time series for each instrument are presented, as well as scattered plots for the different comparable sets. Corresponding linear regression and correlation coeficients are given and commented.

A good correlation have been found between all instruments except in the intercomparioson PCASP-100X/GRIMM, when particle concentration falls below 1 $part/cm^{-3}$. PCASP losses sentitvity when particle concentration is below this limit. The correlation coefficients of the fits reach values between 0.8 and 1.0 when particle concentration for particle concentrations higher than 1 $part/cm^{-3}$.

Acknowledgements

This work has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 227159 (EUFAR: European Facility for Airborne Research in Environmental and Geo-sciences). We would like to thank to QAD organizers and the EUFAR team for giving us the opportunity to extend our knowledge in using aircrafts measurements. The authors are grateful to SAFIRE, DLR and NCAR for operating these flights and provide and process the data.

AMS Collection Efficiencies of dry smog chamber aerosols, dependence on $(NH_4)_2SO_4$, NH_4NO_3 and SOA fractions

The Aerodyne Aerosol Mass Spectrometer (AMS) measures the average chemical composition of non-refractory species, i.e. particulate matter which vaporizes when impacted on a surface heated to 600 C. The instrument provides quantitative data on-line with time resolution down to seconds (dependent on mass loading). This is accomplished through mass spectrometric measurements subsequent to aerodynamic lens focusing. Each particle type (with respect to shape, size and composition) has associated collection efficiency (CE) which data analysis needs to take into account in order to yield quantitative results.

CE is a collective name for any effect on instrument sensitivity associated with particle sampling, and was given by Huffman *et al* (2005) as

$$CE(d_{va})=E_L(d_{va})*E_s(d_{va})*E_b(d_{va})$$

The expression above emphasizes three particle properties which may bias the sampling; lens transmission (E_L), non-spherical shape (E_S), bouncing from the vaporizer plate (E_b), and their possible dependence on size. E_L and E_S are close to unity for most ambient accumulation mode particles, making E_B the main contributor to uncertainty in quantification.

This study is a summary of CE estimates from inter comparison with other aerosol instrumentation (primarily Scanning Mobility Particle Sizer, SMPS, and Aerosol Particle Mass analyzer- Differential mobility Analyzer, APM-DMA) on data from two light duty vehicle exhaust ageing campaigns. The experiments were performed by nebulizing $(NH_4)_2SO_4$ and injecting it into a 6 m^3 smog chamber, mixing with real exhaust or precursor species and irradiating the chamber with UV-light under dry (RH~5%) conditions (Nordin et al 2011). This typically resulted in condensation of SOA and/or NH_4NO_3 (NH_3 forms in the oxidation catalyst of the vehicle), a process which was monitored for approximately 5 hours. These internally mixed aerosols spanned a wide range of chemical compositions, from pure seeds to particles dominated by either condensate, enabling investigation of the effects of these proportions on CE.

Figure 1 below illustrates one of the experiments were NH_4NO_3 and SOA condense onto $(NH_4)_2SO_4$ seeds. In the two hours plotted, the particles transform from salt cores lightly coated with organic matter (this coating occurred while injecting the exhaust) to heavily coated (approximately 50% SOA, 30% NH_4NO_3, and 20% $(NH_4)_2SO_4$) particles. During this process, the ratio of reported AMS/SMPS mass increases from 0.23 to 0.37. This is in agreement with ambient observations, where dry aerosols dominated by $(NH_4)_2SO_4$ typically is found to have E_B=0.25 while dried SOA gives E_B=0.5.

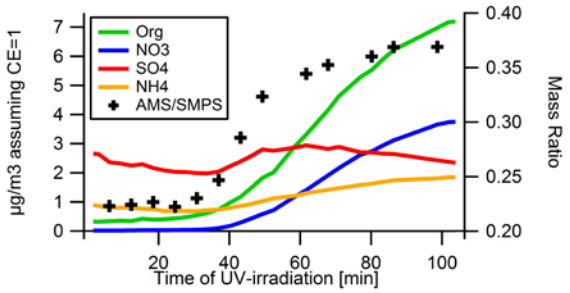

Figure 1. Chemical composition during an exhaust ageing experiment. The increase in AMS/SMPS mass ratio is likely due to an increase in E_b of the sampled aerosol. The time trace of SO_4 supports this.

Although the increasing ratio illustrated above is mainly due to increasing E_b, it should be noted that other aspects of instrumental response (in both instruments) also may affect the ratio. E_B is believed to be an effect of particle phase (Matthew et al 2008). Ambient AMS measurements usually employ a dried sampling line (to reduce interference from gaseous and particulate water), which may perturb the phase of the sampled particles. Since these experiments were performed under dry conditions, this effect is presumably captured here.

Simplified approximations to Centrifugal Particle Mass Analyser performance

K.StJ. Reavell, J.P.R. Symonds and M.G. Rushton

Cambustion Ltd, J6 The Paddocks, Cambridge CB1 8DH, United Kingdom
Keywords: Instrumentation, Particle Mass, Aerosol Particle Mass Analyser.
ksr@cambustion.com

The Centrifugal Particle Mass Analyser, CPMA, (Olfert and Collings 2005) is an instrument for classifying aerosol particles on the basis of their mass:charge ratio. In that reference and (Ehara et al, 1996), the classification of particles due to drift and the action of the electric field and rotation of the classifier is described based on a parameter λ. In this work, an alternative simplified approximation to the operation is proposed, with advantages in more easily understanding the dependence of the instrument performance on the operating parameters.

In a CPMA an annular channel is formed between rotating inner and outer cylinders, with an electric field applied between them. The radial electrical and centrifugal forces on a suspended particle in the channel are only in equilibrium for a particular mass:charge ratio, $(m/q)_{eqm}$, and only particles of close to this ratio are carried axially down the column by a flow. Other particles are precipitated: heavier particles (or with less charge) on the outer cylinder, and lighter ones on the inner. The classifier is shown schematically in Fig. 1.

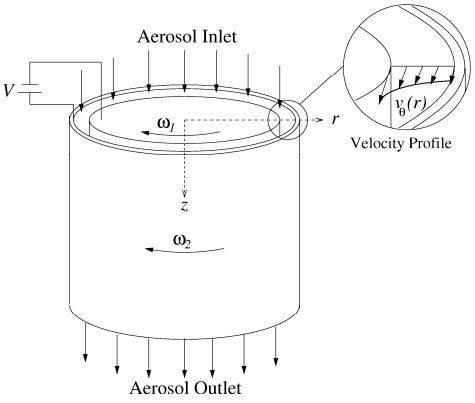

Fig 1. CPMA Classifier (Olfert 2005)

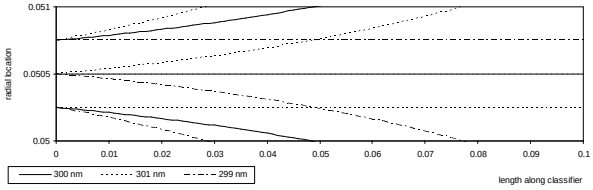
The electrical field strength, E, in the annular gap varies as r^{-1}. When the inner and outer walls rotate at slightly different speeds, ω_1 and ω_2, there is a tangential velocity profile, v_θ. Here we propose that for the narrow gap this can be approximated by a power law:

$$\omega(r) \propto r^{n_\omega}$$

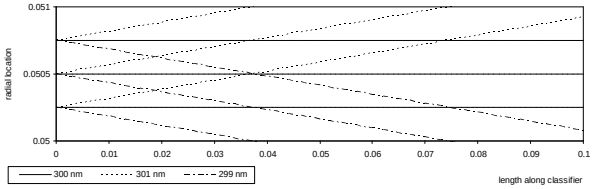
The variation of equilibrium mass:charge ratio across the channel can then be written:

$$\left(m/q\right)_{eqm} \propto r^{n_m} \text{ where } n_m = -2n_\omega - 2$$

The Aerosol Particle Mass analyser, APM, (Ehara 1996) is a special case of the CPMA where the inner and outer cylinders are joined together so $\omega_1 = \omega_2$. In this case, n_ω=0 and so n_m=-2. Therefore, as r increases, $(m/q)_{eqm}$ is lower. This is an unstable situation: a particle of $(m/q)_{eqm}$ perturbed from its trajectory increasingly departs from it, modelled below:



The parameter n_m thus describes the stability of the forces in a CPMA. If n_m is negative, the forces are unstable: this results in a reduction of particle transmission efficiency shown in (Olfert et al, 2006) and also a broadening of the range of (m/q) transmitted, referred to as the transfer function. If n_m=0, achieved by rotating the inner and outer cylinders at angular velocities in inverse proportion to their radii so n_ω=-1, then $(m/q)_{eqm}$ is constant across the classifier section, achieving the narrowest theoretical transfer function:



When n_m is positive, $(m/q)_{eqm}$ again varies across the channel, but in the opposite sense from the unstable case: this broadens the transfer function but may have benefits in reduced particle losses when diffusion is accounted for, or may be relevant in scanning applications.

The CPMA transfer function is also affected by drift. For the neutrally stable, n_m=0, case, when particle diffusion is neglected, this approximates a triangle equivalent to the non-diffusing transfer function of a DMA. For singly charged particles, the width of the transfer function is related to the classifier size and conditions by a non-dimensional relationship:

$$\left(\frac{m'}{m_{eqm}}\right)^{(n_B+1)} - \left(\frac{m'}{m_{eqm}}\right)^{n_B} = \frac{Q}{m_{eqm} B \cdot 2\pi r^2 l \omega^2}$$

where m_{eqm} is the peak mass of the transfer function, m' is the maximum transmitted mass, Q is the volumetric flow rate in the classifier, B the particle mobility, r the mean classifier radius, l the classifier length, ω the mean classifier angular velocity and n_B the power with which mobility varies with particle mass.

EC/OC Measurements on Aerosol Samples by Thermal-Optical Methods: Benchmarking Different Protocols

F. Lucarelli[1], M. Chiari[1], M. Giannoni[2], G. Calzolai[1], A. Cincinelli[2], S. Nava[1]

Presenting author email: lucarelli@fi.infn.it

Thermal-optical analysis is a standard method for determining the carbonaceous aerosol fraction and for separating it into Organic Carbon (OC) and Elemental Carbon (EC). Unfortunately, no reference method for these measurements is established yet, so the implement of the different thermal evolution protocols available in the literature, differing in temperature and duration of the heating ramps, affects the results and can result in a wide variation of EC and OC values. Moreover, the presence of Water-Soluble Organic Compounds (WSOC) in the sample may enhance the charring process during OC thermal evolution, strongly affecting and complicating the EC quantification.

The aim of this work is to provide a pragmatic guide to the EC/OC practitioners through an intercomparison between the results obtained on real samples using a Sunset Thermal-Optical-Transmittance analyzer running under different measurement protocols:

- QUARTZ (a variation of the NIOSH protocol);
- IMPROVE (J.C. Chow et al., 1993), as implemented in the analyzer;
- EUSAAR_2 (F. Cavalli et al., 2010).

This intercomparison exercise was carried out on PM2.5 samples collected in parallel on quartz fibre filters during the PATOS ("Particolato Atmosferico in TOScana") campaign from March 2009 till March 2010 in Italy, in sites of different typologies (urban traffic, urban background, rural background). One of the two sample series was analysed as-is and the other was analysed after WSOC removal by washing the filters with 100 ml of milli-Q water.

The results of the intercomparison between the three different thermal protocols will be shown. In general, a very good agreement as regards TC measurements was found, as expected. EC values obtained by EUSAAR_2 and IMPROVE protocols resulted 20%-30% higher than EC values by the QUARTZ protocol, regardless of the season and the sampling site typology. The difference tends to reduce (in particular, between EUSAAR_2 and QUARTZ protocols it becomes less than 10%) if the comparison is made on washed samples, after WSOC removal.

Finally, an indication about the "best" protocol to be adopted, on the basis of a better agreement between the EC concentrations measured on washed or not-washed samples, and thus of a minor influence of pyrolitic carbon on EC quantification when the measurements are performed on samples analysed as-is (i.e. not-washed), will be provided.

Atmospheric aerosols - Aerosol Processes and Properties

The influence of particle shape on optical particle sizers

S. Pfeifer, T. Müller, A. Weigelt, A. Wiedensohler

Leibniz Institute for Tropospheric Research , Leipzig, 04318, Germany
Keywords: optical particle counter, light scattering, non-spherical particles.
Presenting author email: sascha.pfeifer@tropos.de

Introduction

There is a lot of research on optical properties and fluid dynamics of non-spherical aerosol particles. Particle shapes are commonly determined by electron microscopy. Nevertheless, this way of size classification is time consuming and therefore often suffers from a poor statistics.

Assumption of spherical particles can lead to errors in sizing. In general, Differential Mobility Particle Sizers (DMPS), Aerodynamic Particle Sizers (APS) and Optical Particle Sizers (OPC) are sensitive to the particle shape. The particle shape influences the fluid dynamics and varies the drag-force on the particles. Furthermore, the shape also influences the scattering phase function of the particle.

A tandem measurement system consisting of e. g. a DMA and an OPC is one method to consider these effects. Heintzenberg et al. (2004) matched the data of OPC spectra for selected DMA mobility sizes with an ensemble of spheroids of different refractive indices by using the method of T-Matrix. It should be pointed out that fitting with an average of orientation ignores the fact of dispersion. The scattering signal is influenced by particle orientation relative to the incident beam, depending on optical receiver system.

The combination of DMA and Multi Angle Light Scattering (MALS) is possible as well. A multi angle detection yields much more information of an individual particle than the single angle detection of a classical OPC. Depending on the aim of the analysis, hence different modifications of the measuring instrument, it is possible to determine a refractive index or to distinguish between spherical and non-spherical particles. (Sachweh et al, 1995, 1999; Dick et al, 2007)

Experimental

The dynamic shape factor is defined as the quotient for the drag force of a non-spherical particle and those of a spherical one with the same volume. To calculate these drag forces we have to solve the Stokes equation for the suitable particle surface. This was done using the Boundary Element Method (BEM). For solving the electromagnetic scattering problem, Discrete Dipole Approximation (DDA) can be used to calculate the phase function. This numerical method allows calculation of nearly every kind of particle shape.

For a test case, we have chosen a polystyrene latex (PSL) doublet. It is easy to generate, has a well defined size, and its density and refractive index are known. The numerical solutions of the dynamic shape factor for a PSL doublet ranges between 1.02 for parallel and 1.15 for perpendicular alignment relative to the flow, respectively. These values are in agreement to experimental results (Zelenyuk et al, 2006).

Referring to the dynamic shape factor we calculated the relative scattering signal, what is defined as the quotient for the integrated phase function of the non-spherical particle and those of a spherical one with the same volume, refractive index and integration area. The calculations were done for the geometry of an OPC which measures side scattering in an angular range of ±45°, with a wavelength of 1000 nm.

For the lower part of the measurement size range we expect continuously smaller signals by 10% to 20% compared to the volume equivalent radii up to 330 nm. Values are higher by 15% to 30% between 330 and 500 nm. Furthermore, we expect that a full random orientation leads to an increase of dispersion by volume equivalent radius (Figure 1). Measurements with PSL spheres with a diameter of 350 nm verified this characteristic and matches to the simulations.

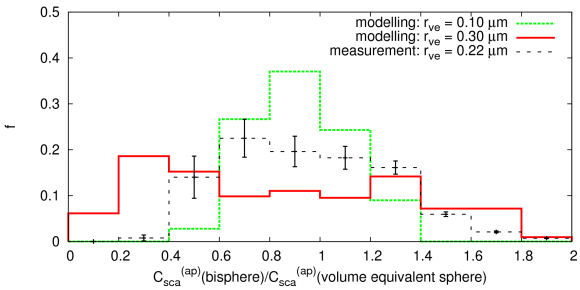

Figure 1. Fractional distribution of the relative scattering signal for random orientated PSL doublets, λ = 1000 nm

Outlook

More laboratory studies to verify results of the numerical simulations are planned. These studies will be extended to deduce significant parameters influenced by the shape. This information should help to improve the information content of DMPS, OPC and APS in-situ measurements in future.

Planetary boundary layer influence at the Jungfraujoch: in-situ and remote sensing measurements.

Presenting author email: martine.collaud@meteoswiss.ch

The high alpine research station Jungfraujoch (JFJ, 3580 m asl) is situated in the middle of the Swiss Alps and is considered as being representative of free tropospheric (FT) air masses most of the time. Fourteen years of meteorological parameters, aerosol variables and trace gases measured at the JFJ have been analyzed as a function of different synoptic weather types (Alpine Weather Statistics classification, AWS) over the whole Swiss region. The planetary boundary layer (PBL) influence was estimated by means of the diurnal cycles of aerosol species. Since aerosols are scavenged by precipitation, the diurnal cycle of the CO concentration was also used to identify polluted air masses in case of precipitation. SO_2 and NO_x concentrations were used as precursor tracers for new particle formation and growth, respectively.

This study confirms the consensus view that the JFJ is mainly influenced by the free troposphere during winter and by injection of air parcels from the PBL during summer. A more detailed picture is, however, drawn where the JFJ is completely influenced by free tropospheric air masses in winter during advective weather types and largely influenced by the PBL also during the night in summer during the subsidence weather type (i.e. CA in Fig 1). From April to September, the JFJ is influenced by the PBL during the afternoon in case of subsidence, whereas the night remains in FT. In case of lifting, the large influence of newly formed particles measured at the JFJ can be explained by the meteorological conditions and the gaseous concentrations on the Swiss plateau.

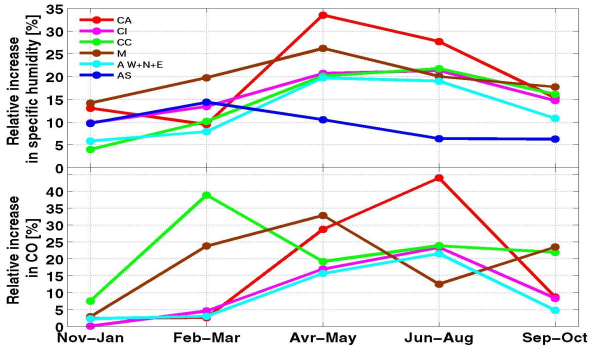

Figure 1. : Relative increase in the specific humidity and in CO concentration calculated from JFJ and Payerne (Stabio for AS) data for different weather types (corresponding to different colors) and for defined periods of the year.

An analysis of the relative increase of the specific humidity and CO concentration allows us to estimate that on average less than 45% of PBL air is found at the JFJ during all synoptic weather conditions (Fig. 1).

Aerosol parameters important to estimate the aerosol radiative forcing (single scattering albedo (SSA), extinction coefficient, backscattering fraction, asymmetry parameter) have also been calculated for dry measurement conditions and corrected for ambient conditions (i.e. elevated humidity). For most of the weather types, the ambient aerosol parameters restricted to clear sky conditions are mostly similar to the dry aerosol parameters (Fig. 2). The RH corrected SSA is usually larger than 0.90 (0.95 in case of advection).

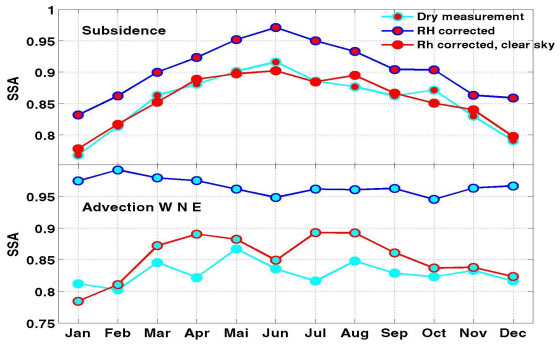

Figure 2: Single scattering albedo annual cycle for dry measurements, RH corrected aerosol parameters for all and for clear sky conditions.

During the Cloud and Aerosol Characterization Experiment (CLACE) 2010, several instruments allowing a determination of the PBL height (ceilometer, windprofiler, radiometer) were measuring vertical profiles from the Kleine Scheidegg at 2061 m asl at the foot of the JFJ. In case of clear sky, the development of the PBL height can be observed from both the ceilometer and the windprofiler measurements and compared to the in-situ aerosol measurements at the JFJ.

Improved cloud screening for aerosol optical depth measurements with a Brewer spectrophotometer

V. De Bock[1], H. De Backer[1] and A. Mangold[1]

[1]Royal Meteorological Institute of Belgium, Ringlaan 3, 1180 Brussels, Belgium

Keywords: AOD, in-situ measurements, CIMEL, seasonal patterns.
Presenting author email: Veerle.DeBock@meteo.be

An improved automatic cloud screening technique for the retrieval of Aerosol Optical Depth (AOD) values with a Brewer spectrophotometer was developed to replace the old manual cloud screening technique. The new cloud screening technique, which uses sunshine duration data, will be presented together with the AOD retrieval method. The retrieved AOD values will be compared with quasi-simultaneous Cimel sunphotometer measurements at Uccle and the seasonal and monthly variability of the AOD at Uccle will be discussed.

The AOD retrieval method (De Bock et al. 2010) uses sun scan measurements (from 335 to 345 nm, convoluted with the Cimel sunphotometer band pass filter at 340 nm) from the Brewer spectrophotometer at Uccle, Belgium (50°48'N, 4°21'E, 100m a.s.l.) whereas previously, direct sun measurements (at 5 specific wavelengths, 320.1 nm being the largest) were used.

The use of sun scans simplifies the comparison of the AOD values with quasi-simultaneous Cimel sunphotometer values since it is no longer necessary to extrapolate the Cimel AOD values to Brewer wavelength. Moreover, due to the convolution with the Cimel band pass filter, we compare physically exactly the same quantity. Another advantage is the larger intensity of the retrieved signal at 340 nm due to lower ozone absorption, thus improving the signal to noise ratio.

To derive the AOD at 340 nm from the Brewer sun scan measurements, we apply the Langley Plot Method (LPM), in a similar way as described in Cheymol and De Backer (2003), to the weighted irradiances. The LPM is a linear regression technique and the quality of this regression depends on the range of the solar zenith angles covered during a certain day. Good observations at both high and low solar zenith angels are needed and the atmospheric conditions must remain stable over the day. We define a set of criteria to select the days ('cloudless days') on which the LPM can be applied. One AOD and one Calibration Factor are calculated for each cloudless day and the average of these Calibration Factors will be used as mean calibration coefficient of the instrument. With this coefficient, the AOD can be calculated for each individual clear sky observation.

We only calculated the AOD for the individual sun scans for which a direct sun observation, made with the Brewer, is available within a time period of 5 minutes. This however did not exclude all cloud-perturbed measurements. To this end the new cloud screening algorithm was developed.

We compared the Brewer AOD values at 340nm retrieved with the old manual cloud screening technique with quasi-simultaneous AOD values (with a maximum time difference of 3 minutes) from the Cimel sunphotometer for a period from 1 September 2006 to 31 August 2010. After removing the outliers, the correlation, slope and intercept of the regression line are respectively 0.974, 0.968+/-0.014 and 0.011+/-0.006. This already showed that good quality AOD observations can be obtained at 340nm from Brewer sun scan measurements. In the poster, we will present the results of the comparison of the new cloud screened Brewer AOD values with Cimel values for an extended period from 1 September 2006 to 30 June 2011.

The seasonal and monthly variability of the new cloud screened AOD at Uccle will also be presented. We already saw a clear seasonal cycle in the observed AOD (with the old manual cloud screening method) at Uccle, with higher values in spring and summer and lower values in autumn and winter. On a weekly scale, no clear cycle could be seen.

Aircraft observations of volcanic ash properties

B.T. Johnson[1], K. T. Turnbull[1] J.R. Dorsey[2] and J.M. Haywood[1]

[1]Met Office, Exeter, United Kingdom
[2]University of Manchester, United Kingdom
Keywords: aerosol, aircraft, optical.
Presenting author email: ben.johnson@metoffice.gov.uk

During April-May 2010 volcanic ash from the Icelandic volcano Eyjafjallajökull caused major disruption to European air travel. In response to the crisis the UK's BAe-146 research aircraft (FAAM: Facility for Airborne Atmospheric Measurement) made a series of flights to map the extent of the ash clouds (via on-board lidar) and make in-situ measurements of ash particle properties. A major objective of these flights was to obtain in-situ estimates of ash mass concentration for the validation of ash forecasts and remote sensing techniques (satellite, lidar, sunphotometer). This required detailed investigation of the ash particle size distribution and their optical properties.

Owing to safety concerns, the aircraft specifically targeted regions where ash concentrations were forecast by the operational model to be in the range 200-2000µg/m^3. Data from the Cloud and Aerosol Spectrometer (CAS; figure 1a) shows that the aircraft encountered ash concentrations of 200-2000µg/m^3 on many occasions during a sequence of seven flights over the UK region from 4 – 18 May. Typically ash was observed in layers 300m – 2km thick at altitudes anywhere below 8km. The aircraft measurements also illustrate the highly inhomogeneous (patchy) nature of the ash layers with horizontal variability on a wide range of scales (10 – 100km). High mass concentrations were also accompanied by elevated levels of SO_2 (up to 100ppbv) and a strong signature of aerosol scattering (up to 300 x 10^{-6} m^{-1}). The 3-wavelength nephelometer showed low Ångstrom exponents (-0.5 – 0.4) across visible wavelengths, typical of coarse aerosol (diameter > 1µm).

The size distribution from the CAS showed a broad peak between 1 – 10µm (volume-equivalent diameter) with volume mean diameters in the range 3 – 8µm and a rapid fall-off beyond 10µm. Very few particles were observed at or above 30µm, somewhat in contrast to the results from dispersion models. This indicates that improvements could be made to the assumed source size distribution and/or losses due to near-source aggregation and fall-out.

The mixing of ash plumes with ice cloud posed a major challenge on some flights. Measurements from a variety of aerosol, cloud and humidity probes have therefore been combined to develop techniques for discriminating between ice and ash. This has been used to give confidence to measurements close to, but outside of, clouded regions.

Asphericity measurements from the Small Ice Detector (SID-2) have also been used to distinguish ash particles (observed to be highly aspherical) from spherical aerosols, such as hydrated sea-salt. At low altitudes (i.e. within the boundary layer) such hydrated aerosol were found to carry around 200µg/m^{-3}, comparable to the observed ash mass concentrations. This shows the need for careful examination of in-situ data to ensure reliable estimates of ash concentration.

Finally, the specific extinction coefficient (k_{ext}) of ash aerosol has been estimated using CAS size distributions and light-scattering models. Preliminary results, based on many sections of flight data suggest k_{ext} values in the range 0.3 – 1.0 m^2/g, with a mean value of 0.5m^2/g. These estimates of k_{ext} are for downwind ash layers observed in the UK and may not be representative of near-source properties. However, these estimates provide a guide for downwind properties in future eruption scenarios and may be useful for remote sensing techniques that rely on an estimate of k_{ext} to convert aerosol extinction to mass concentration.

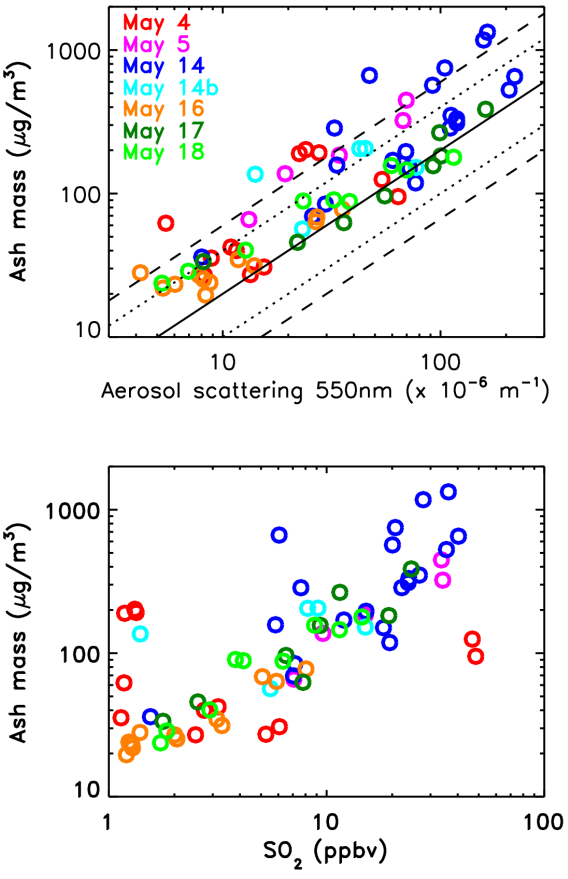

Figure 1. Mean ash mass concentration (from CAS), aerosol light-scattering coefficient (from nephelometer) and SO_2 concentration from selected aircraft runs.

One Year Aerosol Measurements with LIDAR in Portugal

F. Wagner [1], J. Preißler[1], J.L. Guerrero-Rascado[1] and A.M. Silva[1]

[1]Geophysics Center of Évora, University of Évora, Évora, 7000-671, Portugal
Keywords: lidar, optical properties, vertical profile.
Presenting author email: frankwagner@uevora.pt

Atmospheric aerosol particles play a major role in the climate system due to their various direct and indirect effects which in turn influence other components of the climate system. The vertical profile of aerosol particles is mainly important for long-range transport of particles, but it has also an influence on the climate effect of absorbing particles.

Since September 2009 a five-wavelength Raman lidar with depolarization channel was installed at Évora, Portugal. It emits light at 355, 532 and 1064 nm and receives backscattered light at the same wavelengths and additionally at the Raman shifted wavelengths 387 and 607 nm. The lidar is from type PollyXT (Althausen et al. 2009) and the only lidar instrument in Portugal. Hence it is the first time that the annual cycle of the vertical profile of aerosol particles could be determined in Portugal. Previous lidar measurements were only performed during measurement campaigns.

In this presentation an overview over one year of lidar measurements will be given. On more than 150 days the instrument was operated and provided height-resolved data. On 26 days aerosols originating in the African Sahara could be observed. The particles emitted from the Icelandic volcano Eyjafjallajokull could be measured on 6 days during May 2010. European pollution and forest fire aerosols were transported to Evora and observed with the lidar, too. However during most of the time the typical rural background persisted over and around Évora.

At the presentation differences and similarities of the vertical profile of aerosol particles will be shown. One major difference becomes obvious when one compare the profiles of desert dust with profiles of volcanic particles. Desert dust can reach altitudes up to 6 km and usually the whole atmosphere below the top of the dust layer is filled with particles. In contrast aerosols from the volcano Eyjafjallajokull could be observed in the whole troposphere but the most intense layer appeared as thin filaments.

Figure 1 one shows an example of the vertical profile of the spectral particle backscatter- and extinction coefficients as well of the volume depolarization ratio. The different quantities cannot be observed all over the whole height range because the signal to noise ratio and the effect of error propagation in the retrievals limit the valid height range.

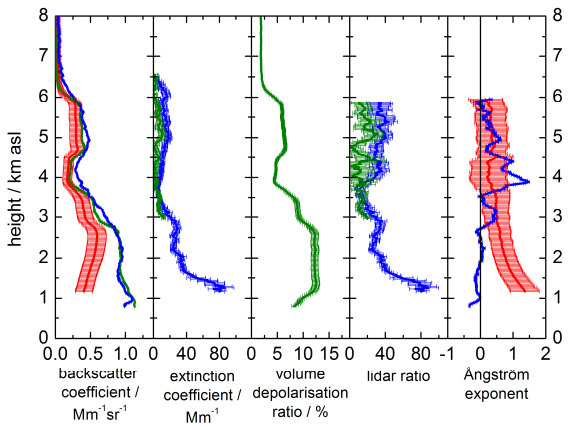

Figure 1. Example of lidar measurements on the 11th of December 2010 showing the particle backscatter coefficients at three wavelengths, the particle extinction coefficients at two wavelengths, the lidar ratios at two wavelengths, two Angstrom exponents, and the volume depolarization ratio at one wavelength.

The authors would like to thank FCT (Fundação para a Ciência e a Tecnologia) for the fellowships of Jana Preißler (SFRH/BD/47521/2008) and Juan Luis Rascado (SFRH/BPD/63090/2009), and for the funding of the lidar system in the framework of the National Re-Equipment program (REDE/1527/RNG/2007) and project PTDC/CTE-ATM/65307/2006. The authors would also like to thank the lidar team of the Leibniz-Institute for Tropospheric Research (IFT) in Leipzig, Germany, for providing data analysis software and support with the PollyXT system. This bilateral collaboration between CGE and IFT was additionally supported by CRUP (Conselho de Reitores das Universidades Portuguesas) (A-34/09) and DAAD (Deutscher Akademischer Austauschdienst) (0811989). Furthermore the authors would also like to acknowledge benefits arising from the membership in EARLINET and SPALINET.

In situ volcanic aerosol measurements made using the FAAM research aircraft; a case study

K.F. Turnbull[1], B.T. Johnson[1], F. Marenco[1], J. Dorsey[2] and J.M. Haywood[1]
[1]Met Office, Exeter, EX1 3PB, United Kingdom
[2]NCAS, University of Manchester, United Kingdom

Keywords: aerosol, aircraft, optical propertie, volcanic particles
Presenting author email: kate.turnbull@metoffice.gov.uk

The Facility for Airborne Atmospheric Measurement (FAAM) BAE-146 research aircraft flew over and around the UK during the April-May 2010 period when European airspace was affected by volcanic aerosol from Eyjafjallajökull. Flights mapped the extent of the volcanic aerosol and made in situ and remote measurements of ash properties.

On 17 May 2010, the FAAM aircraft profiled through a plume from Eyjafjallajökull as it extended southwards over the North Sea (figure 1). The aircraft was equipped with a comprehensive suite of instruments measuring standard meteorological quantities, aerosol, cloud and chemical tracers. A downward pointing elastic backscatter LIDAR manufactured by Leosphere, operating at 355nm was also flown.

Aerosol Optical Depths (AOD) associated with the volcanic aerosol were derived from 1-minute averages of LIDAR profile data. These were integrated between altitudes of 3 km and 7 km where the volcanic plumes had been observed (Figure 2). Figure 1 shows the location of the volcanic plume, based on these AOD estimates.

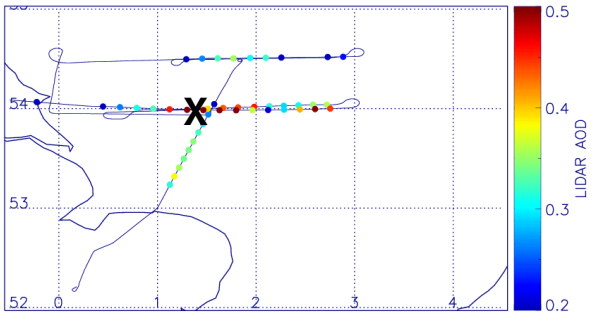

Figure 1. FAAM flight track. X indicates the approximate location of profile 1.

Total scattering coefficients were measured by a 3-wavelength TSI-3563 nephelometer (red, green, blue), Sulphur Dioxide (SO_2) concentration from a TECO-43C monitor (purple) and aerosol mass derived from the University of Manchester Cloud and Aerosol Spectrometer (CAS) covering diameters between 0.6 and 50 µm (black), as in figure 2. The optical scattering from the nephelometer was well correlated with the CAS mass concentration and also with SO_2 concentration, as shown by profile 1 (figure 2), a descent into the case study region. The plume extended between 3.3 and 6.4 km and exhibits a filamentary structure.

A specific extinction coefficient of 0.5 m^2g^{-1} was derived from CAS size spectra for this flight and used to provide a proxy estimate of aerosol mass based on the nephelometer scattering coefficient, also shown (Figure 2, orange dashed line). The nephelometer-derived mass concentrations are in reasonable agreement with the more direct measurements from CAS.

AODs derived for this profile from CAS and from nephelometer scattering measurements were 0.57 and 0.52 respectively which falls within the spatial variability of AODs estimated from LIDAR retrievals in the same location as the profile descent (see figure 1).

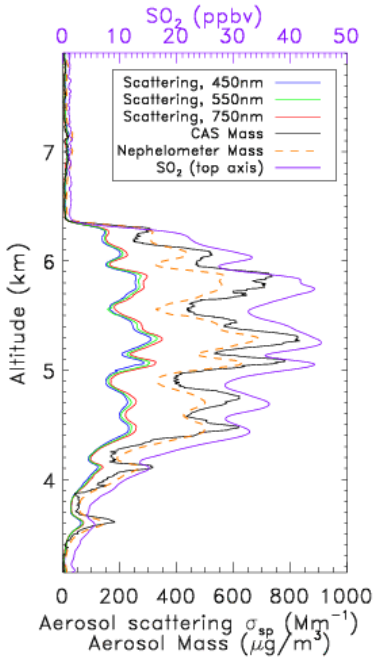

Figure 2. Profile 1 (descent) from FAAM flight B530 on 17th May 2010 near 54°N 1.2°E. For details see text.

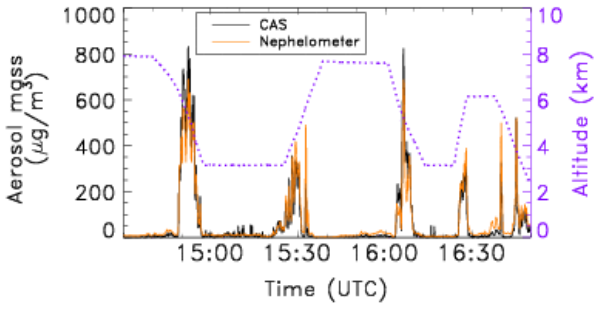

Figure 3. Time series of aerosol mass derived from CAS (black) and nephelometer scattering measurements (orange). The aircraft altitude is shown in purple.

Figure 3 shows the magnitude and variability of aerosol mass observed in the study region. These measurements are in good agreement with those made from the DLR Falcon 20E which flew in this plume 2-3 hours later around 52.5-53.0°N (not shown here).

Optical properties of rural aerosol as the function of mass concentration in Central Europe

Keywords: scattering and absorption coefficient, backscattering, single scattering albedo, Angström-exponent

Presenting author email: amolnar@almos.uni-pannon.hu

In this work the optical properties of the regional background aerosol as a function of the aerosol mass concentration (PM10) are summarized. Beside the scattering and absorption coefficients backscattering, single scattering albedo and Angström-exponent is also discussed.

All data (optical parameters and PM10) presented in this work are monitored at the Hungarian background air pollution monitoring station, K-puszta. The total and backscattering coefficients have been measured at three wavelengths (450nm, 550nm, 700nm) by TSI 3563, while the absorption coefficient has been measured at 550nm by PSAP. PM10 mass concentration is detected by β-gauge measurements.

Our results show that below of 85μgm^{-3}, the absorption and the scattering coefficients are quasi linear functions of the PM10. The backscattered fraction of the total scattering is in an inverse relationship with PM10, the backscattered fraction decreases if the mass concentration increases. The decrease of this parameter depends on the wavelength: the longer the wavelength the higher its value. Thus, the backscattering fraction, which is an important factor in climate models, cannot be considered constant.

The single scattering albedo is also studied as a function of PM10. The data also show that the increase of PM10 results in the rise of the single scattering albedo (Fig. 1). This is due to the fact that the increase of scattering coefficient is higher than that of the absorption coefficient.

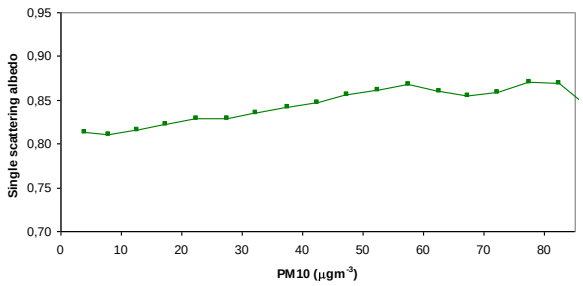

Figure 1. Single scattering albedo as a function of PM10.

The wavelength dependence of scattering coefficients (total and backscattered) is evaluated by the Angström-exponent (α). It is found that when PM10 increases, the value of α decreases in the whole wavelength range (450-700nm) (Fig. 2). This suggests that in background air the growth of PM10 mass concentration involves the increase of mean particle size. This can be explained by the fact that in clean air (low PM10) the role of freshly formed secondary particles (which are very small in size and consequently have small mass concentration) is higher than that of aged and coarse particles. Finally, the results make it clear that the values of Angström-exponent in different wavelength ranges are not equal, they are smaller at shorter (450-550nm) than at longer (550-700nm) wavelengths.

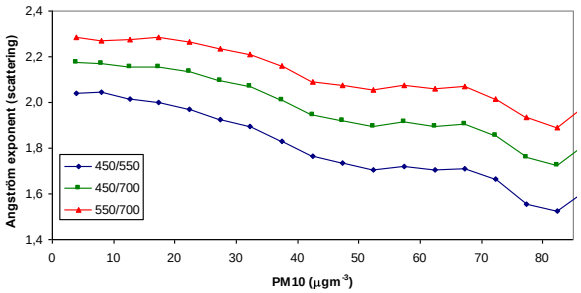

Figure 2. Variation of the Angström-exponent as a function of PM10 concentration.

Seasonal characteristics of the radiative properties of aerosols at Mace Head, Ireland

A. Vaishya, S.G. Jennings, and C.D. O'Dowd

Centre for Climate & Air Pollution Studies, School of Physics, Ryan Institute,
National University of Ireland Galway, Galway, Ireland.
Keywords: marine aerosols, scattering coefficient, seasonal patterns, Nephelometer.
Presenting author email: a.vaishya1@nuigalway.ie

The Mace Head Atmospheric Research Station (53^0 19'N, 9^0 54' W) on the west coast of Ireland is an important GAW measurement site and is designated as a clean marine background station for aerosol research. Long term continuous measurements of aerosol radiative properties, specifically the light absorption coefficient (Junker, 2006) and the light scattering coefficient, have been carried out since 1989 and 1997, respectively.

Being a coastal research station, Mace Head is dominated by air masses arriving from the clean marine sector, from 180^0 to 300^0, approximately 52% times throughout the year (Jennings et al, 2003). Junker et al, (2006) found that the hourly average absorption coefficient of marine aerosols follows a lognormal distribution with a geometric mean of 0.31 Mm^{-1}. Yoon et al, (2007) reported a seasonal trend in the light scattering values at Mace Head with aerosol scattering coefficient showing a minimum value of 5.5 Mm^{-1} in the summer and a maximum value of 21 Mm^{-1} in the winter season.

In this study we have analysed 12 years of aerosol scattering data, from 1999 to 2010, from a three wavelength (TSI 3563) and a single wavelength (TSI 3551) Nephelometer instruments. Black carbon mass concentration was used as a criterion for classification of the scattering coefficient data into clean and polluted sector scattering. Black carbon mass concentrations of <50 ng/m^3 and >150 ng/m^3 were used as indicators for the clean sector and polluted sector, respectively. Black carbon mass concentration values used in this study were obtained from three different instruments: Aethalometer model's AE-9 from 1999 up to April 2005; an Aethalometer AE-16 from May, 2005 up to 2010 and a MAAP instrument from April, 2005 up to 2010. Adjustments were made to MAAP data in order to make it comparable with AE-16 data using the analysis of Jennings et al, (2007). MAAP data were used to fill the gaps when AE-16 data were not available.

There was a three fold increase in aerosol scattering values during the winter months as compared to summer months. This increase is mainly driven by enhanced sea-salt production due to high wind speed during the winter season. In contrast the weather systems during the summer months are less active (Jennings et al, 2003) and the ocean water is dominated by water insoluble organic compounds (O'Dowd et al. 2004). A detailed study of the seasonal variation of aerosol scattering coefficient values over the twelve year period with respect to clean and polluted sectors is presented.

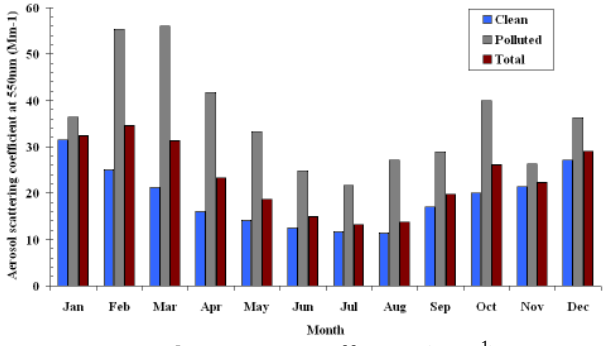

Figure 1: Aerosol scattering coefficient (Mm^{-1}) at 550nm for clean (blue) and polluted (grey) sectors, at Mace Head from 1999-2010.

Aerosol-halogen interaction: Change of aerosol optical properties

J. Ofner[1], N. Balzer[1], H. Grothe[2], H.-U. Krüger[1], Ph. Schmitt-Kopplin[3], C. Zetzsch[1]

[1]Atmospheric Chemistry Research Laboratory, University of Bayreuth, Bayreuth, Germany

Keywords: organic aerosols, halogenation processes, optical properties..
Presenting author email: Johannes.ofner@uni-bayreuth.de

Reactive halogen species, released by sea-salt activation, offer a class of reactants of utmost importance for heterogeneous reactions with organic aerosols. To study the interaction of organic aerosols with these halogen species, secondary organic aerosol (SOA) was produced from α-pinene, catechol and guaiacol (Ofner et al., 2011) in a 700 L glass smog-chamber and in a 3500 L Teflon smog-chamber at defined environmental conditions (with and without simulated sunlight and ozone at various humidities). The well-characterized and aged organic aerosols were exposed to molecular halogens in the presence of UV/VIS irradiation and to halogens released from simulated natural halogen sources to study the halogen-SOA interaction process.

Various spectroscopic methods were used to investigate optical and structural changes of the organic aerosols. Diffuse reflectance UV/VIS spectroscopy was employed to characterize optical properties in the UV/VIS spectral range. Using FTIR spectroscopy both, the aerosol formation and transformation process and, using ATR (Attenuated Total Reflectance) spectroscopy, the appearance of functional and structural elements of the particulate phase were characterized. Using Temperature-Programmed-Pyrolysis Mass-Spectroscopy (TPP-MS) and Ultra-high resolution Fourier-Transform/Mass-Spectroscopy (ICR-FT/MS), degrees of halogenations and single halogenated molecules could be determined.

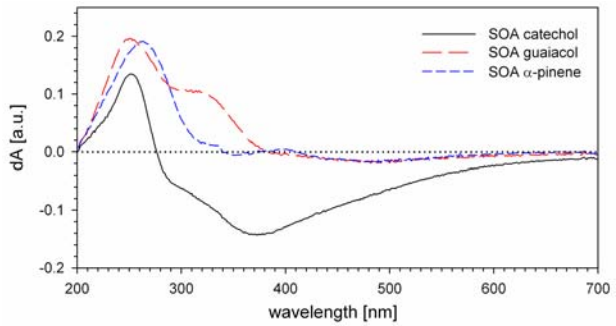

Figure 1. Differential absorbance of the organic aerosols, calculated from the diffuse spectra before and after the reaction with natural released halogens

Overall, the optical properties of organic aerosols appear to be significantly changed due to the reaction with those reactive halogen species. While the interaction with chlorine was found to lead to some bleaching (corresponding to a blue-shift), the reaction with bromine shifts the absorption in the UV/VIS range to the red. Those changes are indicated by calculating the differential absorbance (dA) from the diffuse UV/VIS spectra (see Fig. 1), where a "bleaching" of the organic aerosols is observed.

Also transformation of relevant functional groups and formation of carbon-halogen bonds was found in the infrared between 800 and 600 cm^{-1}. While the carbonyl stretch region is the most dominant absorption at simulated (from α-pinene, catechol and guaiacol) and natural SOA samples (at about 1730 cm^{-1}), the infrared spectra of the halogenated SOA from the model precursors significantly differ (see Fig. 2) from the reported spectra of unprocessed SOA (Ofner et al., 2011).

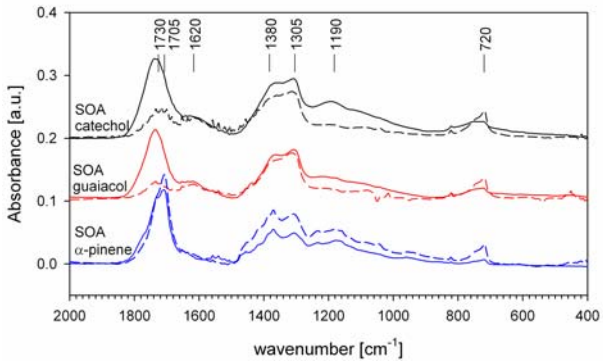

Figure 2. Comparison of ATR FTIR spectra of the unprocessed (solid lines) and halogenated (dashed lines) organic aerosols.

Due to the change of the chemical properties a change of the physical properties is expected, that is related to the atmospheric environment like ability to act as CCN, their potential to adsorb other low-volatile gases or even their contribution to radiative forcing.

This work was supported by the German Research Foundation within the HALOPROC project.

Seasonality of aerosol optical properties in the Amazon Basin

L.V. Rizzo[1], K.T. Wiedemann[2], F. G. Morais[2], P. Artaxo[2], T. Muller[3], A. Wiedensohler[3]

Keywords: Biogenic particles, Biomass burning, Absorption coefficient, Scattering coefficient.
Presenting author email: artaxo@if.usp.br

Aerosol physical and chemical properties were measured at a pristine Amazonian forest site from Febuary 2008 to December 2010, under the scope of EUCAARI (European Integrated Project on Aerosol Cloud Climate and Air Quality interactions) and AEROCLIMA (Direct and indirect effects of aerosols on climate in Amazônia and Pantanal) projects. The dataset obtained encompass the first long term aerosol measurements ever performed in Amazonia, elucidating the differences between the biogenic aerosol population naturally released by the forest metabolism and the anthropogenic aerosols brought to the ecosystem by outer sources.

Measurements were taken at the Cuieiras forest site, tower TT34, above the canopy (45m), under dry conditions. A MAAP photometer in series with a nephelometer (TSI 3563) was used to measure aerosol absorption and scattering, respectively. Scattering coefficients were corrected for truncation errors. Observations were adjusted to 1000 mbar and 0^{o}C.

Aerosol scattering coefficients ranged between 1 and 200 Mm^{-1} at 450 nm (Figure 1), while absorption ranged between 1 and 20 Mm^{-1} at 637 nm (Figure 2). A strong seasonal behavior was observed, with greater aerosol loadings during the dry season (Jul-Nov) as compared to the wet season (Dec-Jun). Although the forest site is well preserved, it receives the influence of regional biomass burning emissions during the dry season.

During the wet season, aerosol scattering (450 nm) and absorption (637 nm) coefficients averaged, respectively, 14 ± 22 and 0.9 ± 0.8 Mm^{-1}. Both optical coefficients were greatly increased during the dry season, averaging 58 ± 58 Mm^{-1} and 4.1 ± 3.8 Mm^{-1}, correspondingly. Angstrom exponents for scattering were lower during the wet season (1.6 ± 0.4) in comparison to the dry season (1.9 ± 0.2), which is consistent with the shift from biomass burning aerosols, predominant in the fine mode, to biogenic and dust aerosols, predominant in the coarse mode. Single scattering albedo, calculated at 637 nm, did not show a significant seasonal variation, averaging 0.86 ± 0.06 and 0.86 ± 0.04, respectively for wet and dry season.

Also, measurements of aerosol elemental composition indicate events of long range transport of African dust to the Amazonian forest site. These outer sources of particles affect the optical properties of the natural aerosol population, with implications to the regional climate and to the forest nutrient cycle.

This work presents a general description of the aerosol optical properties in Amazonia, both during the Amazonian wet season, when the aerosol population is dominated by particles of biogenic origin, and during the dry season, when there is a strong influence of biomass burning emissions. It is important to describe accurately the optical behavior of these particles in order to assess the impact of anthropogenic changes on the regional climate. Furthermore, since the Amazon forest is located in a region of intense convective activity, the aerosols released there can be long-range transported, potentially resulting in climate effects that are globally relevant.

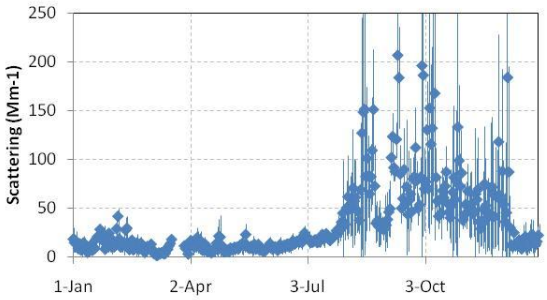

Figure 1. Daily averages of scattering coefficients measured at 450 nm from Feb 2008 to Dec 2010.

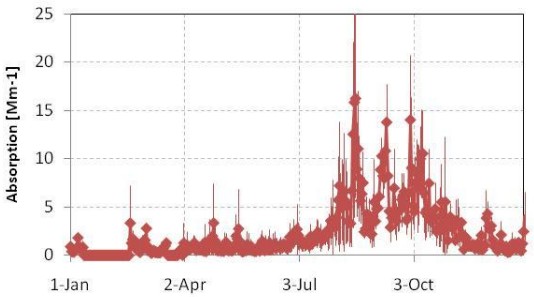

Figure 2. Daily averages of absorption coefficients measured at 637 nm from Feb 2008 to Dec 2010.

Comparison of MODIS Deep Blue aerosol single scattering albedo and asymmetry parameter with AERONET for northern Africa, Middle East and Europe

M. Korras Carraca, A. Gkikas and N. Hatzianastassiou

Department of Physics, University of Ioannina, Ioannina, Epirus, 45110, Greece
Keywords: aerosol single scattering albedo, asymmetry parameter, MODIS, AERONET
Presenting author email: agkikas@cc.uoi.gr

The interaction of aerosols with radiation, which determines their climatic effects, is strongly dependent on their optical properties (Hatzianastassiou et al., 2004). Spectral radiative transfer models usually require data for three optical properties, namely aerosol optical depth (AOD), single scattering albedo (SSA) and asymmetry parameter (g_{aer}). Apart from AOD, which quantifies the aerosol loading, SSA expresses the scattering/absorbing ability of aerosols whereas g_{aer} describes the angular distribution of the scattered radiation from aerosol particles. Although globally distributed AOD data are quite abundant nowdays, those of SSA and g_{aer} are still limited, despite the fact that both critically affect the aerosol radiative and climatic effects, as it has been shown in the literature. Recently, an unprecedented availability of globally distributed SSA and g_{aer} data was made possible thanks to the MODerate Resolution Imaging Spectroradiometer (MODIS) Deep Blue algorithm (Hsu et al., 2004). However, given the difficulties in deriving these properties, which are highly depended on relevant assumptions that are made, it is necessary to intercompare these products with corresponding groundbased ones.

In the present study, we attempt an intercomparison of MODIS Deep Blue SSA and g_{aer} data with corresponding measurements from stations of the globally distributed reference AERONET network. The intercomparison is performed for the greater Mediterranean basin and the surrounding regions of North Africa, Middle East and Europe. The study region extends from 5^o N to 70^o N and from 25^o W to 60^o E. The intercomparison of SSA and g_{aer} in the study region is of primary importance because of the co-existence of different types of aerosol (e.g. dust, urban, maritime, continental, biomass burning) originating from local, neighbouring and remote sources. We use daily gridded (1^ox1^o) data from the latest MODIS Deep Blue C051 collection over the period 24 February 2000-22 September 2010 from Terra, and over 4 July 2002-18 September 2010 from Aqua satellite. The MODIS Terra and Aqua SSA and g_{aer} data are compared against daily AERONET measurements from 156 stations within the study region. The MODIS wavelengths, 470nm (g_{aer}, SSA), 660nm (g_{aer}, SSA) and 870nm (g_{aer}) have been selected to ensure satisfactory spectral coverage and consistency with the available AERONET wavelengths (close to 440nm, 675nm and 870nm).

According to MODIS-Aqua, the mean annual g_{aer} values range from 0.58 to 0.73 at 470nm, from 0.49 to 0.71 at 660nm and from 0.43 to 0.7 at 870nm, exhibiting a decreasing tendency with increasing wavelengths. The MODIS-Terra values are slightly larger (by 0.02-0.04) than Aqua ones. In general, g_{aer} takes slightly larger values in the Atlantic Ocean and Arabian Sea, probably due to the influence of dust outflows from the Saharan and Arabian deserts, against smaller g_{aer} values in the North, Baltic and Black Seas and off the region's coasts. Especially low g_{aer} values are observed in the closed Black Sea and off the coasts of northern Europe and Siberia, which can be attributed to the fine pollution aerosols from anthropogenic activities. The MODIS SSA_{470nm} values, which essentially cover North Africa and Middle East, range from 0.89 to 0.95 over most of these desert areas. The smallest values are observed in Tunisia and northeastern Algeria. On the other hand, SSA_{470nm} values larger than 0.95 (up to 0.99) are found at the west parts of the sub-Sahel.

Two specific sub-regions have been discriminated based on the different nature of aerosol sources which are included in them. The first sub-region consists of Europe (significant anthropogenic aerosols) and the second one consists of North Africa and Middle East (natural aerosols). The frequency histograms of MODIS g_{aer} values at 470nm, reveal distributions shifted to smaller values for Europe (centered at 0.7) against larger values for North Africa and Middle East (centered at 0.72), explained by the smaller sizes of anthropogenic aerosols in Europe. This is in accordance with a similar finding based on the corresponding frequency distributions for the AERONET stations.

The MODIS SSA_{470nm} values seem to be slightly overestimated, with respect to AERONET ones (bias ≈ 0.03). The MODIS frequency distributions are generally shifted to larger values, ranging from 0.86 to 1, whereas the AERONET histograms indicate values ranging from 0.68 to 0.99, but with only 10% of them below 0.86.

Reducing the uncertainty in estimates of the impact of aerosol on climate remains at the center of interest in the climate changes discussion. The Amazon Basin is one of the most crucial regions in the world where these effects may be studied from many points of view. In particular, it is important to identify and to quantify the processes and sources that control the regional aerosol concentrations, in order to obtain a reliable quantification of their global impacts. We expect that a better understanding - and modelling - of these processes and sources may provide a better understanding of the feedbacks between climate and aerosol concentrations.

As a part of the LBA/BARCA experiment, an airborne campaign was conducted, using the two engine INPE aircraft (National Institute for Space Research), from 16 November to 2 December, 2008, corresponding to the transition period from dry to wet season in Amazon Basin. The flight legs are shown in the Figure 1, where the main cities are indicated. The aircraft was instrumented for collecting data on aerosol spatial distribution/concentration and size distribution and, in addition, measurements of trace-gases including O_3, CH_4, CO, CO_2 and N_2O were also performed. Sixty-eight profiles were obtained up to 4 km, covering an important part of the Amazon Basin. Total aerosol number concentration was measured at 1 Hz time resolution using a TSI 3010 Condensation Particle Counter model. A Thermo Multi Angle Absorption Photometer model 5012, operating at 637 nm, was used for measurements on aerosol light absorption, and for optical scattering by atmospheric particles, the aircraft was equipped with a three wavelength (450, 550, and 700 nm) TSI 3665 nephelometer. Aerosol number size distributions were measured with a TSI SMPS 3080 for particles ranging 10–354 nm.

This work presents the spatial distribution of the aerosol optical properties in Amazonia during the transition between dry and wet season, when the aerosol population is strongly influenced by biomass burning emissions (Figure 2). The Amazon Basin is a region of intense convective activity, and the spatial and temporal description of the optical properties of these particles supports the assessment of the impact of changes in the regional land use, not only on the regional climate, but also at the global scale.

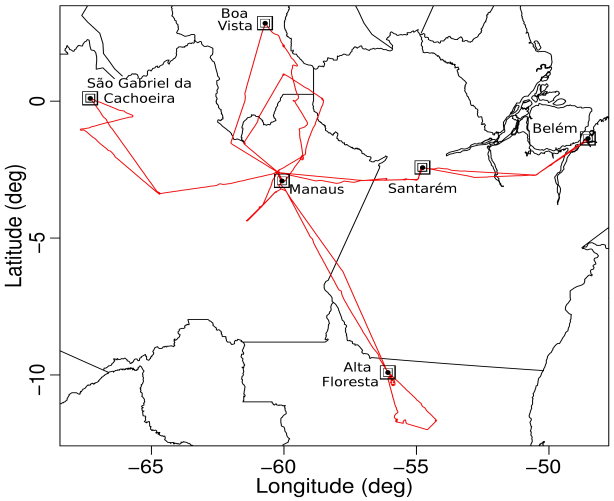

Figure 1: Mapping of the flight tracks during the BARCA-A airborne campaign, covering an important part of the Amazon basin during the dry season.

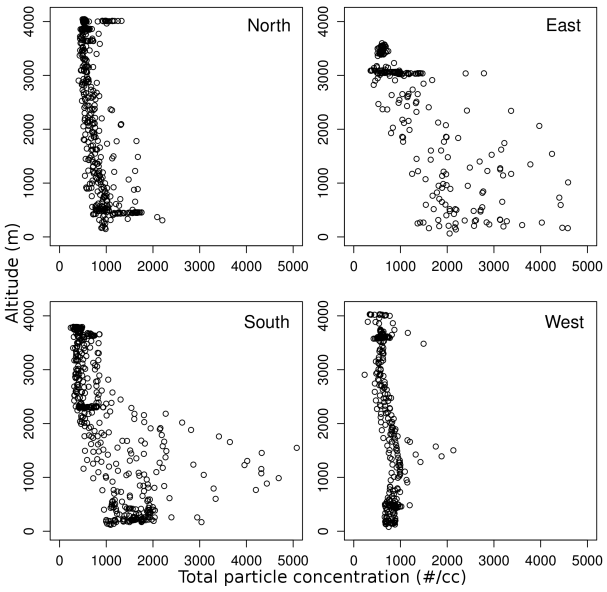

Figure 2: Total aerosol concentration vertical profiles for the northern, eastern, southern and western sectors of Amazonia during the transition from dry to wet season, November 2008. The aerosol population is strongly influenced by biomass emissions.

Keywords: particles, isocyanates, PU,

Workplace atmosphere is an important distribution of various pollutants, resulting from the handled products and concerned processes. The fate of these pollutants in the air (transport, deposition, degradation), is determined by their distribution between atmospheric particles and gas phase (Lohmann et al. 1998). Harmfulness of particles in workplace atmosphere and the disease hazards that they present are related to their chemical nature and size. The production of one kilogramme rigid polyurethane foam releases nearly 7362 milligrams of solid particles in air.

In this work, we used the personal aerosol sampler CIP10-R (Courbon et al. 1988) and filters for evaluation of alveolar (Gorner et al. 1996) and inhalable fractions of particles during clean of casts after injection of the polyurethane foam (PU) (fig 1). HPLC was used for detection of MDI in different post (fig 2).

Obtained Results reveal that MDI in alveolar fraction prevail the total collected particles, this can be allotted to the process used for cleaning and to the quality of formulated foam.

Presenting author email: yhsieh@famu.edu

Organic matter is a major constituent of aerosols. Analyzing organic matter in aerosols, however, is still a tedious and difficult procedure except for the bulk elemental analysis. In order to fill this analytical gap, we developed the multi-element scanning thermal analysis (MESTA) method to provide a rapid and sensitive means for organic matter analysis in aerosols. MESTA heats up a sample from ambient temperature to 800 ºC under a given atmosphere and a constant heating rate. The result is simultaneous C, N and S thermograms of a sample representing the chemical nature and thermal stability characteristics of its compounds (Hsieh, 2007). We report here the application of MESTA to the analysis of particulate matter ($PM_{2.5}$) from the ambient air and that emitted from biomass burnings. We also investigated the feasibility of using the MESTA thermograms as a chemical signature to differentiate the $PM_{2.5}$ sources between the biomass burning and the ambient air. We collected $PM_{2.5}$ samples from the ambient air and prescribed burnings of pine forests and analyzed them with the MESTA method. The MESTA thermograms show that the $PM_{2.5}$ emitted from the biomass burning has a characteristic high-temperature-volatile (>300 ºC) component with very low N and S contents whereas those of the $PM_{2.5}$ in the ambient air have a characteristic low-temperature-volatile (<300 ºC) component with very high N and S contents (Fig. 1).

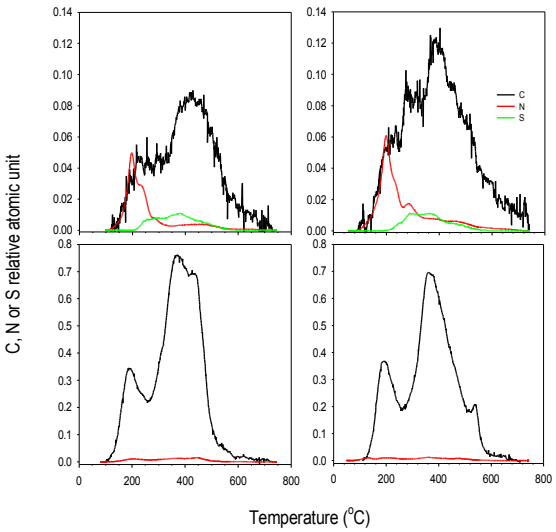

Fig. 1. The MESTA thermograms of the ambient PM (top) and those of biomass burning emitted (bottom).

The S detected in those MESTA thermograms are all organic as they are totally different from the thermograms of reference elemental sulfur, sulfides and sulfates compounds. The black carbon (thermally stable carbon peaks >525 ºC, Hsieh and Bugna, 2008) content of biomass burning PM averaged 12.8% of the total C in comparison to that of the 23% in the ambient air. All MESTA thermograms are quantitative and the detection limits for C, N and S are better than 0.2, 0.05 and 0.01 µg, respectively. The sharply contrasting MESTA chemical signatures between the experimental biomass burning $PM_{2.5}$ and the ambient air $PM_{2.5}$ provide a sensitive and quantitative means to quantify the presence of the biomass burning emitted $PM_{2.5}$ in the air. MESTA can also provide carbon isotopic ratio information of the compounds according to their thermal stability. The carbon isotopic analysis of MESTA indicates that C3 wood and grass burning produced insignificant carbon isotopic fractionation while some C4 grasses produced significant carbon isotopic fractionation resulting a heavier carbon signature in the smokes. This study shows that MESTA is a sensitive and convenient method for aerosol analysis and characterization, a fundamentally important step in air quality research and regulation.

Correlating the opacity-based dustiness behaviour to material specific properties

S. Bach, E. Schmidt

Department of Safety Engineering / Environmental Protection, University of Wuppertal, Germany
Keywords: Dust, Air quality, Optical instrumentation, Respirable aerosols.
Presenting author email: sbach@uni-wuppertal.de

The background of this research project is to examine the possibilities of a single-drop apparatus for the measurement of the dustiness behaviour of powders called DustView (Palas® GmbH, Karlsruhe). Objective is to find an algorithm for the coherence between the opacity values of the DustView respectively their time-related development and the concentration of specific aerosol fractions inside its so-called dust chamber.

Figure 1 shows the laboratory set-up, where an aerosol spectrometer (OPC) is directly connected to the dust chamber of the single-drop apparatus. It allows the simultaneous measurement of the extinction of two laser beams in different heights (3 resp. 13 cm above ground plate) and the particle size distribution and number concentration of the aerosol dispersed in the chamber in the same heights respectively.

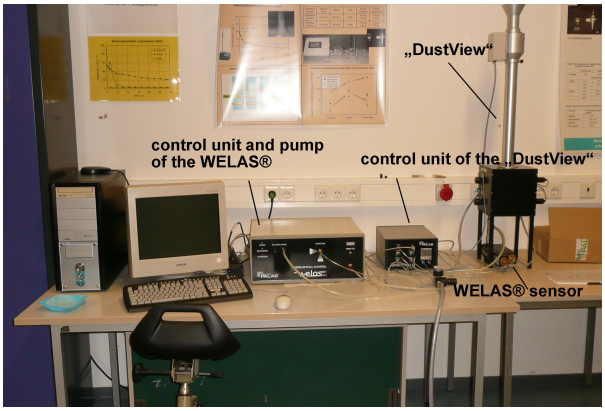

Figure 1. Modified version of the Palas DustView®, including single-drop apparatus and OPC “WELAS®”

Additionally, other material-specific properties have been measured, to ensure the best possible knowledge of the examined powders. Figure 2 shows all assimilated material features.

In Germany, there are limit values for the mass concentration of the respirable and inhalable dust fraction in workplace atmospheres. These are defined in the TRGS 900 (2010) and are 3 resp. 10 mg/m^3 at present.

The size fractions refer to the aerodynamic diameter of a particle, whereas the aerosol spectrometry gives the light scattering diameter. Van Buijtenen *et al.* (1974) define two possible ways of converting one into the other. Either, the aerodynamic shape factor of the material is known or the aerosol spectrometer has to be calibrated for each material. Here, only the particle density has been used as in Schmidt (2001), for the aerodynamic shape factor of the materials was mostly unknown and the calibration would have been too time-consuming for an uncertain outcome.

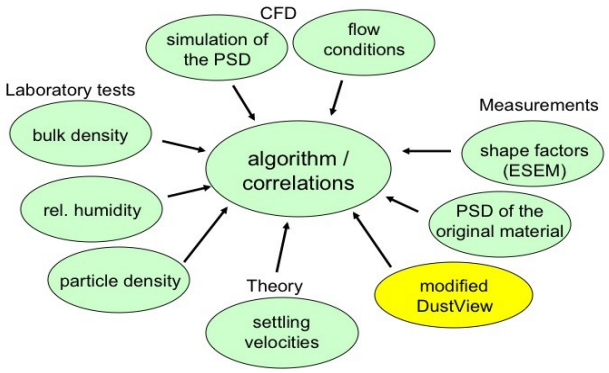

Figure 2. Measured and calculated material specific properties

The large amount of data collected for each material makes it difficult to locate correlations between two or more properties. What kind of dustiness-based data is suitable for the data mining process is yet to be determined. Additionally to the so-called dustiness number, calculated from the maximum opacity value and the 30-second-value of each measurement, it may also be the integral under the opacity curve or the offset between the peaks of the opacity curves of the two lasers. Also conceivable would be a value at a specific time, where the sedimentation process has already removed particles of a defined size. This would have to take the particle-specific settling velocity into account. All above named data could possibly correlate with the mass concentration of a specific aerosol fraction.

The correlation analysis is being carried out with the software “The Unscrambler X”, developed by CAMO®, Norway. Considering the two laser units, the correlation between OPC results and opacity seem to be better in the height of the lower laser.

An improved version of Wide Range Aerosol Spectrometer (WRAS) for aerosol particles size range from 3 to 1000 nm has been designed. WRAS consists of a combination of NADB (Ankilov *et al.,* 2002) and optical particle counter. NADB consists of 8-stage screen diffusion battery, turbulent-mixing type CNC and interface controller. NADB operates under PC control *via* standard COM-port. Data inversion procedure is based on MSA algorithm (Eremenko, 1995). The measurement, data processing and storage, and results presentation are fully automated. The scattered light signal from OPC is digitized by 16-bit ADC and then transferred to PC *via* USB-port. The specially designed software allows operating NADB and OPC either individually, or together.

The measured aerosol particle size range is from 3 to 1000 nm (from 3 to 200 nm by NADB and from 300 to 1000 nm by OPC). Particles' concentration range is from 5 to $2x10^5$ cm^{-3} without dilution for NADB and up to 300 cm^{-3} for OPC. The accuracy of concentration and size distribution measurement is ± 10% and ± 30% for NADB and OPC respectively. The general view of WRAS is presented in Figure 1.

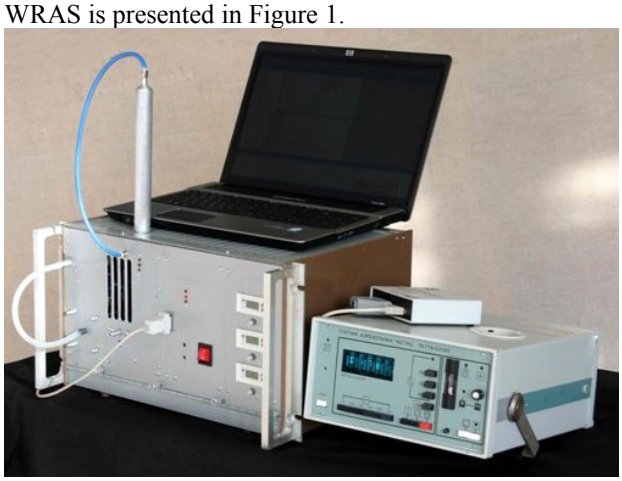

Figure 1. General view of the wide range aerosol spectrometer

WRAS is widely used in both basic (photonucleation, medical aerosol inhalation studies, etc.) and applied (laser –induced nanomaterial synthesis, etc.) research. Figures 2 and 3 present some examples of size distribution measurement with NADB.

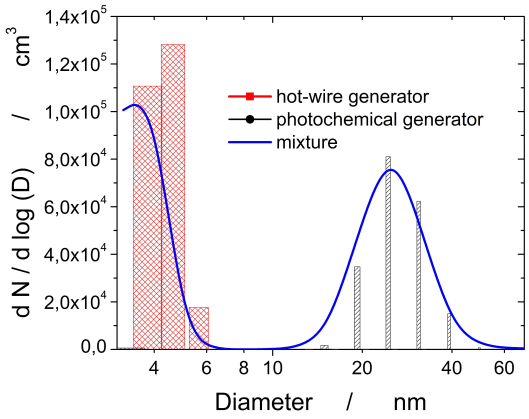

Figure 2. Size distributions of two individual aerosols and their mixture, measured with NADB. Red bars – aerosol from hot-wire generator, (Ankilov *et al.,* 2002), black bars – aerosol from photochemical aerosol generator (Dubtsov, 1996), line– mixture.

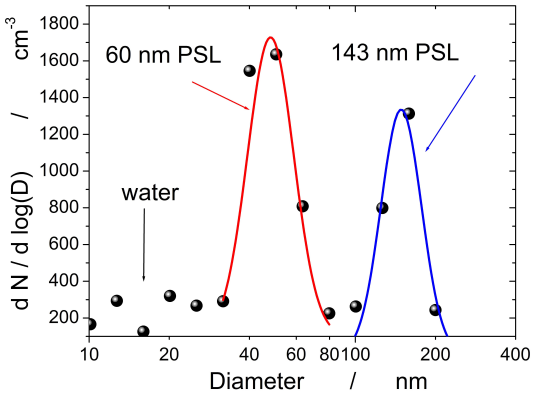

Figure 3. Size distribution of 60 nm and 143 nm PSL particles mixture, measured by WRAS. Dots - experimental results, lines – log-normal fits.

Performance of a High Resolution Optical Particle Spectrometer

H.S. Han[1], A. Sreenath[1], N.T. Birkeland[1], and G.J. Chancellor[1]

[1]TSI Incorporated, Shoreview, MN, USA
Keywords: Optical particle counter, Mie scattering, Light scattering, Filtration efficiency
Presenting author email: ryan.han@tsi.com

The optical particle spectrometer is one of the most widely used particle instruments in many areas such as aerosol research, filter testing, indoor air quality, etc. Light scattering technique is extremely sensitive and it has the advantage of minimally disturbing the aerosols and providing instantaneous information that is often suitable for continuous monitoring.

In this work, a recently developed high resolution optical particle spectrometer, TSI 3330 Optical Particle Sizer (OPS), was evaluated. The OPS is a light, portable, battery-powered unit that provides fast and accurate measurement based on single particle side scattering technology. It is capable of detecting particles from 0.3 to 10 um in diameter in up to 16 channels. Dead time correction is also available for high concentration measurements. The OPS also features real-time Mie scattering calculation capability to adjust the PSL calibration curve to a curve that better fits the aerosols of interest. For non-spherical particles, an additional shape factor is available to perform further adjustment on the calibration curve.

The OPS was evaluated with various monodisperse and polydisperse particles, namely, PSL, dioctyl sebacate (DOS or DEHS), sodium chloride, and methylene blue particles. The resolution of the OPS at 0.5 um was determined based on the ISO21501-1 method. It was found that resolutions of 10 OPS prototypes evaluated were all better than 5%. With 10% accuracy, the upper concentration limits of the OPS with and without dead time correction were found to be 3000 and 1000 particles/cm3, respectively. The refractive index algorithm performed quite well. Without refractive index adjustment, the size errors for methylene blue particles were as high as 40%. With Mie scattering correction, the sizing accuracy improved significantly, as shown in Table 1.

Table 1. Methylene blue particle size errors with and without refractive index correction.

Diameter (um)	No Correction (%)	Mie Scattering (%)	Mie Scattering + Shape Factor (%)
0.5	-21.14	9.70	10.88
0.6	-30.49	-0.78	0.65
0.7	-38.18	-9.73	-8.22
0.8	-42.78	-12.19	-10.79
0.9	-40.43	-4.47	-3.79

Sensor for vehicle on-board particle measurements

L. Ntziachristos[1], P. Fragkiadoulakis[1], Z. Samaras[1], K. Janka[2], J. Tikkanen[2]

[1]Lab of Applied Thermodynamics, Aristotle University, Thessaloniki, 54124, Greece

Presenting author email: leon@auth.gr

Efforts to develop particle sensors for on-board diagnostics (OBD) of diesel vehicles are intensive as diesel particulate filters (DPFs) have become widespread around the world. According to the regulations, DPFs will have to be continuously monitored on the vehicle, to make sure that they achieve high filtration efficiencies.

This study presents a novel sensor that has been successfully tested for on-board diagnosis of damaged DPFs. The patented (Tikkanen, 2009) Pegasor Particle Sensor (PPS) operates by electrostatically charging particles passing through its body and then measuring the current produced by the charged particles as they leave the sensor. The basic principle of directly measuring the current escaping with charged particles was first described by Lehtimäki (1983). Figure 1 schematically shows the operation principle. The particles are charged by ions generated by a corona discharge, which is generated around a sharp tip at high voltage. After charging, the particles are neither collected on any filter nor accumulate on any part of the sensor. However, as charged particles leave the sensor, they produce an electrical current escaping the Faraday cup. Measurement of this current is proportional to the particle concentration.

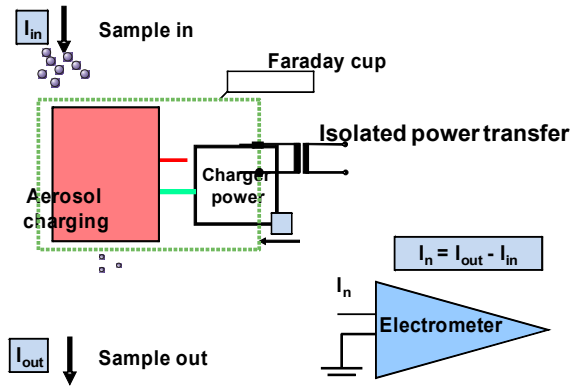

Figure 1. Schematic of sensor operating principle.

Determination of the concentration of particles by measuring the current produced by ions diffused on their surface has been shown to be a reliable technique (Ntziachristos *et al.* 2004. The signal produced scales with a power law of particle size (mobility diameter), with an exponent between one and two. For a known particle source (such as an engine), the signal can be calibrated to provide either the mass or the number of particles emitted.

Such a sensor has been developed and tested in real-exhaust of a diesel car and a diesel engine. The sensor provides high resolution (1 Hz, 0.3 s response time) and high sensitivity superseding the regulatory OBD requirements.

Measurements on an engine revealed the applicability of the sensor to monitor the failures of diesel particle filters. Its signal was found to perform similar to the smokemeter, a widespread instrument used for routine testing in automotive laboratories. The sensor could be used to identify damaged from undamaged filters and also to distinguish the degree of damage of failed filters.

The sensor was then installed in the exhaust of a vehicle to test the DPF efficiency of a well operating and a damaged DPF over a transient test. The sensor was found to be sensitive enough to clearly detect a defected from a well-operating particle filter even at levels as low as 6 mg km^{-1}.

This study demonstrates that a soot sensor based on the escaping current technique has the potential to be used for OBD and DPF control on forthcoming light duty and heavy duty diesel vehicles.

Development of an instrument to simulate puffing, inhaling and exhaling cigarette smoke

P. Warrington, C.M. McGrath, J. Perkins, C.J. Dickens

British American Tobacco, Group R&D, Southampton SO15 8TL, UK
Keywords: Aerosol measurement, Deposition, Inhalation, Respirable aerosols.
Presenting author email: paul_warrington@bat.com

The human smoking process for cigarettes consists of a puffing phase, followed by a mouth hold, where the tobacco smoke aerosol can change rapidly in terms of size and concentration due to coagulation and diffusional deposition. Smoke is then inhaled into the respiratory system along with dilution air through the mouth, and undeposited smoke exhaled.

Existing human smoking deposition studies are conducted where the puffing, inhalation and exhalation flows and times are accurately measured in real time. If these human smoking profiles can be simulated through in-vitro casts of parts of the human respiratory system, estimates of particle growth, coagulation and deposition within the respiratory system can be made without the need for a human smoker. The aim of this work was to develop an instrument to simulate the human smoking process.

The Puff Inhale Exhale (PIE) simulator comprises two sampling heads. The cigarette under test is mounted on the first sampling head which puffs on the cigarette following a pre-recorded human puffing profile. The puffed smoke is collected in an artificial mouth cavity. The second sampling head is then used to draw dilution air through the artificial mouth cavity following the inhalation section of a pre-recorded human respiratory profile. This flushes the smoke into a “lung” chamber where it may be sampled directly for analysis, or can be exhaled from the PIE through the artificial mouth and the second sampling head, following the exhalation section of the pre-recorded human respiratory profile. Exhaled smoke can be sampled and analysed as required.

The PIE was evaluated for puff volume compliance to generated bell, rectangular and triangular flow patterns with an average coefficient of variation of 1.1%. For consistency of exhaled smoke under a constant profile, there was no significant difference ($p < 0.05$) in the median particle size and concentration for multiple sampling flow rates and positions.

Effect of Different Sampling Methods on the Collection of CNF- and CNT-Fibres

Particle sampling is an integral part of exposure assessment, especially for fibrous particles like carbon nanontubes (CNT) or carbon nanofibres (CNF). Due to the expected increasing use of these materials, validated techniques for sampling are required. We investigated the characteristics of different samplers when challenged by an aerosol comprised of either CNT or CNF fibres.

Two different types of commercially available high aspect ratio nanoobjects (HARN, Carbon Nanofibres from Future Carbon and Baytubes® C150P from Bayer) were used for the comparison of sampling performance. The material under investigation was aerosolized either by wet dispersion of an aqueous suspension using an atomizer followed by a nafion dryer or by dry dispersion of the CNT or CNF powder, respectively. Dry dispersion was performed using a so called shaker (Broßell 2010). The aerosol was introduced into a 20 L compensation chamber for homogenisation. The number size distribution within the chamber was measured using an SMPS (Grimm, SMPS+C) in the size range from 10 nm up to 1100 nm for control purposes.

Three different samplers were utilized within the test series: Two commercial nanoaerosol samplers (NAS, TSI model 3089) with different polarity and a thermal precipitator (TP, BAuA prototype of personal sampler). Thus, differences due to the sampling principle (electrostatic versus thermophoretic deposition) are accessible. Due to the low flow rate of 2 ml/min the TP was placed inside the chamber. The two NAS were operated with a flow rate of 1.5 L/min and were placed outside the chamber. Furthermore, one of the NAS was equipped with a unipolar corona charger operating at 4.5 kV and a newly developed pre-separator with a nominal cut-off of 450 nm (Asbach 2010). This NAS was operated either without charger and pre-separator, with charger only or with both charger and pre-separator.

Within the TP silicon substrates with high purity and very low surface roughness were used. In case of the NAS the test was extended to silicon substrates, glassy carbon substrates and TEM grids. All substrates were investigated by applying high resolution scanning or transmission electron microscopy.

Figure 1 shows an example of CNF (A) and CNT (B) sampled on glassy carbon substrates without applying the pre-separator, but with the charger in operation. For a statistically sound comparison of the different sampling methods about 1000 particles were counted on each substrate. The different types of particles were divided in six categories (spheres, fibres/tubes, fibres/tubes+attachment, disperse clusters, compact clusters, matrix material) and three different size ranges (< 500 nm, 500 nm-1 µm, > 1 µm). We will present the setup and the statistical evaluation of the intercomparison of the different sampling methods. Recommendations on sampling of HARN will be presented based on the acquired information.

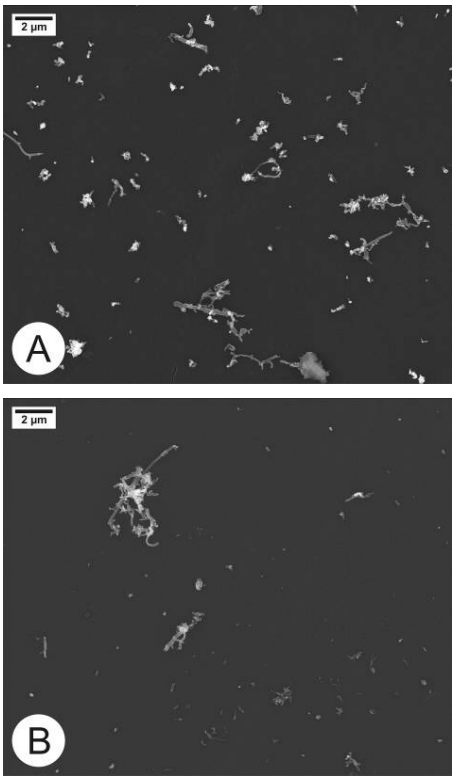

Figure 1. Examples of sampled CNF (A) and CNT (B) fibres.

Development of a Versatile Size Analyzing Nuclei Counter (vSANC)

T. Pinterich[1], P. M.Winkler[1, 2], P. E. Wagner[1] and A. Vrtala[1]

[1]Faculty of Physics, University of Vienna, Vienna, Boltzmanngasse 5, A-1090, Austria
[2] Advanced Study Program, National Center for Atmospheric Research, 1850 Table Mesa Drive, Boulder, Colorado, 80305, USA
Keywords: heterogeneous nucleation, condensation particle counter, nanoparticles.
Presenting author email: tamara.pinterich@univie.ac.at

The influence of charged molecular clusters and ionizing radiation on the formation of nanoparticles in the atmosphere and thus on cloud formation and climate has recently received considerable attention. In this connection as well as for various other applications accurate determination of aerosol properties, particularly for particles in the size range above approximately 1 nm diameter, is of great importance.

In the past an expansion chamber measuring system, the Size Analyzing Nuclei Counter (SANC) has been developed. Details of this experimental system are presented elsewhere (see, e.g. Wagner *et al*, 2003). Using this device various experiments on nucleation and condensational growth in supersaturated vapours were performed (e.g. Winkler *et al*, 2008).

The SANC is currently set up as a measuring system to be used for laboratory studies. However for various applications the use of a mobile measuring system would be important.Therefore a versatile version applying the same measuring principle – the vSANC – is being developed.

Just as for other CPCs the operation of the vSANC is based on heterogeneous nucleation of supersaturated vapour on aerosol particles and subsequent droplet growth. Thereby particles, which are too small to be detected by most other methods, grow to visible sizes and can be counted by optical techniques. In this way the present instrument allows detection of particles and ions with diameters down to 1nm (Winkler *et al*, 2008). Provided that each growing droplet corresponds to just one aerosol particle, the measured droplet concentration is equal to the aerosol number concentration. Expansion chamber and optical arrangement are designed to provide a comparatively wide range of droplet concentrations including atmospheric aerosol concentrations.

Essentially the experimental apparatus consists of two humidifiers, an expansion chamber, subpressure vessels, pumps and critical orifices. To analyse humidified aerosols containing e. g. sulphuric acid safely without damaging the instrument special materials such as 1.4571 stainless steel, FEP O-rings, a coated glass ring etc. are used for all parts in contact with the aerosol. Furthermore humidifiers, expansion chamber, connecting tubes and valves are thermostated separately. This allows measurements in a temperature range from -10°C to 30°C and avoids losses due to vapour condensation. Another important feature of this expansion type CNC is the possibility to operate either in active (aerosol flow regulation via various critical orifices) or passive sampling mode.

An electronic control unit in connection with pneumatic and solenoid valves was designed to control the measurement cycle. Vapour supersaturation is achieved by adiabatic expansion in a computer-controlled thermostated expansion chamber. Droplet growth is observed by means of the constant angle Mie-scattering (CAMS) detection method (Wagner, 1985). Here the droplets, growing in the expansion chamber are illuminated by a solid state laser beam. The light flux, scattered by the growing droplets, is monitored simultaneously under 10 different scattering angles. Depending on the selected scattering angle, the experimental scattered light flux vs. Time curves show series of maxima and minima in excellent agreement with theoretical scattered light flux vs. Size curves, calculated by means of Mie-theory. In order to enable an automatic establishment of a correspondence between experimental and theoretical light scattering extrema, scattering intensities for two specific angles are divided by eacht other(Hollaender, 2002). The resulting structure has far better pronounced extrema as can be seen in Fig. 1. Hence an automated data evaluation is possible.

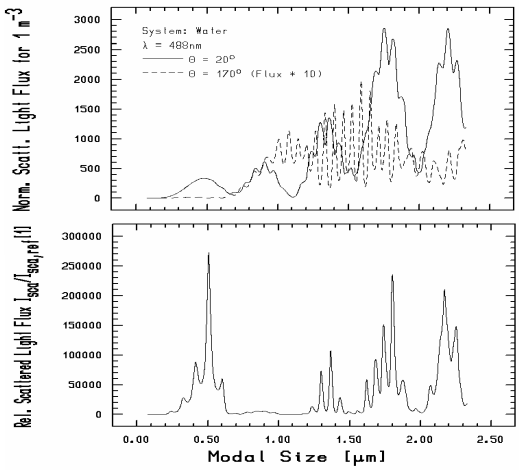

Figure 1. Normalized scattering light flux for scattering angles θ = 20° and 170° (upper graph) and their ratio (lower graph) both as a function of modal size.

A more detailed description of the vSANC including all its features will be presented later.

Impaction velocities of particles in low pressure impactor

A. Arffman, M. Marjamäki and J. Keskinen

Aerosol Physics Laboratory, Tampere University of Technology, Tampere, Finland
Keywords: aerosol instrumentation, impactor, aerosol modelling
email: anssi.arffman@tut.fi

Mechanical behavior of an agglomerate or an aggregate particles can be important in some industrial applications like creating a drug aerosol to be inhaled (Santoso, 2011) or as a filler component in a polymer material(Friedlander, 1999). Interparticle forces define the strengthness of the agglomerate particle. These interparticle forces have been studied lately for example by Seipenbusch *et al* (2010). Low pressure impactor (LPI) can be used in defining the energy needed to break the bonds between the primary particles of an agglomerate as done by Froescke *et al* (2002). Phase of a sub-micron aerosol particles can also be investigated by impacting them against a collection plate in the LPI. This method has been used in investigating the phase of the atmospheric SOA particles by Virtanen *et al* (2010).

When the LPI is used to find out the interparticle bond energies of the agglomerate aerosol, particles need to be impacted to the collection plate with well defined energy. By scanning this energy the limit when the particles change their shape or break into parts can be found. The impaction energy depends on the velocity of the particles before the collision to the wall. Phase of the aerosol particles can be identified by examining if the particles bounce from the collection plate. The probability of the bounce depends also on the impaction velocity of the particle. Therefore the velocity of particle is a crucial parameter in these experiments.

The impaction velocity of the particles in the impactor can be adjusted by changing the pressure ratio of the impactor upstream to downstream pressure or changing the size of the particles. However, the velocity of the particles right before the impaction occurs, depends not just on the average properties of the impactor jet, but on the local flow field conditions. Arffman *et al* (2011) showed that the impaction conditions vary in a cross-section of the jet.

We used numerical simulations to study the impaction velocities of the particles in the LPI. Simulations were done using the methods presented by Arffman *et al* (2011). The impaction velocities of the particles in the round nozzle LPI as a function of the particle size and the radial position of the particles were simulated. It was found that the impaction velocity of the particle depends strongly on the particle size and its radial position in the jet. Figure 1 shows the velocity field at the cross-section of the impactor nozzle which upstream and downstream pressures are 100mbar and 40mbar and the diameter of the nozzle is 0,3mm. Cutpoint of the stage is approximately 30nm. Figure 2 shows the impaction velocities of 60nm particles as a function of the radial starting position. High variations in the impaction velocities across the jet can be seen. Velocities are higher at the edges of the jet because of the larger slip correction factor.

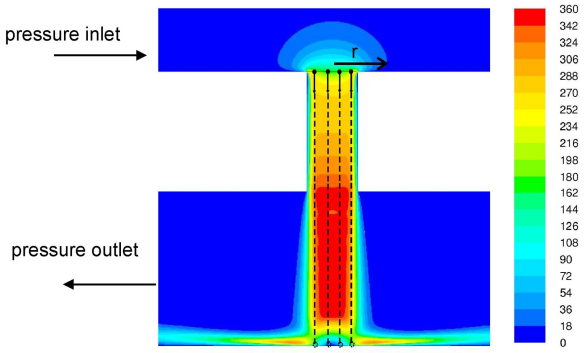

Figure 1. Velocity contours in the LPI nozzle. Particles and their tracks are schematically marked in the figure.

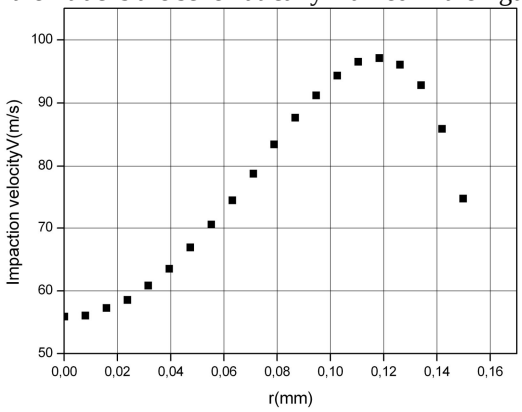

Figure 2. The impaction velocities of 60nm particles as a function of the radial distance from the axis of the jet.

Simulation of light scattering from air borne tea dust particles: possible carriers of pathogen

S Roy[*,1], N Barua[2], A. K Buragohain[2] and G. A Ahmed[1]

[1]Optoelectronics and Photonics Research laboratory, Department of Physics, Tezpur University, Tezpur -784028, Assam, India.
[2]Department of Molecular Biology and Biotechnology, Tezpur University, Tezpur -784028, Assam, India.

Keywords: light scattering, Mie scattering, Monte Carlo simulation, Bacterial activity

Abstract: A biotechnical method was followed to investigate whether tea dust particles might be a possible carrier of pathogenic species *Mycobacterium tuberculosis* by using novel light scattering techniques. An indigenously designed and fabricated laser-based light scattering setup was developed and used to carry out experiments on tea dust particles. In this paper we report for the first time the simulation of light scattering by these dust particles based on Monte Carlo code.

Introduction: Optical characterization of small particles which are suspended in air or when dispersed in a medium, by light scattering technique [1] is very important for a wide variety of applications. This includes optical diagnostics for industrial aerosol processes and combustion, environmental issues like visibility and haze problems, remote atmospheric sensing (lidar), and now specially to monitor hazardous air-borne particles. One type of such organic airborne dust is tea (*Camellia Sinensis*) dust which is released into the atmosphere by tea factories where tea is processed. As tea is grown in many tropical regions of the world this type of tea dust is found in abundance in these localities. This paper reports the work done in one such region, namely Assam in India, where tea is grown in large gardens and processed on a very large scale. The objective was to investigate if air-borne tea dust particles are a possible carrier of *Mycobacterium* pathogens, and then simulating the light scattering by these particles for better understanding of the physical processes and verification of experimental results.

Experimental Details: For monitoring the specimen a designed and fabricated laser based experimental setup (figure 1) was used to optically study the light scattering properties at a wavelength of 632nm. The system can measure scattered light signals from an angle of 10° to 160° for θ, and from 10° to 80° for ϕ to subsequently account for recording the volume scattering of size distributed dust particles. The effect on tea dust, when exposed to *Mycobacterium* species, was studied by using the Agar Well Diffusion Method [2]. In order to maintain safe laboratory procedures, the non-pathogenic species *Mycobacterium smegmatis* which has all the characteristic properties of the pathogenic species *Mycobacterium tuberculosis* was used as a model organism for carrying out investigations. Monte Carlo program (simscat.c) was developed in standard ANSI C language, and used for simulating the light scattering behaviour of these tea dust particles. The technique involves distribution of the photons in the simulation program between the particles according to their density as they were found to be governed by a Gaussian size distribution function [3].

Results: From the biotechnical experiments it was observed that the dust particles did not exhibit any antimycobacterial activity and might act as potent carriers. After the light scattering behaviour of both *Mycobacteriu*m contaminated and uncontaminated tea dust particles was studied as a function of scattering angle, and compared by the established Mie theory of light scattering [1], it was found that the light scattering behaviour of *Mycobacterium* contaminated and uncontaminated tea dust particles vary significantly. The simulation results were found to agree well with the experimental results within acceptable margins of error validating the efficiency of our program.

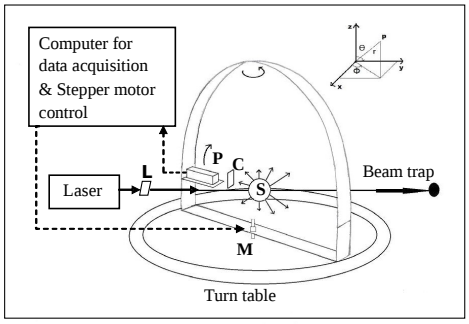

Figure 1: Schematic lay out of the scattering setup

Aerosol mass spectrometry has become an important tool for the chemical speciation of particles and particle populations. The chemical characterization of atmospheric aerosols has benefited greatly from instruments such as the Aerodyne Aerosol Mass Spectrometer (AMS) which provides a measure of the average chemical composition of sub micron particle populations (Canagaratna, et al. 2007). Laser ablation aerosol mass spectrometers have also evolved over the past decade. This class of instrumentation is capable of measuring chemical composition of individual particles.

One of the first bipolar laser mass spectrometer for single particle analysis (LAMPAS) was build by Hinz (Hinz et al 1996) and subsequently a number of other successful single particle aerosol laser ablation systems were also built and operated such as PALMS (Lee S. et al 2002), SPLAT (Zelenyuk et al 2005) and ATOFMS (TSI Corp.). Only one of these instruments was commercially available, while the others are unique single version research instruments.

We have developed a new compact bipolar single particle aerosol mass spectrometer LAAPTOF (Laser Ablation of Aerosol Particles Time of Flight Mass Spectrometer). The bench top instrument is built in a rack measuring 80 cm x 80 cm x 80 cm and is one of the smallest laser based aerosol mass spectrometers which is now commercially available.

The instrument features an aerodynamic particle lens inlet, a particle sizing region using cw scattering lasers, a bipolar TOF mass spectrometer and an excimer laser as ablation/ionization laser. The ablation laser operates at a wavelength of 193 nm with a power of up to 12 mJ /pulse (pulse duration ~ 10 ns). The TOF mass spectrometer is from TOFWerk (B-TOF) with a resolving power of $M/\Delta M \geq 600$ Th/Th FWHM for both ion polarities.

We will present the design and features of this newly developed instrument and show data illustrating its potential as a compact single particle aerosol mass spectrometer.

Setup and characterization of a new fast mixing type CPC

B. Wehner, M. Hermann, H. Siebert, F. Ditas, and A. Wiedensohler

Leibniz Institute for Tropospheric Research, 04318 Leipzig, Germany

Keywords: particle counting, response time, CPC

Condensation Particle Counters (CPCs) are the most widely used instruments for measuring submicrometer aerosol particle number concentrations. In atmospheric science, many open questions about particle dynamics require highly time-resolved particle measurements, e.g. when particle number concentrations vary on small scales due to turbulent processes. The response time of widely used unsheathed laminar flow-type CPCs is usually about 1 s. This results in a low spatial resolution, e.g., when deployed for aircraft-borne measurements. Therefore, we constructed a new fast mixing-type CPC (FCPC) based on the setup described by Wang et al. (2002).

Basically, the FCPC consists of four parts: the saturator, the mixing unit, the condenser, and the optics-block. All parts, except the optics (CPC 3772 optics bought from TSI Inc., St. Paul MN, USA) have been constructed at the Leibniz Institute for Tropospheric Research (IfT). The setup is based on the one described by Wang et al. (2002) and details are given in Wehner et al. (2010). Basically, a warm butanol-saturated air flow is mixed with the aerosol flow in a small mixing volume. Similar to Wang et al. (2002) who used a ¼-inch Swagelok cross in our case a ¼-inch Swagelok tee has been used as mixing chamber. In the following condenser block the air is cooled causing the required growth of aerosol particles. Afterwards the flow enters the optics, where the particles are counted.

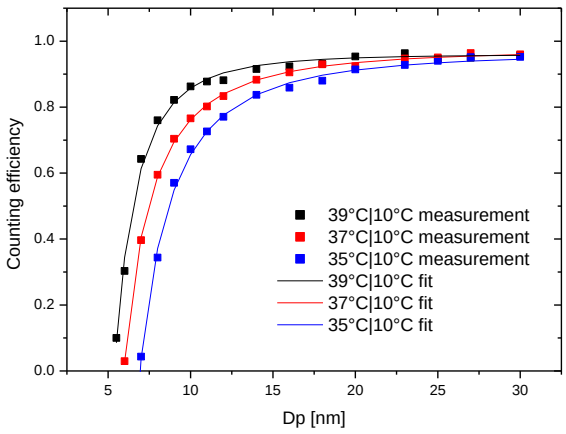

Figure 1: Counting efficiency of the Fast CPC (FCPC) at three temperature differences. Squares present mean values of three runs, the solid lines are fitted using the four-parameter equation: $\eta = a - b/(\exp(c*\log(x))-d)$.

The particle counting efficiency curve was determined by using silver particles generated in a tube furnace. Details are given in Wehner et al. (2010) and references therein. A monodisperse particle fraction was selected by a DMA and the counting efficiency was obtained with regard to a reference electrometer (EM, TSI 3068B). Results for three different temperature (saturator|condenser temperature) settings in the FCPC are shown in Fig. 1.

The measurement stability of the FCPC was tested in the laboratory in comparison with the electrometer as well as other commercial CPCs, such as a TSI 3776. These measurements show a stable behavior over at least five hours without refilling butanol (Wehner et al., 2010). As the FCPC has been developed for application on the helicopter-borne platform ACTOS, where measurement flights usually last less than 2 hours, this period is sufficient.

A field version of the FCPC was built and was applied to atmospheric measurements. Here, a combination of atmospheric turbulence and a strong isolated particle source which results in high fluctuations due to sharp gradients in particle number concentration has been used to estimate the time response of the instrument. The analysis of selected concentration steps illustrates that the FCPC is able to reach 1-1/e of the concentration step within 16 ms after a sharp increase in particle number concentration. The analysis of a 5-min time series shows that at frequencies higher than 30 Hz white noise becomes visible. However also at the maximum recorded frequency of 50 Hz the signal was not completely noisy, meaning that a response time of 20 ms is possible with the FCPC.

Extinction of aerosols in an atmosphere simulation chamber: broadband cavity spectrometer measurements extending from 320 to 450 nm

J. Chen[1,2], J.C.Wenger[1,2] and D.S. Venables[1,2]

[1]Department of Chemistry, University College Cork, Cork, Ireland

Presenting author email: d.venables@ucc.ie

Levels of near-ultraviolet solar radiation in urban areas are significantly lower than those above the urban boundary layer.(Peterson *et al.*, 1978) Jacobson proposed that absorption of light by aerosols was responsible for this phenomenon, and showed that anthropogenic species, particularly aromatic compounds and their oxidation products, could account for this absorption.(Jacobson, 1999) More recent investigations have also found that the radiation losses of carbonaceous aerosols below 450 nm increase steeply.(Andeae and Gelencser, 2006; Martins et al., 2009) Taken together, these results indicate that organic aerosol absorption plays a consequential role in the near-UV (300 nm to 400 nm). However, the near-UV optical properties of aerosols have been experimentally neglected and remain poorly understood. The lack of research into this question is largely due to the limitations of current techniques for measuring optical properties of aerosols at such short wavelengths

In this work, we demonstrate the use of a novel broadband optical cavity spectrometer to measure the extinction coefficient from 320 to 450 nm (Fig. 1). The unique capabilities of this technique – for broadband, in situ measurements at short wavelengths – make it ideally suited to investigating the optical properties of aerosols in an atmosphere simulation chamber, as we have recently demonstrated at longer wavelengths (Varma *et al.*, 2009).

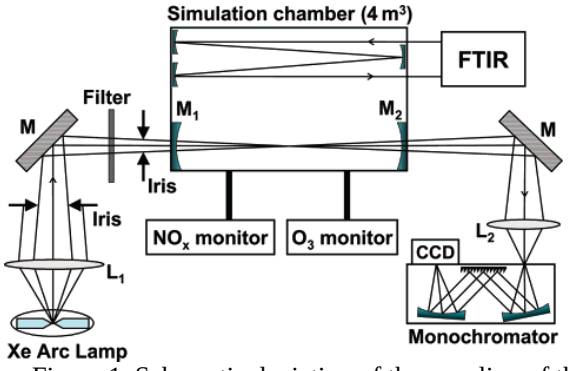

Figure 1. Schematic depiction of the coupling of the atmosphere simulation chamber and the IBBCEAS spectrometer (after Venables *et al.*, 2006).

We present extinction measurements following secondary organic aerosol formation in a 4 m^3 atmosphere simulation chamber. In one study, SOA was produced following photolysis of 2-nitrophenol, a strongly absorbing anthropogenic species. In another study, SOA was formed from the oxidation of the major biogenic species isoprene. We present the spectral dependence of the aerosol extinction and also study changes in the aerosol optical properties with aging of the particles. The analysis of the extinction spectra and the advantages and limitations of the approach are discussed.

Design and Evaluation of a Mini Catalytic Stripper

J.J. Swanson[1], D.B. Kittelson[1], A. Bergmann[2], B. Giechaskiel[2], M. Twigg[3]

[1]Department of Mechanical Engineering, University of Minnesota, Minneapolis, Minnesota, 55455, USA
[2]AVL List GmbH, Hans-List-Platz 1, A-8020, Graz, Austria

Keywords: solid particles, sulfuric acid, hydrocarbon removal, nanoparticle instrumentation
Presenting author email: jswanson@me.umn.edu

The principle of operation of the catalytic stripper (CS) is to evaporate particle phase semi-volatile material and to remove resulting gas phase compounds. Organic carbon is removed via oxidation and inorganic compounds such as sulfate are chemically absorbed. This approach contrasts methods such as the thermal denuder that removes gas phase material via physical adsorption and the volatile particle remover (VPR) that is relies on dilution to prevent nucleation of gas phase material.

The objective of this project is to design, build, and evaluate a CS that is optimized for particle loss and hydrocarbon and sulfate removal efficiency. The CS is similar in concept to previous versions some features are unique to this design. The substrate geometry has been configured to maximize removal and minimize solid particle loss; design values and calculated performance are shown in Table 1 and the catalytic core is pictured in Figure 1. Additionally, the catalyst, heating source, and cooling region have been integrated into a compact package. This allows the CS to serve as a convenient and portable aerosol-conditioning inlet for any instruments that requires an inlet flowrate of 1.5 L/min.

Table 1. Design specifications of the UMN mini CS.

Length	3.8	cm
Width	1.7	cm
Cell density	600	cells/in
Cell wall thickness	2.5	mil
Flowrate	1.5	L/min
$C_{40}H_{82}$ removal	99.5	%
50% cut off size	7	nm

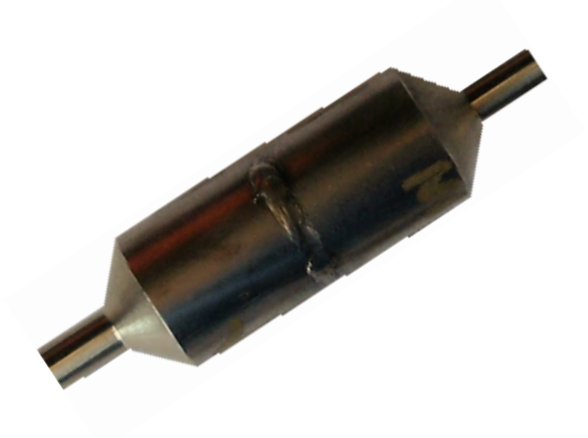

Figure 1. Mini CS catalytic core (Prints actual size on 11 x 8.5" paper) designed for a flowrate of 1.5 L/min.

To evaluate solid particle penetration through the CS, solid silver nanoparticles are generated using an evaporation/condensation technique. The CS is challenged with size selected silver particles while up and downstream concentrations are measured simultaneously. Results shown in Figure 2 indicate that the measured 50% lower particle cutpoint is near the predicted value (10 vs. 7 nm). The slightly reduced performance may be attributable to maldistributed or recirculating flow in the inlet that impacts the smallest particles.

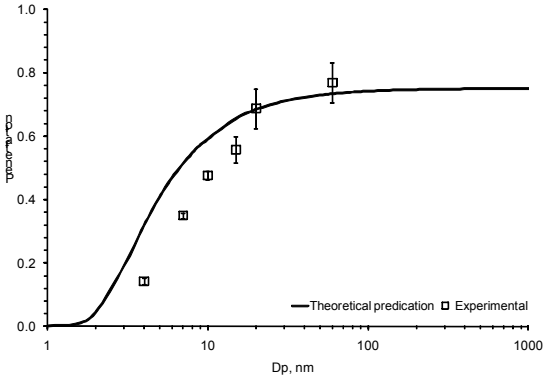

Figure 2. Comparison between theory and experimentally measured solid particle penetration.

Additional experiments were conducted to evaluate the hydrocarbon removal performance of the CS. The CS was challenged with dioctyl sebacate particles ($(CH2)_8(COOC_8H_{17})_2$) that were also generated using an evaporation/condensation technique. Generated particles were size selected at sizes of 30, 40, 50, and 60 nm and were used to challenge the CS. Results indicated that the CS could fully remove (efficiency of 100.0%) concentrations of >10,000 part/cm^3 for all particle sizes, which meets and exceeds the removal requirements of the VPR method. Experiments to evaluate sulfate removal efficiency are ongoing.

Diisocyanate aerosols in polyurethane manufacture

A. Akachat[1], H. Rebbah[1]

[1] Laboratoire de matériaux minéraux et composites, Université Med Bougara, Avenue de l'Indépendance, 35000 Boumerdes, Algérie.

Keywords: particles, isocyanates, PU,

Workplace atmosphere is an important distribution of various pollutants, resulting from the handled products and concerned processes. The fate of these pollutants in the air (transport, deposition, degradation), is determined by their distribution between atmospheric particles and gas phase (Lohmann et al. 1998). Harmfulness of particles in workplace atmosphere and the disease hazards that they present are related to their chemical nature and size. The production of one kilogramme rigid polyurethane foam releases nearly 7362 milligrams of solid particles in air.

In this work, we used the personal aerosol sampler CIP10-R (Courbon et al. 1988) and filters for evaluation of alveolar (Gorner et al. 1996) and inhalable fractions of particles during clean of casts after injection of the polyurethane foam (PU) (fig 1). HPLC was used for detection of MDI in different post (fig 2).

Obtained Results reveal that MDI in alveolar fraction prevail the total collected particles, this can be allotted to the process used for cleaning and to the quality of formulated foam.

[5]Present address: Karlsruhe Institute of Technology, 76344 Eggenstein-Leopoldshafen, Germany

Keywords: Biogenic particles, Morphology, Electrospray, Instrumentation/physical char.

The structure of biomolecules such as peptide hormones and proteins is important since it affects their receptor recognition, activity, and the precision with which they can be isolated. Molecule structures can be investigated using a wide variety of techniques including gels, spectroscopy, NMR, and X–ray crystallography. Here, we describe the first use of a high resolution (HR) DMA to rapidly and quantitatively differentiate between the cyclic and linear forms of the peptide hormone oxytocin, the smallest biomolecule measured using a DMA.

A previous DMA study of biomolecules focused only on approximating molecular mass not molecular morphology, by assuming globular proteins to be constant density spheres (Bacher *et al.*, 2001)[†]. A later study found that particle morphology plays an important role in determining the mobility diameter with a DMA (Pease *et al.*, 2007).

Here, oxytocin was added to aqueous ammonium acetate solutions. To some samples, the reducing agent TCEP was added to break the disulphide bond in oxytocin, thus changing its shape from circular to linear. The solutions were electrosprayed using home-built electrospray system (*cf.* Ude *et al.*, 2005). Size spectra were obtained in less than 5 min by scanning the DMA voltage and recording the ion current with an electrometer. The DMA was designed to remain in the laminar flow regime despite Reynolds numbers exceeding 35000, with the use of a funnel shaped injector (Herrmann *et al.*, 2000). The DMA was calibrated before each run by electrospraying solutions of tetraheptyl ammonium bromide (THAB), producing ions of known mobilities (Ude *et al.*, 2005). In Fig. 1, we find that oxytocin peptide has two peaks at 1.52 nm and 1.55 nm that are statistically distinguishable due to an instrument resolution of 0.011 nm.

Molecular dynamics simulations of oxytocin were performed to determine the most probable configurations for both the cyclical and linear forms. The resulting spherically equivalent mobility diameters of the two forms were 1.52 ± 0.04 nm (cyclic) and 1.55 ± 0.06 nm (linear), respectively. These results are in excellent agreement with the experiments.

The ability to differentiate two forms differing in spherically equivalent size of only 0.03 nm is remarkable. The combination of electrospray and HR-DMA prevents fragmentation of macromolecules in contrast to high vacuum electrospray mass spectrometry systems, and can, in a very cost-efficient way, easily measure molecular diameters from below 1 nm up to 10 nm with sub-angstrom uncertainty in diameter. The measured differences in oxytocin before and after TCEP treatment agree with refined DMA predictions made by coupling molecular dynamics simulations with the analytical models of Pease, *et al.* (2007).

The present work demonstrates that DMAs can be used to differentiate subtle differences in nanoparticle structure and opens opportunities to use high resolution DMAs to experimentally validate molecular dynamics simulations to accelerate advances in proteomics, enzymology, catalysis, and molecular biology.

Direct integration of a GPS/GPRS unit into a miniature diffusion size classifer

M.Fierz, P.Steigmeier, M.Glettig, B.Wyrsch and H.Burtscher

University of Applied Sciences Northwestern Switzerland, 5210 Windisch, Switzerland
Keywords: instrumentation, air quality network, personal sampling.
Presenting author email: martin.fierz@fhnw.ch

We have recently developed a miniaturized version of the diffusion size classifier (miniDiSC, Fierz et al. 2011). It can measure particle number concentration, average particle diameter and lung-deposited surface area with a one-second time resolution. It operates on a purely electrical basis, with a unipolar charger followed by two electrometer stages, i.e. there are no working fluids or radioactive sources. The instrument is about the size of a multimeter, and thus one of the smallest aerosol instruments available today, which makes it ideal for personal monitoring.

For personal monitoring, it is useful to record location information with a GPS. While a separate GPS receiver can be used with any instrument, it is a bit cumbersome to operate because the data of instrument and GPS have to be combined manually. We have therefore integrated a GPS receiver directly in the miniDiSC. Furthermore, we also added a GPRS chip to transmit data from the instrument to a server in the internet in real time. The transmitter board measures 60x80mm and can easily be accommodated in a slightly larger housing than the standard miniDiSC housing (45mm thickness instead of 40mm).

Data is transmitted by the miniDiSC to a TCP server located in the internet, which stores the data in an SQL database. A standard 3-tier-architecture (Database, web-application, browser) is used to view the data in near-realtime (about 5 seconds delay) in any internet browser. Figure 1 shows an overview of the measurement network structure. The instruments also transmit status information besides the measurement data. This allows for a quick overview of the status of all deployed minidiscs (see Figure 2), which is useful when running a measurement campaign - problems with the instruments can be detected and resolved easily during the campaign.

Data can be displayed as real-time chart or as table or downloaded as delimited text file or as a Google Earth file. The Google Earth download is perhaps the prettiest way of visualizing the data (see Figure 3).

In conclusion, we have developed an enabling technology to easily collect and view data of the miniDiSC online. We anticipate that this will be useful for measurement campaigns, both for personal monitoring and for stationary measurements.

Influence of probe nozzle diameter on aerosol particle size distribution for isokinetic sampling in gas streams

T. Barth[1] and M.Lustfeld[2]

[1]Institut für Sicherheitsforschung, Helmholtz-Zentrum Dresden-Rossendorf, Bautzner Landstraße 400, 01328 Dresden, Germany

Presenting author email: t.barth@hzdr.de

Isokinetic sampling from stacks and ducts is a widely used method for air pollution control in many industrial and environmental applications.
During the last 40 years, U.S. EPA developed reference methods for air pollutant emission sampling of stationary sources, which included a compendium of technical guidelines for the monitoring of aerosol particles. One of the main parts of the sampling system is the sampling probe nozzle for which it was suggested in the reference methods that the lower bound diameter should be greater than $d_i = 6\ mm$ (Cohen, 2001). The influences of sampling nozzle tube diameter, the velocity ratio between free stream and the sampling tube as well as the tube inclination have been considered widely (Vincent, 2007). On the other hand, the influence of tube diameter has not been quantified by means of aerosol particle size spectrometry yet.
McFarland et al. (1997) as well as Peters and Leith (2004) experimentally investigated the deposition losses of aerosol particles in pipe bends. Both found a strong increase of deposition losses in the sampling tube for particle Stokes number of $Stk > 0.3$.
In this work, the influence of the nozzle diameter of the sampling probe on the aerosol particle size distribution was investigated by means of TSI APS 3321 and TOPAS LAP 321 measurements.
The considered gas/aerosol test facility is a small scale wind tunnel, which consists of a HEPA at the inlet and a square duct section in diameter of $d_{hyd} = 10\ cm$ and length of $l = 20 d_{hyd} = 2\ m$. The test section, where sampling takes place, is followed by a diffuser stage, an electrical precipitator and a radial fan in order to generate the desired pressure head. The average air velocity can be regulated over the range $<u> = 1..7\ m/s$, corresponding to Reynolds numbers between $Re_d = 8.9k..42k$. In order to achieve isokinetic sampling, the flow rate of the sampling device has been accurately adjusted using Particle Image Velocimetry data.
AC Fine Test Dust (ISO 12103-1, $d_{nom} = 0.1..80\ \mu m$, bimodal distribution) was injected 17 diameter lengths upstream of the sampling point by means of a dust disperser TOPAS SAG 410. Four probe nozzle diameters $d_i = [3,5,7,9]\ mm$ were chosen.
Figure 1 displays the volume weighted aerodynamic particle size distribution of AC Fine under variation of nozzle tube diameter as measured by the APS 3321. The modal $d_{P,aero} = 5\ \mu m$ is roughly independent of nozzle size, whereas the values of the distribution for particle diameters above $d_{P,aero} > 12\ \mu m$ increase continuously with increasing nozzle diameter.
A similar upward tendency in size distribution with increasing nozzle diameter is observed in the LAP measurement results (not shown here). This leads to the conclusion that deposition losses due to inertia, which consequently affect the larger particles, can be considerably reduced by accordingly increasing tube nozzle diameter. In addition, a comparison of aerodynamic particle size (APS 3321) and scattering particle size (LAP 321) will be presented.

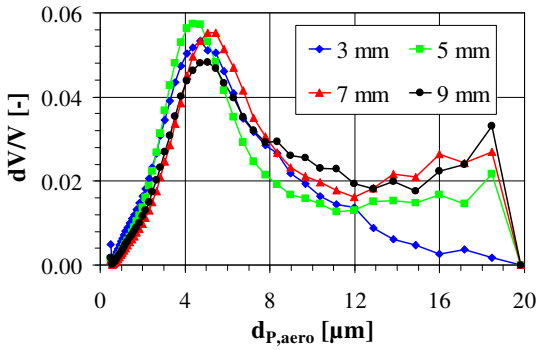

Figure 1 q_3 Aerodynamic particle size distribution of AC fine (ISO 12103-1) for different nozzle sizes

Keywords: Passive sampling, guideline, coarse particles, microscopic analysis, size distribution
Presenting author email: eckart.schultz@online.de

Ambient particle concentrations of d > 2.5 µm are characterised by growing spatial variability with increasing particle size. Local sources, therefore, become more important and an estimate of the exposure to this fraction becomes uncertain the larger the particles are. The employment of passive samplers may be well suited to reduce this uncertainty because passive samplers allow denser networks than active ones, due to simple technique, low price and easy use. Errors in estimating the exposure to ambient particles can be more important than errors due to imprecision in the monitoring instruments themselves (Leith et al., 2007). Moreover, in passive samplers there is more of a choice of appropriate sampling media suitable for microscopic analysis and compositional characterisation of particles than in active ones.

Already in 1997, a passive sampler for ambient particles > 3 µm was described by a guideline of the Verein Deutscher Ingenieure (VDI). It described the passive sampler Sigma-2, developed at the Institut für Physik der Atmosphäre at the Universität Mainz, modified by the Deutscher Wetterdienst in Freiburg and in use for air quality measurement in German health resorts since the late 1980's. A revised version of this guideline elaborated by the above listed authors will be available this year (VDI 2119, 2011). This new guideline will comprise the latest enhancements in passive particle sampling and analysis: (1) new collection media suitable for further analytical methods, (2) advances in automated microscopic analysis, (3) a calculation method for particle concentrations d > 2.5 µm from the deposit.

The revised guideline is based on the experiences of the still ongoing air quality measurements in German health resorts but also on the methodological enhancements achieved while being used in various research projects. The major objectives are to obtain spatially highly resolved particle data in order to identify hot spots in urban areas and to distinguish between natural and anthropogenic sources. Valuable information for these objectives was extracted by measuring geometric and optical parameters of individual particles and by specifying corresponding size distributions. For example, the spatial distribution of microscopically distinguished particles was found to differ considerably in cities as well as in rural areas. The results indicate that the applied microscopic analysis can be essential for reliably assessing health effects of the exposure to coarse particles (Wolf-Benning et al., 2011).

A study in W-Greenland confirmed the value of the technique in extreme remote conditions. Results of this study show a surprisingly high load of coarse particles, comparable to Central Europe or even higher (Fig. 1), while the fine particles show the expected very low concentration. The passive sampler Sigma-2 described in the revised VDI guideline provides further applicabilities, for example in electron-microscopic single particle analysis (Kandler et al., 2009) and in µ-synchrotron analysis (Schleicher et al., 2010) in various spatio-temporal studies, especially for remote or observational network studies.

Using nigrosin as a surrogate for black carbon to study aerosol light absorption

Jeonghoon Lee[1] and Seung Cheol Han[1]

[1]School of Mechanical Engineering, Korea University of Technology and Education, Cheonan, Choong Nam, 330-708, South Korea

Keywords: nigrosin, black carbon, absorption

Presenting author email: jlee@kut.ac.kr

The aerosol light absorption from black carbon draws attention to atmospheric aerosol scientists because a small mass fraction of black carbon may contribute the equivalent of 1/4 of radiative forcing caused by CO_2 (Lack et al 2008). It has been reported that the black carbon radiative forcing could even be as much as 55% of the CO_2 forcing (Ramanathan and Carmichael, 2008). The black carbon is generated from various sources such as a tail pipe of a vehicle, the chimney of power plant, biomass burning, and so on. The black carbon ages in the atmosphere through a coating process. Normally, the shape of black carbon differs depending on the condition where it is produced. The aggregatelike shape of black carbon may cause the change in the optical properties of black carbon. It is very difficult to quantify the optical properties of aggregates coated with transparent materials.

To alleviate the difficulty of determining the absorption coefficient of the black carbon coated with transparent materials, we have recently initiated the experimental efforts using nigrosin as a proxy for black carbon. Nigrosin is spherical and absorbs light in the visible range. The simple structure of nigrosin allows us to easily estimate the absorption coefficient.

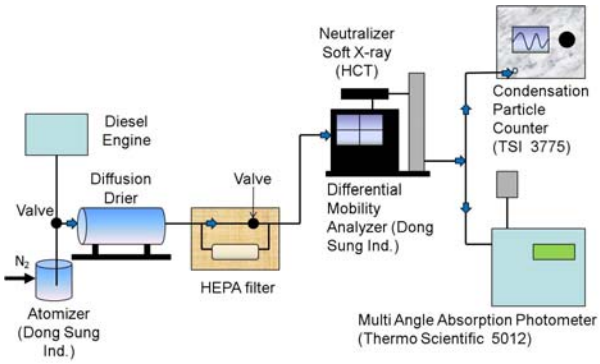

Figure 1. The schematic of experimental apparatus used in the present study.

Figure 1 shows the schematic of the experimental apparatus used in the present study. Water soluble nigrosin particles were prepared in a home-made constant atomizer. Polydisperse nigrosin aerosols were produced using the atomizer. Black carbon aerosol was produced using a single cylinder diesel engine. A diffusion drier eliminated the moisture contained in the aerosols. The number concentration of aerosols was controlled by a HEPA filter. Monodispersely sized aerosols were selected using a DMA (Differential Mobility Analyzer, Dong Sung Ind.) and concentrations of the aerosol were measured by a CPC (Condensation Particle Counter, TSI 3775). Simultaneously, the size selected aerosols were sampled in the MAAP (Multi-angle Absorption Photometer, Thermo Scientific 5012). Aerosol absorptions were measured by the MAAP which requires no post measurement data correction or parallel-measured aerosol light-scattering coefficients (Petzold *et al*, 2005).

The absorption coefficients were measured for nigrosin aerosols with different sizes. The absorption coefficients of black carbon particles generated in a diesel engine were also measured in a similar way to the nigrosin aerosols. Figure 2 shows that the absorption coefficient of 100 nm nigrosin aerosol increased as the number concentration was increased. The absorption coefficients for black carbon were compared with those for nigrosin aerosols. The results show that the nigrosin can be used as a proxy for black carbon in the measurement of aerosol absorption properties. More detailed discussion along with the results of black carbon will be presented.

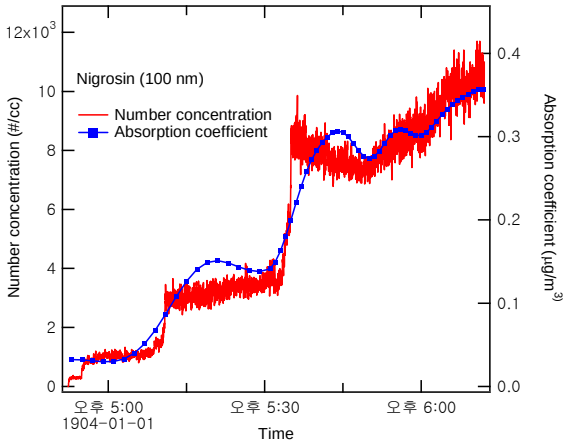

Figure 2. Real-time measurement of absorption coefficients and number concentrations.

Diffusion of charged particles in a DMA with inclined electric field and with a particle collector in gas outlet

J. Salm and U. Hõrrak

Institute of Physics, University of Tartu, 18 Ülikooli St., 50090, Tartu, Estonia
Keywords: DMA, size analysis, diffusion, measurement errors.
Email: jaan.salm@ut.ee

In general lines, a differential mobility analyser (DMA) has gas inlet(s), gas outlet(s), electrodes, and collector(s) of electric current. Diffusion distortions in a simple DMA have been studied in (Salm, 2000). The distortions in a similar DMA with inclined electric field have been studied in (Salm and Hõrrak, 2009). The method developed in the above papers is applicable also for a DMA with inclined electric field and with a particle collector in gas outlet that was developed by Tammet (1999, 2003).

In this abstract we systematically refer to the paper (Salm and Hõrrak, 2009) and the corresponding equation numbers. Figure 1 of the paper is retained, only the structure of collector is modified.

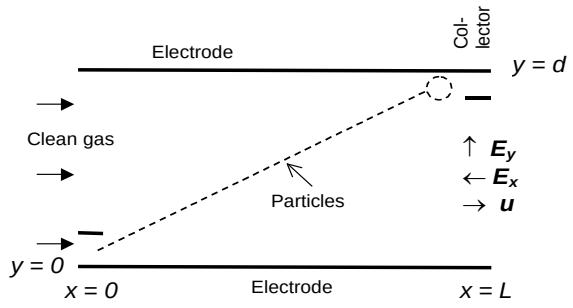

Figure 1. Schematic representation of the DMA.

According to Figure 1, the horizontal velocity of charged particles is

$u - Z_1 E_x$,

where Z_1 is the mobility of entering aerosol particles.

Equation for the characteristic (limiting) mobility is

$$Z_0 = \frac{u}{E_y}\frac{d}{L+kd} .$$

We will consider here the case $E_x \propto E_y$. Let us express $E_x = kE_y$, where k is the coefficient of proportionality.

The following derivation of equations is quite similar to that in (Salm and Hõrrak, 2009), with understandable replacements. Equations (7) – (12) are retained. In Equations (13) – (15), the velocity Z_1E_y is replaced by the velocity u, and the factor d/L appears in Equations (16) and (17). The derivation results in the normalized apparent spectrum $w^*(Z,Z_1)$. Equation (18) in (Salm and Hõrrak, 2009) is replaced by the following equation:

$$w^*(Z,Z_1) = \frac{\mathrm{Pe}\,(L+kd)}{2\pi LZ} \times \exp\left(\frac{\mathrm{Pe}}{2}\left(\frac{L}{d}\left(1-\frac{kd}{L+kd}\frac{Z_1}{Z}\right)+\frac{d}{L+kd}\frac{Z_1}{Z}\right)\right) \times \mathrm{K}_0\left(\frac{\mathrm{Pe}}{2}\sqrt{\left(\left(1-\frac{kd}{L+kd}\frac{Z_1}{Z}\right)^2+\left(\frac{d}{L+kd}\frac{Z_1}{Z}\right)^2\right)\left(1+\frac{L^2}{d^2}\right)}\right) ,$$

where Z is the variable mobility, Pe is the Peclet number, $\mathrm{K}_0(\zeta)$ is the Macdonald's function. The simplification of the equation is possible analogically as in (Salm and Hõrrak, 2009).

Rough estimations of the influence of diffusion on the resolution of mobility spectrometers are possible also by means of simpler methods. However, a precise knowledge of the apparent spectrum opens a way to the improvement of resolution by calculations.

If we know the normalized apparent spectrum $w^*(Z,Z_1)$ for one mobility Z_1, then the apparent spectrum $\rho^*(Z)$ for any general case is expressed as

$$\rho^*(Z) = \int w^*(Z,Z_1)\rho(Z_1)\mathrm{d}Z_1 , \qquad (*)$$

where $\rho(Z_1)$ is the differential distribution of polar charge density of particles by mobility or the mobility spectrum. In many cases the apparent spectrum $w^*(Z,Z_1)$ depends on the ratio Z/Z_1. Then, using a simple exponential transformation, it is possible to express Equation (*) in the shape of convolution, and to solve the convolution equation by means of the Fourier transform.

Adapting the Aerodyne Aerosol Mass Spectrometer for Zeppelin-based measurements

F. Rubach[1], A. Trimborn[2], Th. F. Mentel[1], A. Wahner[1]

[1]Institute for Energy and Climate 8: Troposphere, Forschungszentrum Jülich GmbH, 52425 Jülich, Germany
[2]AeroMegt GmbH, 40723 Hilden, Germany
Keywords: aerosol instrumentation, mass spectrometry.
Presenting author email: f.rubach@fz-juelich.de

The Aerodyne High-Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS, DeCarlo et al., 2006; Canagaratna et al., 2007) is an instrument to gather real-time information about the composition of non-refractory aerosol particles. The used High-Resolution Time-of-Flight Mass Spectrometer allows for direct distinction between most inorganic and organic ions at the same nominal m/z. This provides the possibility to gain information about the average oxidation state of organics in particles of mixed compositions (Aiken et. al., 2007).

The HR-ToF-AMS has so far mainly been used for ground-based measurements (e.g. Aiken et. al, 2007; Farmer et. al., 2010; Ulbrich et. al. 2009), although some measurements have taken place on aeroplanes (e.g. DeCarlo et. al. 2008; Murphy et. al., 2009).

Usage of the Zeppelin Airship as measurement platform is highly advantageous because of several reasons:

- Flight speed 0-125 km/h
- Flight altitudes of 80 m to 2500 m are achievable
- Lagrange-type experiments are easily possible
- Hover capability, vertical profiling
- Flight endurance of 14 h or more

In contrast to the advantages, the maximum payload is limited (approx. 2 t), carried weight directly influences achievable flight height and the available space inside the cabin is constricted. Therefore, instrumentation has to be optimized concerning weight and space requirements. Beyond that, measurements should be automated and facilitated as far as possible to require less service personnel.

By different means, a weight reduction of more than 20 % was achieved for this instrument. At the same time, the instrument now occupies approx. 30 % less volume and has an approx. 25 % smaller base area.

Design, construction and first applications of the instrument will be shown.

Calibration of Condensation Particle Counters – analysis of sub-3nm calibration ions using mass spectrometry

J. Kangasluoma[1], H. Junninen[1], K. Lehtipalo[1,2], T. Toivola[2], T. Petäjä[1], M. Kulmala[1]

[1]Department of Physics, University of Helsinki, 00560 Helsinki, FINLAND
[2]Airmodus Oy, 00560 Helsinki, FINLAND

Keywords: PSM, APi-TOF, particle generation.
Presenting author email: juha.kangasluoma@helsinki.fi

Small nano-size particles are measured with condensation particle counters (CPC), which operate by condensing working fluid on particles. Particles grow large enough to be optically detected due to condensation. Newly developed particle size magnifier (PSM, Vanhanen *et al.* 2011) uses diethylene glycol as a working fluid to avoid homogenous nucleation. The cut-off diameter of the PSM can be adjusted between about 1-2nm by changing the mixing ratio of the saturator and inlet flow. These particle counters are calibrated with differential mobility analyzers (DMA) which allow choosing particles of known mobilities. The particles used in calibrations are often the mobility standards (Ude & Fernandez de la Mora, 2005), silver, WOx-particles and some others. Still the chemical composition of these particles is not well known.

In order to measure the chemical composition a time of flight mass spectrometer (APi-TOF, Junninen *et al.* 2010) is used. The APi-TOF classifies ions by giving them certain kinetic energy and then measuring the time of flight. In this way high mass resolution is achieved which allows to distinguish between ions of same integer mass, but different mass defect.

Particles are produced with various methods including electrospray, wire generator and oven. They are led to a high resolution Herrmann-type DMA (Herrmann *et al.* 2000) after passing through a bipolar charger and thereon to the APi-TOF, PSM and electrometer. The APi-TOF is the first one in sampling because of its weak sensitivity, the PSM and electrometer are sampling after the APi-TOF inlet.

In figure 1 is an example of activation curves for the PSM with NaCl, WOx-particles, Silver and the mobility standards. Chemical composition and charge seems to have some effect on detection efficiency. Negative particles tend to activate more easily. All data points were also measured with the APi-TOF, which gave some interesting results. For example for positive NaCl, there was a wide spectrum of different atomic masses for fixed voltage in the HDMA. Certainly more studies related to this are needed to understand the processes between the particle generator and the APi-TOF and particle counter.

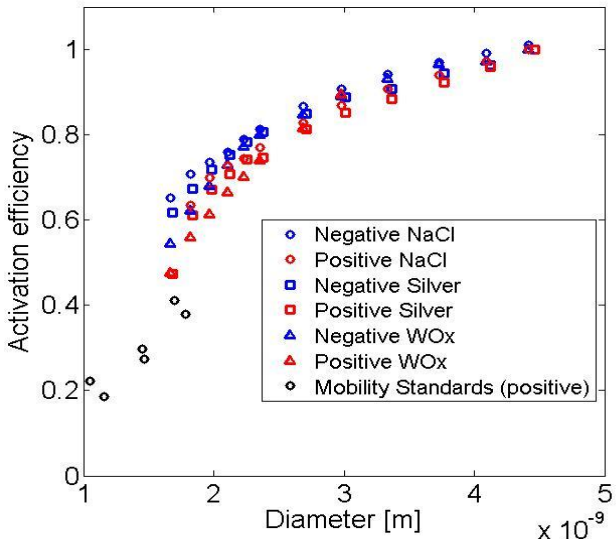

Figure 1. Activation curves of the PSM for both polarities of Silver, NaCl, WOx-particles and the mobility standards. Silver seems to be activated a little better than WOx-particles and NaCl of same mobility diameter.

Mobilization of Aerosol MALDI Mass Spectrometry for Bioaerosol Analysis

Yurteri C.U., Stowers M., Kleefsman W.A., and Marijnissen, J.C.M.

Delft University of Technology, Delft, 2628 BL, The Netherlands

Keywords: MALDI, Bioaerosol, Instrumentation

Presenting author email: c.u.yurteri@tudelft.nl

Systems for early detection of malign bio aerosols are becoming attractive due to possible biological attacks, infection dangers in hospitals, animal farms, forensics, ..etc. Because of their small size, averaging 1 to 10 um in size, bacterial bioaerosols are extremely difficult to detect. In addition, size and concentration are not absolute criteria for determination of harmful aerosols. Timely detection of a broad range of bioaerosols with a small response time and a very low false alarm rate, discrimination and identification allows timely execution of procedures to save local people from harm and further contamination. With the currently available instruments it is impossible to measure and identify a biological attack within a short time range, and on-line techniques are required. One of the instruments enabling this is the aerosol MALDI (matrix-assisted laser desorption/ionization) mass spectrometer for the analysis of single bioaerosol particles developed at TU Delft (Kleefsman 2008, Kleefsman et al. 2008). The strength of the aerosol MALDI mass spectrometer is based on three subsequent steps: particle detection, particle selection and the analysis of the particles based on MALDI mass spectrometry. The aerosol mass spectrometer has been improved to make the instrument suitable for bioaerosol detection. The implemented instrumental improvements include a new design of the repeller and the extractor plate as well as the implementation of delayed extraction. The application of the MALDI technique for *on-line* analysis of aerosol particles, implies the need of an on-line sample preparation method. So an on-line coating method was also implemented. We are now in the process of implementing this instrument as a mobile system. We will present the recent status of development and considerations for portability of the system.

Development and validation of a novel experimental system to investigate particulate matter emitted from a steelworks

M. Barker*[1], C.W. McLeod[1], D. Ciaparra[2], K.Jackson[2]

[1]Centre of Analytical Sciences, University of Sheffield, Sheffield, S3 7HF, UK
[2]Tata Steel RD&T, Swinden Technology Centre, Rotherham, S60 3AR, UK
Keywords: PM, Morphology, ELPI, Dust, Industrial Aerosols
Presenting author email: M.L.Barker@Sheffield.ac.uk

Work place exposure to particulate matter (PM) can be a potential health risk, especially if it is able to penetrate into the respiratory system (Petavratzi *et al*, 2005). Both the shape and size of PM determines how far it can penetrate into the respiratory tract and the rate of particulate removal following deposition. To help further the understanding of the sources and formation of PM and allow efficient abatement, full characterisation must be completed.

PM suspended within the atmosphere may also be known as dust. Dustiness is defined as the likelihood of a material to emit dust during handling (Hjemsted and Schneider, 1996). One method currently used to test the dustiness of a material, and referred to in the British and European standard BS EN 15051, is the rotating drum sampler (RDS). The RDS was originally developed by Warren Springs Laboratories to simulate the general handling of powder materials. It is commonly used to measure the dustiness index of a sample as well as collecting size fractionated particulate matter (PM) into three health related size fractions; inhalable, thoracic and respirable, defined by BS EN 481. Unlike other methods the rotating drum is capable of sampling moist, dry, coarse and fine samples. By testing raw and recycled materials from an integrated steel works using the RDS, dustiness may be quantified and control measures put in place to prevent PM entering the atmosphere.

This work simultaneously couples an Aspect morphology analyser (Biral, UK) and an electrical low pressure impactor (ELPI, Dekati, Finland) to a RDS, as shown in Figure 1. It follows on from previous research completed by Jackson (2009), who coupled a RDS with an ELPI to obtain real time data and chemical information for resuspended particulates

This unique set up allows determination of real time morphological information for particles ranging from 0.5 µm to 20 µm and mass size distributions ranging from 30 nm to 20 µm. The Aspect morphology analyser works by measuring irregularities in the light scattered by single particles passing through a laser beam within the measurement chamber. The ELPI is based on inertial impaction of aerosol particles combined with particle charging and electrical detection. It is capable of determining particle size distributions and concentration in real-time whilst also collecting size fractionated PM onto substrates for subsequent gravimetric and chemical analyses.

One current source of PM within the iron and steel making industry is the handling and stockpiling of raw materials. During this work eleven granular samples originating from stockyards and processes based at an integrated steelworks have been tested, including a selection of iron ores, recycled materials and fluxes such as limestone.

Simultaneous coupling of both the Aspect and the ELPI instruments to the RDS has been successfully completed and morphological data of PM has been obtained. Size distribution profiles have been acquired from both the Aspect and the ELPI allowing comparisons to be made between each instrument.

Development of a pulmonary waveform generator for study the aerosol propagation and deposition in transparent hollow airway models

A. Kerekes, A. Nagy, D. Oszetzky, A. Czitrovszky

Department of Laser Applications, Research Institute for Solid State Physics and Optics, Budapest, H1121, Hungary

Keywords: lda, airway, bronchial, lung model, pulmonology
Presenting author email: anagy@szfki.hu

Proportional bronchial airway models with one to one scaling based on a resin human lung cast and a laboratory prototype of a pulmonary waveform generator were designed and manufactured for the experimental validation of the theoretical calculations made by the stochastic lung deposition model or CFD code (Kerekes *et al.* 2010, Hofmann *et al.* 1991, 2001, Balásházy *et al.* 1990, 1991, Salma *et al.* 2002, Farkas & Balásházy 2008). The preliminary experimental results show good agreement with the theory and encouraged us to develop and build the complete system.

The fully computer controlled pulmonary waveform generator (Fig. 1.) consists of a 8 litre volume piston pump and a controlled servo motor which can follow any pre-programmed waveform to simulate different breathing parameters, like resting, sitting awake, light exercise, heavy exercise. All inhalation parameters are adjustable, so it is easy to study different cases of various health conditions of patients like healthy, asthmatic, COPD, emphysema, and also for adults and children with different ages.

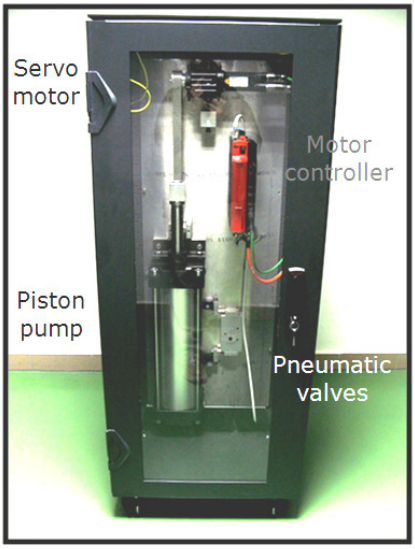

Figure 1. The pulmonary waveform generator

A particle measurement system was developed based on laser Doppler anemometry to detect the particles and measure their concentrations, size- and velocity-distributions inside the airway model, across the cross section in different airways generations (Fig. 2.). This system is optimised to the requirements of this special task, it is compact to fit into the chamber where the airway model is located and easily adjustable.

Measured flow patterns and deposition fraction values will be compared with published computed results at more particle sizes in the size range of 100 nm – 10 µm to validate computational fluid dynamics techniques and lung deposition models.

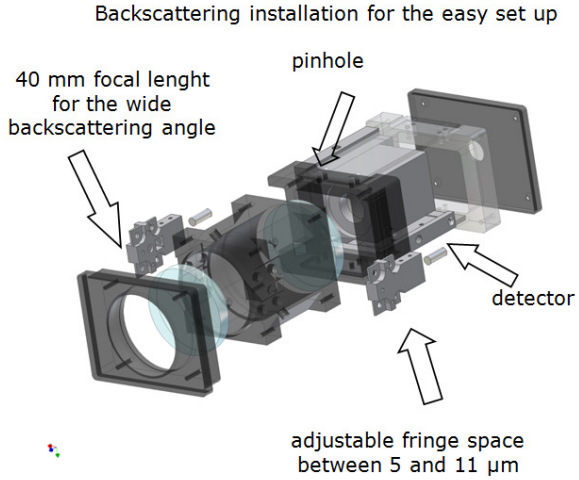

Figure 2. Design of the LDA probe head

Session 9A: Aerosols in Geoengineering

Implications of geoengineering assessed in simulations with complex climate models

In the context of global warming, various geoengineering techniques have been proposed as a "last resort", in case mitigation efforts fail or the consequences of the warming prove more severe than expected. Some of the suggested approaches would rely on the injection of aerosol into different parts of the atmosphere to enhance the global albedo. A deliberate global-scale manipulation of the radiative budget of the Earth may allow a counterbalancing of global mean temperature increase due to the effects of continued greenhouse gas emissions, but may also result in undesirable side effects for crucial parts of the Earth system. Earlier climate model simulations of geoengineering have led to partly inconclusive results, and it is unclear to what extent this may be due to differences in the model formulations or in the simulated scenarios. To overcome this situation the GeoMIP initiative (Kravitz *et al*., 2011) and the EU project IMPLICC have defined a set of experiments to be performed jointly by several climate models where solar radiation management is applied on top of CMIP5 future emission scenarios. Here, we present results obtained with three climate models applied within IMPLICC.

The simulation scenarios include an idealized experiment, where a quadrupling of CO2 is balanced by a reduction of the solar constant (G1), and a possibly more realistic experiment, in which stratospheric sulphur injections are used to limit temperature increase in the 21st century (G3). Furthermore, within IMPLICC we perform an additional scenario (G5) in which we attempt to obtain the same effect as in G3 by the manipulation of low level clouds through injection of sea salt. The goal is to assess proposed geoengineering techniques by comparing their efficiency and side effects in climate model simulations.

A preliminary analysis of experiment G1 provides the following robust results: To balance the global temperature, i.e. to keep it at the preindustrial level, the necessary reduction of the solar forcing is larger (on the order of 10 to 20%) than the forcing estimated from the change in CO_2. This means that the efficiency of solar shortwave forcing is smaller than that of CO_2 longwave forcing. The climate in such a geoengineered world would not be the same as in preindustrial times. Fig. 1 shows the latitudinal dependence of the temperature response to the forcing in G1 (with respect to preindustrial). A common result among the models is

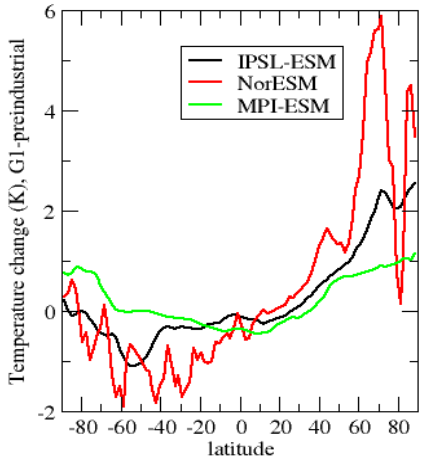

Figure 1: Zonally averaged surface temperature response in experiment G1 relative to the preindustrial control run averaged over 50 years in the IPSL and MPI-ESM, and over 10 years in the NorESM model outputs. Note: In results for IPSL-ESM and NorESM a temperature bias has been removed that was resulting from an inexact balancing of radiative forcing.

that high latitudes (and in particular the Arctic) still tend to be warmer under geoengineering while low latitudes would cool slightly. The solar dimming is obviously more effective in regions with strong insolation.

Global precipitation is reduced in experiment G1 with respect to preindustrial times by about 3-4% although a quadrupling of CO_2 alone (without geoengineering) would strongly enhance precipitation. Regional changes in precipitation differ considerably among the models.

The research leading to these results has received funding from the European Union's Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 226567 - IMPLICC.

The deliberate injection of aerosol into the stratosphere has been suggested as a solar radiation management scheme, which would cool the Earth's surface reflecting solar radiation back to space. Such a scheme is believed to be both affordable and have a high effectiveness when compared to other geoengineering schemes for mitigation of global warming (Shepherd, 2009). The lower stratosphere already contains a sulphate aerosol layer which is produced from both biogenic and volcanic sources.

Recently, most research has focused on the deliberate injection of sulphate aerosol (or precursors) into the stratosphere. However, aerosols other than sulphate could be cheaper to produce and be more affective at scattering radiation by virtue of having a greater refractive index. They could also be designed to have lower absorption characteristics, and would therefore result in smaller warming of the stratosphere.

In addition to containing a sulphate aerosol layer, the lower stratosphere also contains the ozone layer which is crucial for protecting the Earth's biosphere from harmful UV radiation. The ozone layer also is a key component of the coupled atmospheric chemistry system, impacting temperatures and dynamics. International regulations are already in place to protect the ozone layer from depletion by man-made halocarbons. Therefore the deliberate injection of aerosols into the stratosphere must be assessed with respect to the possible interactions between the geoengineered aerosol and the ozone layer.

We will present a review of the possible effects of aerosols upon stratospheric ozone. We consider both sulphate aerosol and other aerosols that offer the possibility of cheap and effective solar radiation management. In particular, the direct destruction of ozone upon the aerosol surface and the activation of ozone destroying catalytic species will be considered (e.g. activation of $ClONO_2$ to ClO, and HCl to Cl). In addition to the ClOx catalytic cycles the extra stratospheric aerosol burden is likely to perturb the NOx cycles. The interaction of aerosols with stratospheric water vapour, and the perturbations to aerosol reactivity, will also be assessed. The possibility of using organic and inorganic coatings to provide an inert aerosol surface to reduce the ozone depletion potential of the aerosol will also be presented.

This review will provide a solid framework with which to assess the suitability of different aerosol candidates for use in geoengineering. In addition to the review, initial laboratory work investigating the interaction of geoengineered aerosol with atmospheric gas phase species will be presented. In particular, the uptake coefficients of ozone depleting gases, or their pre-cursors, will be measured. A variety of particle compositions are being investigated including TiO_2 and Al_2O_3. The effect of different surface coatings, both organic and inorganic, upon the aerosol reactivity will also be examined.

Two distinct laboratory studies are being employed to investigate the candidate geoengineered particles. Laser tweezers are used to investigate the changing chemistry of the aerosol bulk phase after interaction with gas phase species (King, 2008). An aerosol flow tube (AFT) with gas phase species detection via chemical ionization mass spectrometry (CIMS) is used to investigate the uptake coefficients of different gas species upon the particle surface (Pradhan, 2010).

Near vessel dynamics of sea salt sprays: How efficient can maritime clouds be seeded?

S. Müller-Klieser[2], U. Platt[2] and T. Leisner[1,2],
[1]Institute of Meteorology and Climate Research, Karlsruhe Institute of Technology, Hermann von Helmholtz Platz 1, 76344 Eggenstein-Leopoldshafen, Germany

Keywords: cloud albedo enhancement, sea salt aerosols, Euler-Lagrange modelling
Presenting author email: Thomas.Leisner@kit.edu

Deliberate modification of the albedo of maritime clouds by seeding them with sea salt particles has been proposed as a viable method of climate engineering (Latham, 1990). In a commonly discussed scenario (Salter et al, 2008), the aerosol is produced by spraying fine droplets of sea water from unmanned vessels. In this contribution, we follow up on this scenario and analyse the dynamics in an artificial cloud of sea water droplets emitted from a ship stack. A finite-volume turbulence model coupled with a Lagrangian particle tracking model is used to simulate the thermodynamic conditions and the aerosol dynamics in the near field around a spraying vessel. Special emphasis is put on the subsidence of the aerosol that originates from the cooling caused by the evaporating droplets.

The model is implemented in Ansys CFX and consists of two parts. For the gas phase, the large eddy turbulence model of Nicoud and Ducros (1999) is used. It is coupled to a Lagrangian particle model which describes the aerosol. Liquid evaporation is implemented using the the model of Langrish and Kockel (2001). Convergence test for grid resolution, time stepping, iterations per time step and number of statistically picked ensemble tracks were made. We are able to solve the equations for a box size of 25*40*150 m^3 (h*w*l in downstream direction). For the final run a grid of 2*105 tetrahedrons was used. The model size was sufficient to follow the aerosol dynamics up to complete thermalization for wind speeds below 7m/s.

As proposed first by Latham (1990, 2002) one would have to disseminate about 10^{17} particles per second and per vessel in order to offset a global radiative forcing of 3.7 Wm^{-2} with a fleet of 1500 vessels. We chose this number as targeted production rate for our initial condition, although different GCM model studies by Korhonen (2010) showed more than 5 times the spray rate previously assumed could be needed due to particle deposition and suppression of cloud supersaturation. The meteorological conditions were chosen from Lewis and Schwartz (2006) representing common stable conditions at sea. We varied the initial droplet radii from 2µm to 0.4µm (Latham, 2002), accordingly the evaporated water mass changed. To test for sensitivity and dependency on the meteorological boundary values, simulations where run at relative humidity levels between 80 % and 98 %. Wind speed was varied between 1m/s to 7 m/s at 10m altitude.

After the evaporation of all droplets the aerosol air mass reaches thermodynamic equilibrium with the environment. The particles surviving that period are available for updraught by turbulent mixing. We estimate the efficiency of this process by using a standard parametrization adapted from Pasquill (1961).

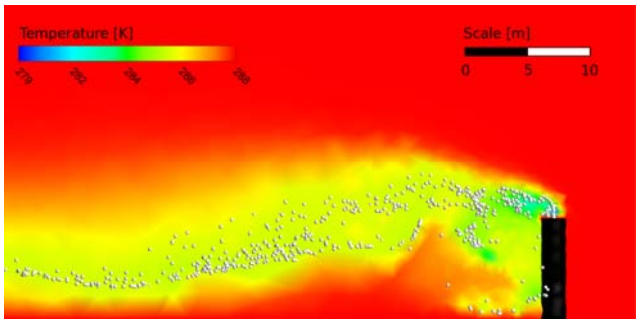

Figure 1. Model output for a single sea-going spraying device at a windspeed of 3 m/s from the right and neutral atmospheric stability. Gas phase temperatures are color coded and the dots represent ensembles of particles

Fig. 1 shows a cross-section of a spraying device parallel to wind speed. Colors indicate the temperature in Kelvin. Ensembles of particles are marked with white dots. We show that the evaporative cooling entrains the particles, forces the aerosol to remain in low altitudes and rising loss rates. In our contribution, we will present results on the cloud seeding efficiency as a function of initial droplet size and stability of the atmosphere and discuss the resulting limitations for cloud seeding.

The impact of controlled sea salt emissions on cloud features based on comprehensive regional model studies

K. Lundgren[1], M. Bangert[1], H. Vogel[1], and B. Vogel[1]

Keywords: geoengineering, sea salt, CCN, modelling (regional).
Presenting author email: Kristina.lundgren@kit.edu

One of the presently suggested methods to control the global warming is to increase the planetary albedo by seeding marine clouds with sub-micron sea salt particles since these act as a major source of cloud condensation nuclei (CCN). By assuming a constant amount of cloud liquid water, an increase in CCN acts to increase the cloud droplet number concentration (CDNC) and decrease the droplet sizes. As a result, the cloud albedo increases.

A proposed technique to inject sub-micron sea salt particles to the atmosphere is to use wind driven vessels (e.g., Salter *et al.*, 2008). These are designed to release micron sized mono-disperse sea water drops.

To investigate the effect of imposing sea salt particle fluxes to the atmosphere is difficult, partly due to the non-linear response of the atmospheric processes. Due to the competition for water vapour, an increase of sea salt particles can e.g., suppress the activation of secondary particles. This can eventually give an opposite effect than originally intended (e.g., Korhonen et al., 2010).

In this study, we investigate the impact of controlled sea salt emission fluxes on the cloud properties for a region that is equipped with vessels homogeneously distributed within distances of 0.25°. We perform detailed calculations with the comprehensive model system COSMO-ART (Vogel *et al.*, 2009). COSMO-ART is online coupled, which makes it possible to investigate feedbacks between particles and the state of the atmosphere. The natural emissions of primary particles are parameterized as function of the ambient conditions. Primary soot emissions are considered and secondary aerosols are formed from gaseous precursors that are treated by complex photochemistry in the model. We use two-moment cloud microphysics including six hydrometeor classes (Seifert and Beheng, 2006) that are coupled to the aerosol particles by a comprehensive parameterisation for aerosol activation (Barahona *et al.*, 2010). The activation parameterization accounts for the competition of different aerosol particles for water vapour during their activation and considers the effect of giant CCN such as sea salt. The emission fluxes of sub-micron sea salt particles from the vessels are described as function of wind speed according to Korhonen *et al.* (2010).

Specific remote regions with high insolation have been favored for geoengineering purposes (Salter *et al.*, 2008). We have the intention to study the impacts in such regions, but here we first investigate the effect of controlled sea salt emissions in a region of anthropogenic influence. In Fig. 1. we present the wind speed and average changes in the sea salt number density (N_{SSA}), CCN, liquid water path (LWP), and cloud optical depth (COD) for a case study over western Europe for the 23-26 July, 2008. During the investigated time period, a low was situated north of Spain. When considering the controlled sea salt emissions, the average CDNC increases by up to 10 cm^{-3} over the Atlantic Ocean, which corresponds to modifications in the order of 100% or higher. Regions of anthropogenic influence show more complex responses. Here increases as well as decreases of the CDNC, LWP, and COD are found. The relative change in the CDNC is locally in the order of 100%.

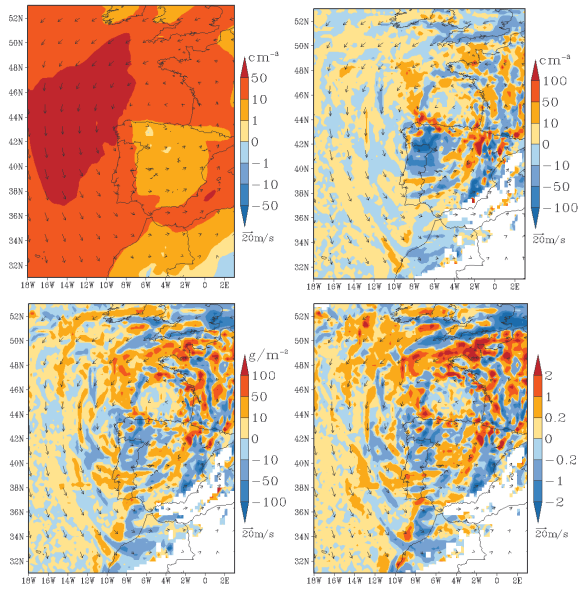

Figure 1. Mean ΔN_{SSA} (top left), ΔCDNC (top right), ΔLWP (bottom left), and ΔCOD (bottom right) when including imposed sea salt emissions.

In the presentation, results for further regions will be discussed, taking also sulphates from oceanic DMS emissions into account.

Presenting author email: antti-ilari.partanen@fmi.fi

Manipulation of the Earth's climate by injecting vast amounts of sea spray into the atmosphere in persistent marine stratocumulus regions (Latham, 1990) has gained interest in recent years. To date, most studies have assumed a prescribed uniform cloud droplet number concentration (CDNC) in the geoengineered regions irrespective of the environmental conditions and have therefore not been able to address the aerosol-cloud interactions or the direct radiative effects of the injected sea spray.

Here we present simulations with the aerosol-climate model ECHAM5-HAM (Stier *et al.*, 2005) which includes explicit and prognostic calculation of cloud microphysics and interaction of aerosol particles with clouds and radiation. We assume a wind-speed dependent number flux for the injected particle population similar to Korhonen *et al.* (2010) and follow its transport and transformation due to microphysical processes in the atmosphere. This additional sea spray flux is simulated either over all the oceans or in three optimized regions which have the strongest radiative flux perturbations (RFP) and cover altogether 3.3% of the Earth's surface (same total area as in Jones *et al.* (2009)).

Applying the baseline scenario (i.e. injected particle size 250 nm and number flux 10% higher than in Korhonen *et al*. (2010)) in the optimized regions, we predict a global mean RFP of −0.8 Wm^{-2}. This compares well with the earlier estimate of −0.97 Wm^{-2} by Jones *et al.* (2009) who assumed a fixed prescribed CDNC of 375 cm^{-3} in the geoengineered regions. In our simulations the mean regional CDNC varies between 194 and 286 cm^{-3}, and cloud cover increases by 2–5 percentage points. It is noteworthy that both the absolute CDNC values as well as their relative changes (74–80%) are clearly higher than predicted in Korhonen *et al.* (2010) using similar emission fluxes. In our simulations, multiples of the baseline sea spray flux cause almost a linear increase in CDNC but the RFP is clearly sublinear (global mean RFP with 5×baseline flux is −2.2 Wm^{-2}).

Since the three optimal geoengineering regions are characterized with persistent stratocumulus decks, inside them practically all of the radiative effect originates from aerosol indirect effects. However, the direct effect can be significant outside these regions: when all oceanic regions are seeded, the direct effect is about 65 % of the aerosol indirect effects.

For a constant volume emission flux of sea spray, the size at which the individual particles are injected becomes very important. Reducing the injection size from 250 nm to 100 nm, which is typically still large enough for cloud activation in marine boundary layer, increases the global mean RFP in the run of optimized regions to −2.1 Wm^{-2}. On the other hand, aerosol direct effect from 100 nm particles is only 50 % of direct effect from larger 250 nm particles. With the largest tested particle size (500 nm) geoengineering has only very minor effects on CDNC or RFP due to the low number flux (13% of the baseline flux).

Based on our results aerosol direct effect originating from artificial sea spray emissions cannot be neglected although indirect effects dominate over regions covered by marine stratocumulus clouds. In these regions it would probably be optimal to use rather small particles to maximize aerosol number concentration and thus aerosol indirect effects. However, if injections were done outside stratocumulus regions, larger particles might be most efficient to maximize aerosol direct effect. These results imply that this geoengineering method has potential to counteract anthropogenic climate warming, should we able to realise the relatively high sea spray fluxes assumed over 3.3% of the Earth's surface.

Detailed studies by cloud-resolving model (Wang *et al.*, 2011) showed that individual cloud cells react differently to sea salt injections based on background aerosol concentration, cloud water content and the injection method. These small-scale effects cannot be properly assessed with a climate model.

Exploring efficiency of sea spray geo-engineering

K. J. Pringle, K. S. Carslaw, T. Fan

Institute of Climate and Atmospheric Science, School of Earth and Environment, University of Leeds, LS2 9JT
Keywords: aerosol modelling, sea spray, clouds, climate change
Presenting author email: kirsty@env.leeds.ac.uk

Artificially increasing the albedo of marine clouds by the mechanical emission of sea spray has been proposed as a possible geoengineering technique to slow the warming attributed to anthropogenic greenhouse gases. For the injected sea spray to cause a net cooling, the additional aerosol must result in an increase in cloud droplet number. In this study we use a physically based parameterisation of aerosol activation to quantify cloud drop number (CDN) changes over the entire parameter space of updraft speed and properties of the injected and background aerosol.

We suggest criteria for when geoengineering may be an effective strategy and also identify conditions where additional aerosol will have a negligible effect or act to decrease CDN. Undesirable decreases in CDN occur when particles are injected into clouds in environments where the number concentration of background accumulation mode aerosol is > 200 cm^{-3}. The effect is particularly strong when (i) the in-cloud updraft velocity is low (< 0.2 ms^{-1}); (ii) the injected mode width is wide (standard deviation of > 1.3) and (iii) the number concentration of the additional aerosol is low (< 200 cm^{-3}). A large increase in CDN is achieved when the converse it true.

To explore the frequency of occurrence of these "high efficiency" and "low efficiency" background conditions, we analyse output from two global aerosol models to identify the percentage change in CDN as a function of the properties of the injected particles. The purpose of this work is to help target sea spray geo-engineering to the conditions when it will be most efficient, and thus to avoid geo-engineering in conditions when it will be inefficient, or even counterproductive.

Africa is one of the least studied and one of the most critical continents with regard to climate change. Thus diverse long term atmospheric observations are needed to study the effects and drivers of the climate change. One of the increasingly important drivers of changes is the urbanization, which increase the importance of megacities as source of pollutants on regional and global scale. Unfortunately, there are essentially no long-term high-time resolution (or real-time) aerosol chemical composition measurements in Africa. These measurements are needed to understand the effects on particulates on climate and regional pollution levels.

The Aerodyne ACSM (Aerosol Chemical Speciation monitor) is designed for continuous long-term measurements of the chemical composition of non-refractory submicron particulate matter in real time and is based on same technology as Aerodyne Aerosol Mass Spectrometers (AMS) (Ng *et al*., 2011). The sampled particles are focused after a critical orifice to the vaporizer by an aerodynamic lens and non-refractory components flash-vaporize. The vapour molecules are ionized by electron impact and positive ions are detected by a quadrupole mass spectrometer. Much of the reduced complexity is due to the fact that the ACSM does not measure size distributions; only aerosol mass spectra are reported.

Our measurements are conducted at a new measurement site about 100 km to West of Johannesburg, South Africa, on a grazed savannah-grassland area with limited local pollution sources, but strongly impacted by the plumes from Gauteng metropolitan area with more than 10 million people. In addition to pollution plumes, the site is influenced by frequent injections of clean air from the sparsely populated sector to the West—South-West. The station has been utilized in South Africa since 2006 (Laakso *et al*., 2008), and was placed on its permanent location near to Potchefstroom in May 2010.

Preliminary results of the ACSM dataset for the period 1 September – 30 November 2010 showed that PM1 aerosol composition was dominated by organics (OA) (54%) and sulphate (SO_4^{2-}) (26%). Observed fractions for ammonium ($NH4^+$) and nitrate (NO_3^-) were 13% and 6%, respectively. Tracer m/z indicated that amount of hydrocarbon-like OA (HOA) was really small and most of organics were oxidised.

For more detailed analysis, the data was divided in dry and wet season periods (Figure 1). During the dry season the organic aerosol concentration was high (> 60 % of total signal) and peaked up to 35 μg/m^3 most probably due to local biomass burning. During the wet season, sulfate concentrations were typically high and overtook organics especially when the air-masses were transported from Johannesburg metropolitan region.

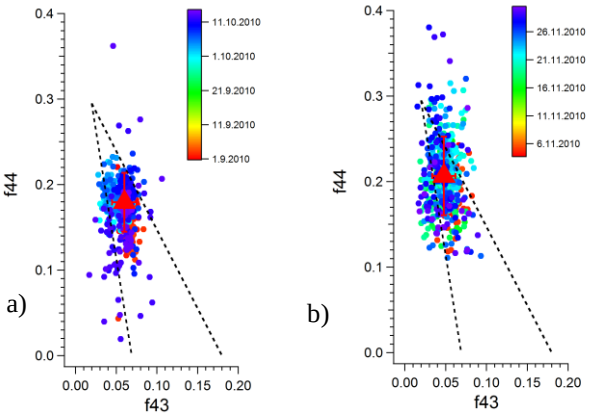

Figure 1: Preliminary results of m/z 43 and m/z 44 ratios to total signal of all OA components in the mass spectrum (f43 and f44) during (a) dry and (b) wet seasons. The dotted lines indicate the triangular space where ambient OOA components usually fall and average values ± s.d marked as triangles.

Detailed positive matrix factorization (PMF) of AMS organic mass spectra will be applied to further characterize the sources and evolution of ambient organic aerosol (OA) material.

Submicron aerosol particles effect climate via direct and indirect mechanisms (Seinfeld and Pandis, 1998), and pose a threat for human health (Pope and Dockery, 2006). Depending on their size, they may scatter light, act as cloud condensation nuclei, or penetrate at different depths in human lungs.

Due to their large variability in size and dynamically driven tendency to occur in different separate size-ranges, modes, the particle size distribution is often expressed as a sum of multiple log-normal modes. Smallest particles (< 25 nm) are classified as nucleation mode, slightly larger (25–100 nm) as Aitken mode, next accumulation mode (100–1000 nm) and particles above 1000 nm as coarse mode particles. Especially for modelling purposes this classification provides clear benefits in e.g. reduced number of differential equations (e.g. Korhonen et al., 2004).

For large observational datasets, the modal representation provides simple way to study the behaviour of aerosols.

In this study, we present analysis of four years of submicron particle size distribution data measured in South Africa during the period 07/2006–05/2010. The period until 02/2008 represent semi-clean background savannah (Botsalano game reserve) (Laakso et al., 2008; Vakkari et al., 2010), whereas the second part of measurements is from polluted mining area (Marikana village) with a strong impact from domestic biomass burning in informal settlements (Venter et al., 2011).

The particle number size distributions were observed with a Differential Mobility Particle Sizer with a size range from 10 to 840 nm. The modal fittings are done by the method described in Vartiainen *et al* (2007). Measurements are explained in detail in Laakso *et al* (2008) and Vakkari *et al* (2011).

In addition to the in-situ measurements, particle size distributions and their representativeness are analyzed as a function of air mass origin utilizing the HYSPLIT air mass trajectories and MODIS satellite data.

Based on this study, we found that source areas of aerosol particles obtained from in-situ measurements combined with air mass trajectories agree with the satellite produced aerosol optical depths. We also found seasonal and spatial differences in particle formation and growth rates indicating the importance of biogenic organics and sulphuric compounds. Also the effects of wild fires were clearly seen. The whole dataset provides unique possibility for modelling purposes in an environment with very few previous observations.

Aerosol physical and chemical properties were measured in two sites in Amazonia. The clean site is at Central Amazonia and is located in a pristine Amazonian forest site. A second sampling site is located in Porto Velho, Rondonia, an area strongly affected by biomass burning emissions. Long term measurements, from February 2008 are being carried out in these two sites, as part of the EUCAARI (European Integrated Project on Aerosol Cloud Climate and Air Quality interactions) and AEROCLIMA (Direct and indirect effects of aerosols on climate in Amazonia and Pantanal) projects. The dataset obtained encompass the first long term aerosol measurements ever performed in Amazonia, elucidating the differences between the biogenic aerosol population naturally released by the forest metabolism and the anthropogenic aerosols brought to the ecosystem by outer sources as well as regional biomass burning emissions.

In the pristine central Amazonia, measurements were taken at the Cuieiras forest site, tower TT34, with coordinates 2°35'40"S and 60°12'33"W, above the canopy (45m), under dry conditions (RH<40%). A MAAP 5012 absorption photometer in series with a nephelometer (TSI 3563) was used to measure aerosol absorption and scattering, respectively. Scattering coefficients were corrected for truncation errors. Observations were adjusted to 1000 mbar and 0^oC. Aerosol size distributions were measure using a Lund DMPS system, as well as a TSI SMPS system. Aerosol composition, and several trace gases that helps to characterize aerosol sources were also measured.

In Rondonia, a sampling station was installed close to the city of Porto Velho, in the "Parque Natural de Porto Velho" at coordinates ($8,69^o$ S; $63,87^o$ O). This region have with important land use change and biomass burning emissions. A MAAP 5012 absorption photometer and an Ecotech Aurora 3000 nephelometer are used to measure aerosol absorption and scattering. A TSI SMPS measure the aerosol size distribution continuously. Diffusion dryers are used to keep the relative humidity below 40%.

In the pristine Amazonian atmosphere, aerosol scattering coefficients ranged between 1 and 200 Mm^{-1} at 450 nm, while absorption ranged between 1 and 20 Mm^{-1} at 637 nm. A strong seasonal behavior was observed, with greater aerosol loadings during the dry season (Jul-Nov) as compared to the wet season (Dec-Jun). Although the forest site is locally well preserved, it receives the influence of regional biomass burning emissions during the dry season.

During the wet season in Manaus, aerosol scattering (450 nm) and absorption (637 nm) coefficients averaged, respectively, 14 ± 22 and 0.9 ± 0.8 Mm^{-1}. Both optical coefficients were greatly increased during the dry season, averaging 58 ± 58 Mm^{-1} and 4.1 ± 3.8 Mm^{-1}, correspondingly. Angstrom exponents for scattering were lower during the wet season (1.6 ± 0.4) in comparison to the dry season (1.9 ± 0.2), which is consistent with the shift from biomass burning aerosols, predominant in the fine mode, to biogenic and dust aerosols, predominant in the coarse mode. Single scattering albedo, calculated at 637 nm, did not show a significant seasonal variation, averaging 0.86 ± 0.06 and 0.86 ± 0.04, respectively for wet and dry season, even with that large variation in aerosol sources and magnitude of scattering and absorption coefficients.

In Porto Velho, even in the wet season it was possible to observe a strong impact from anthropogenic sources. Biomass burning emissions in the dry season. $PM_{2.5}$ aerosol concentrations of about 300 ug/m² were measured in August and September for most of the years. AOT values at 550 nm above 3 are frequently observed in Porto Velho with AERONET sunphotometers. Black Carbon were measured at 20 ug/m³ in the dry season, indicating strong aerosol absorption. Aerosol light scattering above 300 Mm^{-1} were measured.

This work presents a general description of the aerosol optical properties in Amazonia, both during the Amazonian wet season, when the aerosol population is dominated by particles of biogenic origin, and during the dry season, when there is a strong influence of biomass burning emissions. It is important to describe accurately the optical behavior of these particles in order to assess the impact of anthropogenic changes on the regional climate.

We present results of detailed aerosol measurements made from a ground site positioned in the rainforest of N.E. Borneo (about 80 km from the coast) and from the FAAM research aircraft around North Borneo, performed as part of the Oxidant and Particular Photochemical Processes Above a South East Asian Rainforest (OP3) project. Aerosol was measured using Aerodyne Aerosol Mass Spectrometers, which provide composition and size resolved measurements of sub-micron aerosol. Off- and on- island aerosol sources influencing the ground site were assessed with the most striking result being far greater loadings of sulphate in off-island air masses than in the continental tropics. Aircraft profiles show that transit of air masses over Borneo depletes regional aerosol and elevates terrestrial aerosol. It also lofts aerosol higher into the atmosphere which is likely to extend their atmospheric lifetime.

The vast majority of detailed atmospheric aerosol studies are performed in the Northern mid-latitudes. There is a comparative paucity of measurements that have been performed in the tropics, with the only studies that have been conducted focusing on the continental land masses in West Africa and Amazonia. The tropics are of particular importance to climate as they have a higher solar flux than the mid-latitudes. This means any perturbations to natural systems will be of more consequence than they would in the mid-latitudes. There is also widespread land-use change occurring, with rainforest being cleared to make way for agriculture. Not only does this release carbon previously trapped in the biosphere, but different emissions to the atmosphere affect atmospheric chemistry. The significant region of the tropics represented by the "maritime continent" — the patchwork of tropical islands in South-East Asia — has so far been overlooked by previous studies. Tropical island aerosol are potentially very different from those over continental land masses due to the influence of marine emissions and dynamical systems.

The relationship of aerosol composition to geographical air mass source was assessed using backwards air mass trajectory techniques. Identified off-island sources included long range transport of sulphate (neutralised by time of arrival at the site) and low concentrations of highly oxidised organics. Marine air masses also contained chloride that was closely correlated with nitrate aerosol. As the AMS is inefficient at detecting NaCl due to is slow vaporisation, it is likely that sea salt aerosol is reacting with terrestrial nitrate to form more readily detectable compounds. On-island sources included less oxidised organic aerosol which was probably Secondary Organic Aerosol (SOA) from rainforest terpene emissions. It appears that aerosol thought to be isoprene SOA was also seen from air masses travelling over oil palms, which are known to emit five times as much isoprene as the rainforest. Regional aerosol is removed by transit over Borneo, probably due to increased precipitation over the mountainous interior.

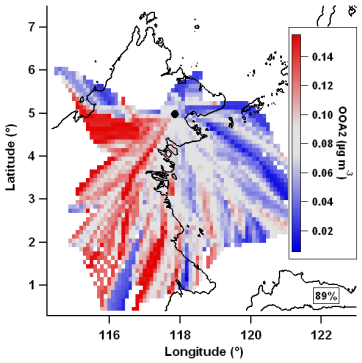

Figure 1: Example of back trajectory analysis. Each cell coloured by the average loading measured at the receptor site (back dot) for an air mass that has travelled over it. Red is above average and blue is below. This shows less-oxidised organic aerosol to originate terrestrially.

Aircraft profiles were used to assess the influence transit over Borneo has on synoptic transport of aerosol. Profiles upwind of the island show a very shallow boundary layer that contained sulphate (and low levels of organic) aerosol. Profiles over the island show a shallow mixed layer of organics with elevated sulphate loadings in a layer above. As the day progresses organic aerosol levels grow in the higher layer. Profiles over the downwind coast of the island show a shallow mixed layer with the above layer containing elevated levels of organics and occasionally sulphate. It seems that transit over Borneo depletes regional aerosol loadings (probably through wet deposition) and enhances SOA loadings from terrestrial emissions. It also lofts aerosol higher into the atmosphere.

Direct Evidence of Elevated Absorbing Layer Associated with Coarse Mode Particles over CTCZ Region from Aircraft Experiment 2009

J. Jaidevi, Priya Choudhry, Marykutty Michael, S.N. Tripathi, Tarun Gupta

Presenting author email: snt@iitk.ac.in

The natural desert dust from west transported through the Indo-Gangetic (IG) plains gets mixed with locally generated anthropogenic aerosols and is further carried over to the Himalayan foothills during the dry pre-monsoon season. Such mixing of natural and anthropogenic absorbing aerosol increases the dust absorption. Studies show strong dependence of radiative forcing on aerosol size distribution and presence of coarse mode absorption (Tripathi et al., 2011). Aircraft measurements were carried out over the Continental Tropical Convergence Zone (CTCZ) region up to 4 km during early monsoon season (Jun-Jul), 2009 to study the vertical and spatial variation of aerosol optical, microphysical, chemical, hygroscopic and morphological properties. The study area for the experiment was the northern part of Continental and Tropical Convergence Zone (CTCZ) region spanning from Khajuraho to Nainital in South-North direction and from Gaya to Jaipur in the East-West direction as shown below in Figure 1. In addition, a ground station was maintained at IIT Kanpur campus throughout the study.

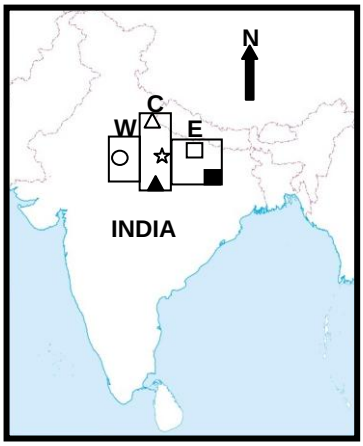

Figure1: Three segments, western (W), central (C) and eastern (E) Indo-Gangetic Basin shown by rectangles on an outline map of India, where the *circle*, *star*, *open triangle*, *filled triangle*, *open square* and *filled square* represent 'Gwalior', 'Kanpur', 'Nainital', 'Khajuraho', 'Gorakpur' and 'Gaya' respectively

Based on simultaneous measurements using four instruments onboard (Photoacoustic Soot Spectrometer, Scanning Mobility Particle Sizer, Aerodynamic Particle Sizer and $PM_{2.5}$ sampler) and the subsequent SEM/EDAX analysis, strong association between absorption and coarse mode aerosols is found. The in situ size distribution obtained using APS and SMPS has been binned for different heights within a zone and for different SSA within a height bin. This has been done in order to see any changes in the absorption pattern with respect to location and altitude. A shift in absorption is seen from accumulation mode in central (78°-81°E) to coarse mode in east (81°-84°E) CTCZ indicating the possibility of ageing of aerosols during long range transport. Aerosols below 2 km show absorption in coarse modes over central and east.

Spot analysis using SEM/EDX were carried out on particles collected on filters over Kanpur on Jun 29 at ground level and at higher altitudes using PM2.5 samplers as simultaneous collection of filter samples at ground and aloft were carried only over Kanpur during the experiment duration. The analysis of ground level filter (quartz filter) showed that particles were angular and flaky. The SEM images also showed chain like structures composed of small spherules making up the chain like structure, approximately 54 nm in size, suggests anthropogenic aerosols like 'fresh' soot which undergoing ageing process The EDX on particles imaged using SEM and EDX analysis were found to be composed of silicon (Si), aluminum (Al) and carbon (C) mainly suggests internal mixing of dust and anthropogenic aerosols.

The analysis of aircraft filter showed particles of relatively smaller size and showed agglomeration. The chain like structure of soot is absent here, and the particles have clustered and agglomerated to form large particles. These clusters are formed during the ageing process by the collapse of chain like soot structures and internally mixing with other elements and dust particles. This may have happened due to the aging of particles. Particles with irregular shape were more common. The EDX results showed them to be a mixture of Si and Al. The fraction of Al was higher in aircraft filters than the ground level particles. The C that was present in the ground level particles is persistent even particles still have about 7 to 8 % carbon. Column-integrated in situ size distributions were also compared with the ground based AERONET columnar size distributions.

We are thankful to the DST ICRP and ISRO GBP programme for the financial support. We are grateful to entire NRSC aircraft crew for their cooperation during this experiment.

Corresponding author email: zhangwj@craes.org.cn

At present, the air pollution around Beijing area has become a complex problem with a combination of different types of sources: coal smoke, traffic emission, dust re-suspension, and so on. Additionally, the transport of particulates seems to be a large-scale regional pollution. It is of great value to conduct aircraft measurements of pollutants at different altitudes (Wang et al., 2008).

In-situ measurements of gaseous pollutants, including ozone (O_3), sulfur dioxide (SO_2), nitrogen oxides (NO_X = NO + NO_2), carbon monoxide (CO), particle concentration (5.6-560 nm and 0.47-30 μm), and related meteorological information (T, RH, P) were conducted around Beijing area during Sep. 17-Oct. 7 in 2008. A two-engine light aero-transport YUN-12 (made in China) was used. The flight altitude ranged from ground to 4000m with the central point of Gucheng (N39°08′, E115°42′) in Hebei province around 5~15 km range, and the cruising velocity was generally kept at about 180 km h^{-1}. The total effective flight time was 23 h with 6 flights. This measurement was to characterize the regional variation of air pollution during and after the Olympics of 2008, the impacts of different transport direction and possible influencing factors.

Results suggested different characteristics of different gaseous pollutants and particles. (1) The meteorological factors showed significant influences for all the pollutants, as shown different pollutant levels at the ground level for different flights. (2) SO_2, NO_X, and CO showed highest concentration at the ground level, and decreased with the increasing of the height. It suggested the characteristics of major sources from ground emission for these gaseous pollutants. Figure 1 showed the variation of gaseous pollutants on flight Oct. 2 as an example. (3) Two different characterization of O_3 variation was obtained. It includes: ①similar variation with other gases, highest at the lowest altitudes, indicating the effects of ground emission sources; ② lowest concentration at the ground level, and increasing with the increase of altitudes until to 3000 m. For the O_3 variation above 3500 m, it showed similar range of 43~53 ppb at all flights, indicating the regional pollution level at high altitudes. (4) Backward trajectory analysis showed different transport direction of air masses, i.e. the pollutant transport of the southern direction with higher pollutants level; the cleaner long-range transport of the northern or northwestern direction with lower pollutants level; the transport from the eastern direction with characteristics of sea sources, i.e. middle level of gases pollutants and higher particle concentration; the transport of mixing directions, i.e. lower altitudes from the pollutant transport direction or local pollution but higher altitudes from the clean transport direction. (5) Coarser particles (0.47-30 μm) showed peaks of 0.6~0.8 μm, and highest in the ground level, and decreased abruptly with the increasing of heights, as Figure 2 showed. (6) For the ultrafine particles, the size distribution showed bimodal or multiple peaks variation, and concentrated on 10 nm and 20~100 nm. While, no obvious peaks were observed above 200 nm in the 5.6~560 nm range.

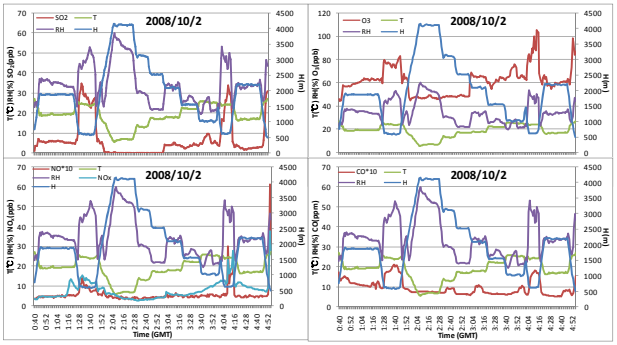

Figure 1. Variation of gaseous pollutants with meteorological factors and height on the flight of Oct. 2.

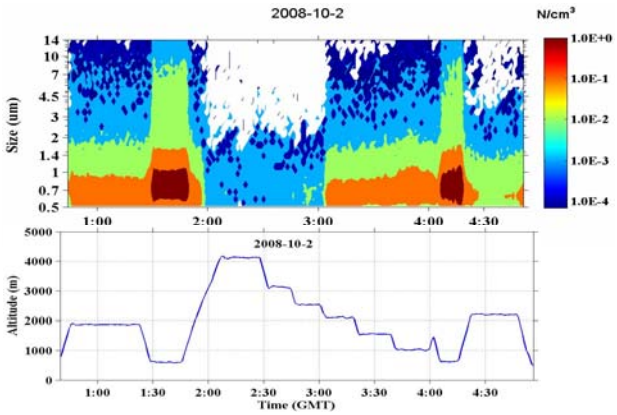

Figure 2. Variation of coarser particles with heights on the flight of Oct. 2.

Presenting author email: luca.ferrero@unimib.it

Aerosols physico-chemical and optical properties are fundamental for climate change (IPCC, 2007; Kaufman et al., 2002) as well as for remote sensing applications (Wang et al., 2010; Di Nicolantonio et al., 2009); for the latter their 3D knowledge, especially along the whole atmospheric column is required (Levy et al., 2007; Wang et al., 2010).

For the reasons above, vertical profiles measurements of aerosol properties were conducted in winter 2010 along Italy over the cities of Terni (Central Appenine Valley), Milan (Po Valley) and Merano (Alpine Valley).

A tethered balloon was fitted with an instrumentation package consisting of: 1) a tandem-OPC system (2 OPCs GRIMM *1.107*; 31 size classes between 0.25 to 32 μm: one dried, the other one at ambient RH), 2) a novel micro-Aethalometer (AE51, Magee Scientific), 3) a miniaturized cascade impactor (Sioutas SKC with 2 impaction stages: <1 μm, >1 μm), 4) a metorological station.

OPCs tandem system data allowed us to determine the aerosol humidographs along height following the method reported in Snider et al. (2008) (Figure 1). Hygroscopic growth (Gf) was found to be not uniform along the vertical profiles (Figure 2) evidencing how the use of simple parameterizations of Gf along the atmospheric column in remote sensing applications can be a source of uncertainty in the results.

Micro-Aethalometer data enabled us to estimate black carbon (BC) concentration and absorption coefficient profiles. BC profiles clearly identified the mixing height (MH), which was characterized by a strong vertical concentration gradient. Over Milan BC profiles also showed a shallow layer of increased concentrations close to the ground (+24% compared to the whole MH), due to the proximity of combustion sources. The BC fraction of aerosol volume fell to 50-70% above the MH, compared to ground-level data. This caused a change in the optical absorption properties of the aerosol at different heights. Fairly constant values of absorption coefficient were found above the MH for each location, between 5-20% (2-15 Mm^{-1}) of those measured within the mixing layer.

PM samples collected with the cascade impactor were analysed by ion chromatography (Dionex ICS90 and ICS2000) system. The chemical speciation (Ions and BC) allowed to estimate a aerosol refractive index, and aerosol optical properties along height were calculated from OPC data using a Mie code (Bohren and Huffman, 1983): vertical optical properties were useful to improve the satellite retrieval of particulate matter at ground-level.

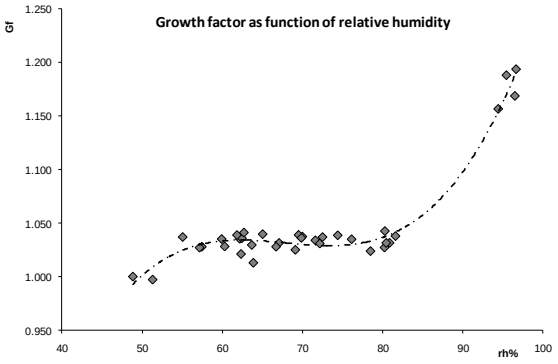

Figure 1. Humidograph along vertical profiles.

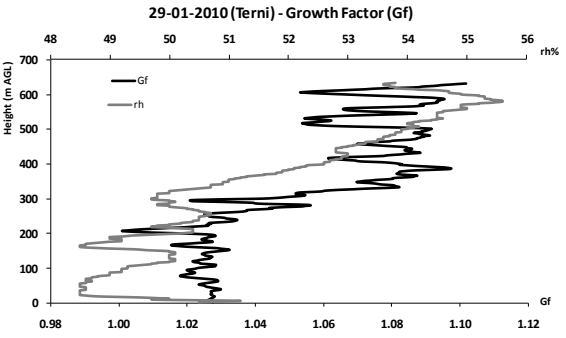

Figure 2. An example of Gf vertical profile.

Micro Smog Chamber: a Candidate Tool for Evaluating Wood Burning Emissions

A. Keller, H. Burtscher

Institute for Aerosol and Sensor Technology, University of Applied Sciences Northwestern Switzerland, Windisch, 5210, Switzerland
Keywords: SOA (Second. Organic Aerosols), Wood Combustion, Emissions, Measurement (characterization).
Presenting author email: alejandro.keller@fhnw.ch

An important part of the ambient particulate matter (PM) pollution related to wood combustion is originally emitted in the form of Organic Gaseous Carbon (OGC) which is transformed into particles known as secondary organic aerosols (SOA) in the atmosphere. Whereas primary particles are easily measured at the combustion site, SOA exists only after a complex chemical process that requires solar radiation and takes hours or even days for completion. This creates a large discrepancy between what is measured on the side of the emissions and the actual atmospheric values.

Current legislation imposes no emission limits for the precursor substances of SOA. This can be understood since only recently several studies have shown the importance of SOA (see, e.g., Szidat 2006 and Grieshop 2009) and there is no standard way to calculate the SOA production potential of a combustion device. Smog chambers are a valuable tool for studying SOA formation. But they are large (tents of cubic meters), slow and expensive to run and, therefore, far from been an acceptable tool for emission monitoring or type approval tests.

In this paper, we present a simple conditioning system that could be used for evaluating the SOA production potential and for comparing the emissions of different wood burning devices. The system is a continuous flow reactor (volume < 100ml) where the sample is irradiated with UV light. The exposure time is of the order of seconds. After the photooxidation takes place, the sample is cooled down in a second chamber of similar volume where the new OGCs species form PM.

The first experimental results are very promising. They show that it is possible to transform OGC into SOA in just a couple of seconds. Figures 1 and 2, for instance, show an experiment using terpenes as a precursor substance and a 1s residence time. This is an unprecedented result in the study of SOA and a first step towards creating a methodology for a real time evaluation of the SOA production potential. As a next step, we will take a closer view on other parameters like humidity and radiation wavelength that also influence SOA production and/or open new reaction paths.

Keywords: Biomass burning, Fossil fuels, Emissions
Presenting author email: Terhi.Penttila@uef.fi

Fossil fuel combustion is known to be the main source of greenhouse gas emissions. Increase in biomass use as energy source aims to reduce these emissions, since biomass combustion is considered to be greenhouse gas neutral energy source. However, one of the major problems with the biomass combustion is high transportation cost and poor availability due to complex logistics. Thus, bioenergy production in small decentralized units within small communities (2000-10 000 inhabitants) is often cost-effective. Another disadvantage of biomass combustion is high PM_1 (particles less than 1 µm in aerodynamic diameter) emission especially in small combustion units. It has been estimated that in Finland 25 % of all fine particle (aerodynamic diameter <2.5 µm) emissions originate from domestic wood combustion (Karvosenoja et al. 2008). Furthermore, small scale district heating units may generate substantial emissions if not equipped with efficient filtration (Sippula et al. 2009)

The aim of this study was to compare four alternatives to arrange decentralized energy production in small communities in respect to their flue gas emissions and toxicological properties of emissions. These options were heavy fuel oil (5.6 MW) and wood chip fired (10 MW) district heating units, light fuel oil fired residential burner (20 kW) and a modern pellet boiler (25 kW). In the wood chip fired plant the flue gas was cleaned with ESP while other systems included no flue gas after treatment. Gaseous compounds were measured with FTIR (Fourier Transform Infrared) analyzer including emission componenents such as CO, CH_4, HCl and NO_x. The particulate samples were diluted using a porous tube diluter and collected with DGI (Dekati Gravimetric Impactor). The samples were thereafter taken for polycyclic aromatic hydrocarbon (PAH), ion, elemental and toxicological analyses. From light fuel oil burner and pellet boiler PM_1 samples for organic carbon (OC) and elemental carbon (EC) analyses were collected with filter holders (Gelman Sciences 2220) and particle mass size distribution samples were collected with DLPI (Dekati Low Pressure Impactor). In addition, number size distribution was measured continuously with ELPI and FMPS. In wood-chip fired boiler the measurements were carried out after ESP.

Table 1. Emissions (mg/MJ) from different fuels and appliances

	Light oil	Heavy oil	Pellet	Wood chip
PM_1	0.6	113	16	4.2
CO	1.3	0.06	80	3.6
NO	56	207	49	97
CH_4	0.01	0.001	0.3	0.0009
HCl	0.18	0.17	0.10	0.13
PAHs	0.013	1.4	0.0001	0.005

Table 1 shows a comparison of emissions between different boilers. PM_1 and PAH emissions were the highest in the heavy fuel oil plant. The lowest PM_1 emission was found from the light fuel oil burner while the lowest PAH emission was found from the pellet boiler. From the pellet boiler, OC and EC emissions were 0.9 and 0.1 mg/MJ, respectively. From the light oil burner EC emission was 0.01 mg/MJ while OC was not found (detection limit 0.2 µg/cm^2). The highest CO emission was found from the pellet boiler and the highest NO emission from the heavy fuel oil plant. CH_4 and HCl were detected only in small amounts. Overall, fine particle emission from heavy oil plant was substantial compared to those measured in previous studies (Sippula et al. 2009). This might be due to intermittent boiler operating since the measurement was conducted during summer in the off season of the heating period.

Presenting author email: Heikki.Lamberg@uef.fi

Biomass fuels are used for heating and energy production to reduce CO_2 emissions and to replace fossil fuels. In the same time, combustion of biomass induces fine particle emissions that are known to cause adverse health effects. The emission characteristics from biomass combustion are affected by many different factors, such as combustion technology and fuel characteristics. One interesting way to produce heat in small-scale with biofuels is the use of wood pellets, which are easy to transport and combustion devices are usually highly automated. Even thought the emissions from pellet combustion are usually low, they are higher than those of light fuel oil combustion, which is often replaced with pellets. Because of this, the increase in the use of biofuels should be done with the best possible combustion technology to minimize the adverse health effects that the increasing PM1 emissions could induce. In this study, two different factors affecting the PM1 emissions are introduced: (1) the effect of air-staging and (2) the effect of pellet fuel raw material on PM1 emissions.

This study was carried out in a laboratory environment to guarantee stable combustion to minimize the alternation in combustion affecting the results. In total 24 different pellet raw materials were tested including stem wood, bark, peat, straw, roundwood and different mixtures of the materials. In the second part the effect of air-staging and the effect of partial-load on PM1 emissions were studied.

A commercial 25 kW pellet boiler was used in the tests which worked with top-feed fuel input and had integrated burner and boiler. Part of the flue gas was transported to a dilution tunnel through a heated sample line. Particle collections were made in the dilution tunnel with a dilution ratio varying between 90 and 120. Particle collections included filter collection for PM1 mass and chemical compositions. From these filters, analyses of elemental and organic carbon were performed together with the most common elements and ions. Furthermore, also fuels were analyzed for elemental composition.

The results show that there are many different factors affecting the PM1 emissions originated from small-scale combustion on pellets. First, the emissions from different raw materials varied between 5.1 mg/MJ and 195 mg/MJ from peat and rye straw, respectively. Furthermore, it was possible to decrease the PM1 emissions by optimizing the combustion air input. When air-to-fuel ratios were calculated for primary (λ_{Prim}) and secondary combustion (λ_{Sec}) zones from total air-to-fuel ratio and combustion air flows, it was seen that the $\lambda_{Prim}/\lambda_{Sec}$ ratio correlated with PM1 and CO emissions, and with the release of potassium from fuel to fine particles.

The releases of different ash forming elements were evaluated from fuel elemental composition and fine particle elemental composition. It was detected that alkali metal release factors vary significantly between different fuels. Two different factors were identified to explain the observed differences. First, the sum of potassium, sodium and chlorine in the fuel (Figure 1). Alkali metals are known to vaporize easily in the combustion and form particles in the flue gas. Second, the fuel chlorine/sulphur ratio; sulphur in fuel converts alkali metals to sulphates which are less volatile than alkali chlorides.

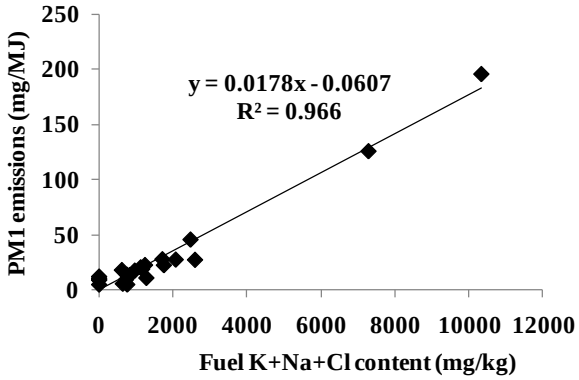

Figure 1. PM1 emissions are presented as a function of fuel K+Na+Cl (mg/kg).

These results show that there are factors affecting the PM1 emissions from small-scale pellet combustion that need to be considered when the use of biofuel combustion is increased. It is possible to reduce the emissions by further development in combustion technology. On the other hand, elemental compositions in pellet fuels affect PM1 emissions significantly. Because of this, it is important to pay attention to fuel qualities as well.

We thank Vapo Ltd. and PELLETime project for providing the pellet fuels, especially Simo Paukkunen and Lasse Okkonen from North Karelia University of Applied Science.

Time resolved PAH-emissions from residential wood combustion investigated with aerosol mass spectrometry

Presenting author email: joakim.pagels@design.lth.se

Polycyclic aromatic hydrocarbons have been denoted key components in particle related toxicology. Emissions of PAHs can under certain circumstances be high in residential wood combustion. However, previous attempts to identify the combustion conditions favouring high PAH emissions have typically been limited to either averages over one to several combustion cycles or been performed by non-specific techniques. In this work we applied aerosol mass spectrometry (AMS) for highly time-resolved direct measurements of PAHs and total organics from three different residential biomass combustion systems. The aim was to identify combustion situations associated with elevated PAH emissions and to suggest recommendations to reduce such emissions.

Three wood combustion appliances were studied; *i*) a conventional wood stove, *ii*) a modern pellet burner and *iii*) a novel pellet reactor with possibility to control the air supply. The wood stove was operated with high and nominal load, respectively, using relatively dry birch logs (14% moisture). Higher load was achieved by using larger batches consisting of smaller logs compared to the nominal load case. The Flue gas was sampled from a temperature of about 150°C and a three stage ejector driven dilution system employing filtered dry air at room temperature was used. The total dilution factor was about 1:2000 and thus the aerosol was sampled at close to ambient mass loadings. On-line gas-phase sampling included O_2, CO, NO_x and THC (total hydrocarbons by FID). A high resolution aerosol mass spectrometer (HR-TOF-AMS, Aerodyne Research) was used for size resolved composition of compounds vaporised at 600°C. The standard PAH AMS fragtable was employed to quantify the PAH emissions. A scanning mobility particle sizer was used for mobility size distributions (10-600 nm).

As seen in Figure 1, the highest concentrations of total organics during high load in the wood stove occured for the first 5 minutes after addition of new batches of logs on glowing embers. In contrast, the particle bound PAHs correlates poorly with total organics and increased levels occured about 10 minutes after refilling fuel. However, the highest PAH-emissions occurred when adding small amounts of fuel during flaming combustion. In these cases, PAHs composed as much as 30% of the total organics. It can be seen that the PAH concentrations correlates with low O_2 and high CO concentrations in the emissions. The particle phase PAHs were typically shifted towards higher molecular weights with increasing total PAH emissions during air deficiency, i.e. low O_2.

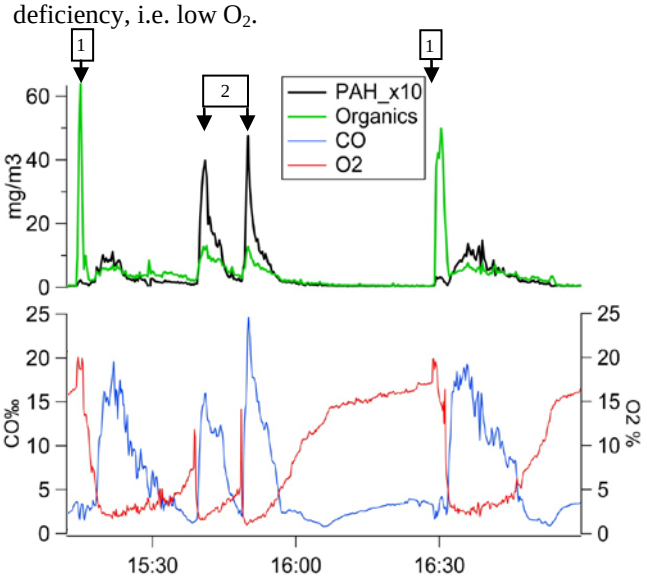

Figure 1. Time resolved total organics, PAHs, CO and O_2 during high load in the wood stove. "1" denotes addition of full batch on glowing embers. "2" denotes addition of 1/3 batch in flaming phase.

The results illustrate a combustion situation with a high burn rate under hot and air-starved combustion conditions, similar to gasification (Milne et al. 1998). Such high temperature fuel rich conditions lead to thermal cracking of primary released oxygenated pyrolysis products (e.g. levoglucosan and methoxy-phenols). At higher temperatures mostly aromatic compounds and soot are stable enough to survive resulting in elevated PAH emissions.

It is well known that poorly insulated stoves, bad mixing and humid fuels lead to high organic emissions. This work illustrates the potential deterioration of emission levels caused by too high burn rates and it shows the potential of using AMS as a tool for advanced emission studies in wood combustion.

Electrostatic precipitators for domestic wood stoves

H. Burtscher, A. Keller, M. Fierz

Institute for Aerosol and Sensor Technology, University of Applied Sciences Northwestern Switzerland, Windisch, CH-5210, Switzerland
Keywords: Wood Combustion, Emissions, Aftertreatment, Electrostatic precipitator.
Presenting author email: heinz.burtscher@fhnw.ch

Besides diesel engines wood combustion is a significant source of ultrafine particles in ambient air. Depending on region and season it may even be dominant. Whereas large utilities for wood combustion (heating plants, electric power stations) meanwhile usually are equipped with exhaust gas cleaning devices, small units are not and often have very high emissions. Besides trying to improve combustion, using filters is an option to reduce particulate emissions. As these units normally are not ventilated but work by convection the pressure drop of a filter for this application has to be very low. Only electrostatic precipitators (ESP) are possible.

Several filters came on the market recently. They are placed somewhere in the chimney, the chimney walls are used as precipitating electrodes. A wire in the centre of the chimney serves as corona electrode and creates the field used for precipitation. A typical configuration is shown in figure 1.

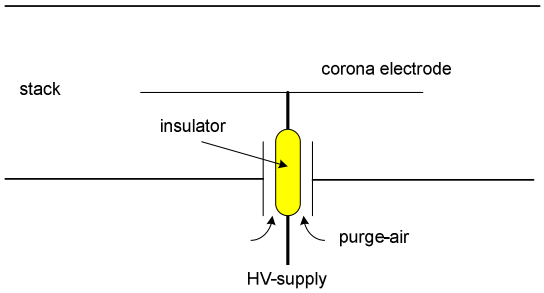

Figure 1. ESP in the stack of a wood stove. The insulator is protected from contamination by a purge air flow.

The length of the corona electrode typically is between 30 cm and 1.5 m. The filter may be located close to the stove or close to the top of the chimney. Some filters are too short to allow an efficient removal already in the vicinity of the corona electrode. A significant fraction of particles may be precipitated in the stack downstream the filter. This is possible because space charge plays an important role due to the specific geometry of these filters.

In Figure 2 the electric field due to the voltage, applied at the corona wire and due to space charge is plotted for the following conditions:
stack diameter: 20cm, corona wire: 0.5mm diameter,
Applied voltage: 20kV
Particle concentration: $10^7 cm^{-3}$, each particle carrying 2 elementary charges on average, no ions considered.

Assuming a turbulent flow only the field close to the wall of the stack is important for precipitation and this field is dominated by space charge for this case. Therefore the precipitation continues after the end of the corona electrode.

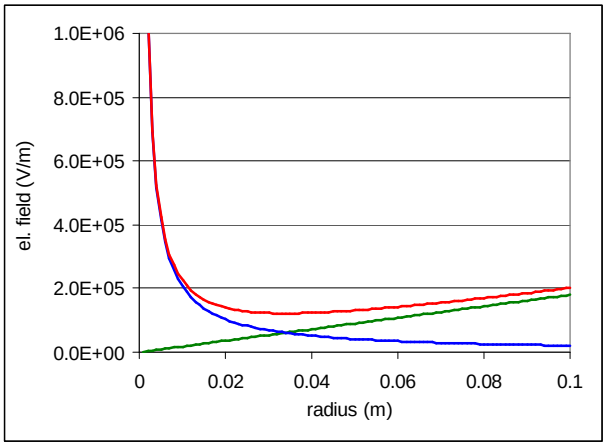

Figure 2. Electrical field due to corona voltage (blue) space charge (green) and total field (red).

Whereas this effect of space charge increases particle deposition in particular when the space charge is high due to high particle concentrations, another effect of space charge is less desirable: It reduces the field close to the corona wire and thus may quench the corona. This may lead to a complete failure of the filter at very high particle concentrations as they occur for example in the starting phase of the combustion. A drastic reduction of the corona current can be observed during this phase.

In a number of test measurements we observed filter efficiencies in the range from 50% up to more than 90%, depending on filter type and operating conditions. Filters close to the top of the chimney have the advantage that the flue gas is colder and thus the flow rate is smaller. The filters not only work for steel- but also for ceramic chimneys, but with reduced efficiency.

Care has to be taken when measuring the particle concentration downstream the filter, because particles often are highly charged (Meyer et al., 2009).

High temperature electrostatic precipitation for small scale biomass combustion

A. Bologa, H.-R. Paur and K. Woletz

Karlsruhe Institute of Technology, Institute for technical Chemistry,
Eggenstein-Leopodshafen, D-76344, Germany
Keywords: biomass combustion, fine particles, emission control, electrostatic precipitator
Presenting author email: andrei.bologa@kit.edu

The small-scale wood combustion is widely used for domestic heating, but it is responsible for emissions of fine particles which are composed of ash, elemental carbon and organic matter. By small scale biomass combustion, the particle chemical composition, particle size distribution, number and mass concentration vary greatly depending on mixing of air and fuel, combustion temperature, design of burning appliance, fuel quality etc.

Electrostatic precipitators (ESP) are effective equipment for reduction of particle emissions from small scale biomass combustion. The design of ESPs range from conventional to space charge, from dry to wet, from units integrated into the combustion appliance up to ESPs installed at the exit of a chimney. Most of the unit operates at temperatures below 200 °C, but there also are some developments of high temperature (HT) ESPs. But, in spite of presence of different data, the review of these developments is not still available, especially for HT units.

The first objective of the study is the overview of the approaches to the development of gas cleaning systems for small-scale wood combustion, especially electrostatic precipitators, and cross-section view through the operation conditions and parameters of the ESPs. The critical points are: gas temperature, stability of operation of the precipitator, collection efficiency, ESP design and applicability.

The second objective of the study is the discussion about the development and results of the tests of a novel high temperature electrostatic precipitator for small-scale biomass combustion. The space charge ESP consists of a corona discharge ionizer and a grounded collector installed downstream the ionizer without any plenum chamber. A brush grounded collector is used for precipitation of charged particles. The main points of the development relate to the design of high temperature ionizer; to particle precipitation mechanisms in the collector and to the position of the ESP in the gas duct.

The ESP was as installed in a thermo-isolated gas duct about 1,5 m downstream a wood-log stove with thermal power 8 kW. The stove was operated ca 5-6 hours per day with wood-logs rate ca. 2,5-3,0 kg/h. Particle mass concentration was measured according to the Guidelines VDI-2066 upstream and downstream the ESP. Particle number concentration in the gas flow was measured by Scanning Mobility Particle Sizer (Fa. Grimm) downstream the ESP when the precipitator was switched-off and switched-on.

The ESP mean input gas temperature was over 300°C achieving shortly maximum values of over 400°C. A DC negative corona discharge was used for particle charging in the ESP ionizer. The operation voltage varied from 10 kV to 14 kV and corona current from 0,4 mA to 1,6 mA depending on the combustion conditions in the stove.

The results of the tests show that the gas temperature influences on the operation stability of the electrostatic precipitator (voltage and corona current). For the same electrode geometry, the increase of the gas temperature decreases the spark-over voltage in the ionizer and results in the increase of the corona current at the same applied voltage.

The special design of the high voltage insulator excluded the spark-overs in the insulator housing and improved the operation stability of the ESP.

The design of the ESP and its position in the gas duct reduced the re-entrainment of collected aerosol into the clean gas flow and enhanced the collection efficiency of the unit by combined use of several mechanism of gas cleaning.

The ESP was in operation over 100 h. The mass collection efficiency of the ESP for stable combustion conditions was about 85% and for total combustion cycle it was 75±3 %. The middle fractional collection efficiency is 80-95% for particles smaller than 0,1 µm and over 95% for particles larger than 0,1 µm (see Figure 1).

Wood combustion emissions in Switzerland and associated impact assessments

Meyer, Nickolas K.[1], Heck, Thomas[1]
[1]Laboratory for Energy Systems Analysis, Paul Scherrer Institute, Switzerland
Keywords: wood combustion emissions, life cycle analysis, sustainability, external costs

Woody biomass combustion produces 5% of Swiss heating energy and 20 - 50 % of airborne, organic and particulate emissions during winter. Further, future energy scenarios suggest that wood consumption could sustainably increase by a factor of two [1], likely leading to increased emissions. On this basis, an inventory describing combustion emissions produced by 25 in-use residential, commercial, and industrial biomass combustion appliance classes was developed for Switzerland. This inventory is used to assess current and historical emissions, to identify those appliance classes contributing most to emissions, to assess future emissions based on sustainable scenarios and finally, to quantify external costs associated with wood combustion in Switzerland.

The inventory incorporates over 200 direct and indirect (life cycle) emission species. Of these species, particulate matter (PM), carbon monoxide (CO), particle bound black carbon (BC), particle bound organic matter (POM) and total organic carbon (TOC), nitrogen oxides (NO_x) and greenhouse gases form a set of core species [2,3]. PM data utilised in this inventory was size classified to represent, total particulate emissions (TPE), and particulate matter having diameters less than 10, 2.5 and 1 μm respectively (PM_{10}, $PM_{2.5}$ and PM_1).

Direct emission factors for core species were collected for average, high and low emission scenarios (based on appliance operating characteristics). Non-core species have so far been considered only for average operating cases. Using these emission factors, annual emissions were determined for each species (for the period 1990 – 2009, with a base year of 2009), and in some cases used to determine future emission scenarios. For the average current emission scenario, annual TPE was calculated to be 6520 tonnes. Analysis of the size dependency of TPE was made (Fig. 1), as was the size dependent contribution of BC and POM to PM (not shown).

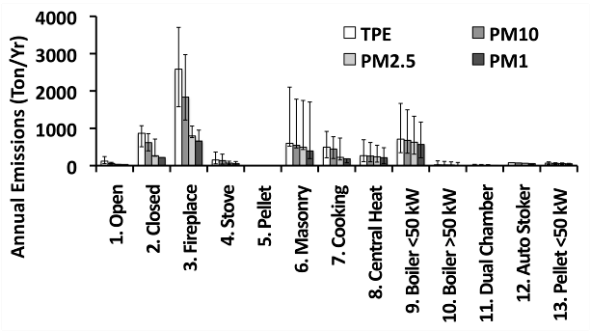

Fig. 1. Annual particulate matter emissions for 13 residential wood combustion appliances in Switzerland, 2009.

In addition to the emission inventory, direct and indirect global warming potentials (GWPs) were calculated for representative systems (Fig. 2). These preliminary GWP calculations highlight variances in potential climate impacts between biomass and fossil systems (particulates are excluded from prelim. GWP)

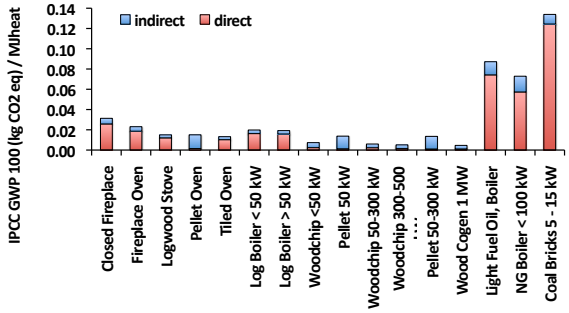

Fig. 2. Direct and indirect global warming potentials for selected combustion systems

As a method of valuing impacts associated with the combustion of wood, external costs methods were employed [3]. Using both direct and indirect emissions, estimates of external costs attributable to wood combustion in Switzerland were made. Further comparison with fossil fuel systems and wood combustion systems incorporating emission reduction devices were also made. Currently, cost estimates exclude aerosol induced climate effects - these should be included within the coming year. Estimates presented here show costs per MJ of useful heat for selected combustion systems (Fig. 3) [3]. Life cycle impact assessment results will be included as well.

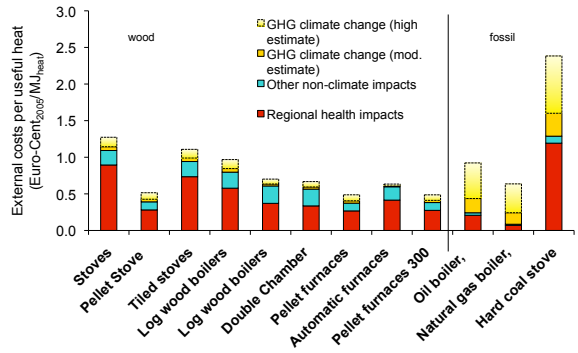

Fig 3. External costs per MJ useful heat for wood and fossil fuel systems in Switzerland.[3]

Session 9D: In-vitro toxicity and health effects of PM

The inflammatory response elicited in vitro by air pollutants is greater in synoviocytes from patients with Rheumatoid Arthritis than in those with osteoarthrosis

M. Galeazzi[1], F. Cetta[1], F. Laghi Pasini[1], E. Balistreri[1], E. Selvi[1], S. Benoni [1], V. Guercio[1], I. Santi[2], L. Cantarini[1] and E. Bolzacchini [3]

[2]Geriatric Institute "Pio Albergo Trivulzio" (PAT), Milan, 20146, Italy
[3]Dept. of Environmental Sciences, University of Milan, Milan, 20126, Italy
keyword: Rheumatoid Arthritis, osteoarthrosis, human fibroblast-like synoviocytes, IL-6
Presenting author email: galeazzi@unisi.it

Rheumatoid Arthritis (RA) is a disease in the occurrence of which autoimmunity plays a crucial role. Genetic factors are thought to be responsible for about 50% of RA risk, suggesting that environmental factors could contribute to the development of RA in the genetically predisposed. In particular, pollution from traffic in adulthood has been considered as a newly identified environment factor for RA.

Aim of the study: to assess the "in vitro" effects of variable concentration of various types of PM when incubated with human Fibroblast-like synoviocytes (FSC), to evaluate the occurrence of proinflammatory effects.

Methods: daily levels of PM10 and PM2.5 and PM1 (diameter < 10 μm, 2.5 μm, 1 μm, respectively) were measured by PM detection units, both outside and inside 2 schools for children and 2 nursing homes for retired people, either in summer and in winter time in Milan, Italy. Both OPC detectors and low volume gravimetric detectors were used. Samples from Teflon filters were used after sonication in sterile phosphate buffer saline (PBS). Aliquots of these samples at various concentration of PM10 (10 μg/ml, 50 μg/ml, 70 μg/ml) were incubated at 37°C for 24, 48, 72 hours with human type B synoviocytes obtained from 5 patients with RA, and 5 with osteoarthrosis (OA) during hip replacement surgery.

Results: -Engulfment of particulate material within synoviocytes was observed even at lower concentrations and after 24 h incubation; -the penetration of PM into the cell was associated with an increased cytokine production. In particular, there was a considerable increase of IL6 concentration, namely after incubation with winter PM, up to 9-folds the basal values, already after 24 h (867,36 vs 100) in FSC obtained from RA patients ($p<0,001$), whereas summer PM determined a significant increase of IL6 (637,39) only after incubation for 72 h (**Fig.1**). This effect was likely due to the greater content of PAH rich OC in winter PM. In addition, after incubation for 24 h of the same type and the same concentration (10 μg/cm2) of PM10, collected during Summer and Winter, with alveolar type cells (A549 cell line), i.e. cells from front-line respiratory district (**Fig 2b**), the previous increase of IL6 observed in subjects with RA (**Fig 2a**) was not found (**Fig2**).

	BASAL	PM10 S 10	PM10 S 50	PM10 S 70	PM10 W10	PM10 W 50	PM10 W 70
24 H	100	93,24	194,8	89,9	867,4	620,1	685,3
48 H	100	248,8	80,74	89,41	523,5	401,6	756,9
72 H	100	637,4	274,6	181,7	606	895,1	701,9

Figure 1. Concentration of IL-6 after incubation with various types of PM10 at various concentrations

Conclusion: The inflammatory response elicited by PM is greater in RA-FLS, than in OA-FLS. Even if affected tissues are distant from the initial site of exposure, they are likely to be part of the "pollution syndrome", i.e. of the health side-effects produced or facilitated by environmental pollutants. PM-related health effects seem to be not only determined by intrinsic toxicity of pollutants, mediated by oxidative stress, but are likely due to more complex responses, namely those typical of autoinflammatory and/or autoimmune diseases, which occur only or mainly in predisposed subjects. In particular, if autoimmunity is crucial for RA occurrence and RA is part of the "pollution related syndrome", even low local concentration of PM could be sufficient to trigger pathological events in predisposed individuals.

Keywords: Biotests, Cytotoxicity, Genotoxicity, Estrogenicity.
Presenting author email: Iris.Gutierrez@tuhh.de

Burning of wood for heating purposes has become extremely popular wordwide due to the increasing costs of fossil fuels. In Germany 25% of the private households use wood logs, pellets, briquettes or woodchips for firing (Fachagentur Nachwachsende Rohstoffe, 2010). Claimed as renewable energy source, wood has often been ignored as a source for fine particles. Especially small fireplaces, not meeting the latest standards, produce supposable harmful fine dust. Rapid reproducible and validated biotests for toxicological characterisation of particles exist neither for cells nor for microorganisms. Thus there is a need for established microscale toxicity screening of unknown particulate samples.

Hence a test battery consisting of two ISO standardised bacterial contact assays and one yeast biotest were modified for the use with fine dust. Having different endpoints these tests provide a toxicological "fingerprint". In order to account for bioavailability of contaminants adsorbed on surfaces of fine particles, such were used as a whole not as extracts.

Table 1. Origin of fine particles.

Sample number	Type of winning	Wooden fuel	Fire place
# 1	Electrostatic precipitator	Briquette/ split logs	Stove 9 kW
# 4	Electrostatic precipitator	Pellets	Pellet boiler 15 kW

Particulate matter was gained electrostatically from different furnaces in the flue gas channel (Table 1). Suspended in water, vortexted for 1 min, and ultrasonificated for 15 min samples were applied in a concentration range of 0.001 – 10 mg/mL. Particle sizes (< 1 µm) in these suspensions were measured by dynamic light scattering. Minusil 5, crystalline quartz sand (1 mg/mL), proven to be non-toxic in bacteria and yeast, served as control.

Cytotoxicity in the aerobic *Arthrobacter globiformis* contact assay was determined via dehydrogenase activity (DHA). Genotoxicity was determined via Umu test using a genetically modified *Salmonella* strain. The YES test was employed to determine potential estrogenicity of particle samples.

Sample # 1 caused a sigmoid dose response curve in both the bacterial contact assay and the YES test (Figure 1, Figure 2). No genotoxic effect was observed in the Umu test for sample # 1. Activation by S9-media is most likely necessary for this test, especially as the active ingredients of sample # 1 appear to be PAHs. The latter would also explain interaction with the YES assay, as PAHs (e.g.) are known to interact with the estrogen receptor. Although sample # 4 also triggered a sigmoid dose response curves, the toxicity profile was different (data not shown). These preliminary results suggest suitability of endpoints determined in the modified tests for risk assessment of fine particles.

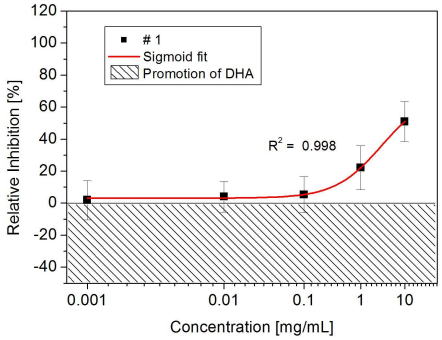

Figure 1. Relative Inhibition of sample # 1 in the bacterial contact test. DHA: Dehydrogenase activity.

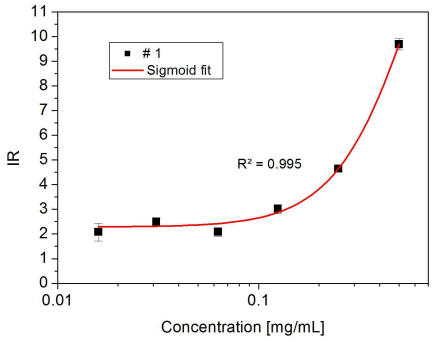

Figure 2. Induction ratio (IR) of sample # 1 in YES test.

Particulate air pollution is one of the most harmful environmental exposures causing mortality and hospitalizations of cardio-respiratory patients worldwide. There is growing demand on increasing the proportion of the renewable energy sources from the total energy consumption. Biomass combustion is one of the main options in this increment. However, it potentially increases the levels of air pollutants that may cause substantial adverse health effects. Recent data have shown that the combustion technology, user practice and fuel type/quality affect the emissions from small scale heating appliances. However, their impact on the toxicological properties of the emissions is poorly known. Moreover, it is unclear what the causative components behind the adverse health effects of the particulate emissions are.

We investigated seven new and old technology heating appliances commonly used in central Europe for the physicochemical and toxicological properties of the emitted particulate matter. The studied appliances included new and old technology log wood boilers and stoves as well as pellet boiler, woodchip boiler and tiled stove, all representing new technology. The three new technology boilers had state-of-the-art technology with air staging and lambda controlled automatic operation.

Particulate samples (D_p <1µm) for both toxicological and chemical characterization (PAHs, water-soluble ions, elements) were collected with Dekati ® gravimetric impactor. Mouse macrophage cell line RAW 264.7 was exposed to four doses of the particulate samples from each appliance for 24h. Inflammatory parameters, proinflammatory cytokine TNFα and chemokine MIP-2 were analyzed with ELISA immunoassay. Cytotoxicity was analyzed with MTT assay and flow cytometric methods detecting both cell cycle and cell membrane permeability of the macrophages. In addition, genotoxicity was determined with comet assay detecting DNA strand breaks in single cell gel electrophoresis.

Most of the PM samples from the studied appliances caused dose dependent increase in at least some of the toxicological parameters.

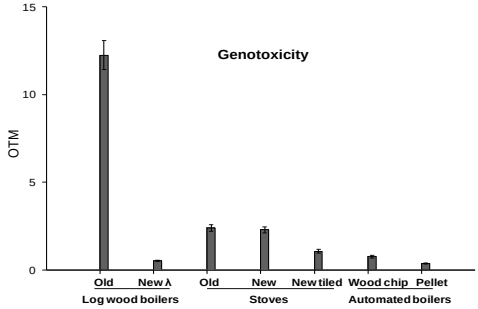

Fig 1. Genotoxicity by the particulate samples (150µg/ml) of each studied appliance. (OTM =Olive tail moment [(tail mean−head mean)×tail%DNA/100].

In general, the inflammatory responses caused by the emission particulate samples were relatively small. There were, however, large differences in the magnitude of the toxic responses between the appliances. Old technology appliances with incomplete combustion were more potent inducers of genotoxic and cytotoxic responses than the respective new technology appliances with more complete combustion. The old technology log wood boiler seemed to cause emissions with the largest toxicological potential and the pellet boiler derived particulate samples were the least potent. The old technology appliances had larger emissions than the new technology appliances, which emphasizes the differences. Moreover, emissions from old technology appliances, especially log wood boiler, had very large PAH concentrations, whereas with the new technology continuous combustion appliances the emissions consisted mostly of the ash compounds. Overall, the present data showed clearly that the combustion technology affects the toxicological responses of RWC emissions that can be reduced with technological development.

Responses of lung cell cultures after realistic exposure to primary and secondary carbonaceous aerosols

The interaction of particles with the inner surface of the lungs, the main pathway of undesired particle uptake, is still poorly understood (Geiser and Kreyling, 2010). Commonly used model systems for in vitro studies deviate significantly from the situation in vivo such that responses possibly are not representative of those induced by the particles in vivo.

To contribute to the closure of this information gap we examined the responses of lung cell cultures to primary and secondary organic aerosols (POA and SOA) originating from diesel exhaust and wood combustion processed and aged in a large-scale smog chamber under conditions replicating the in vivo situation. The particles were applied to the cell cultures under realistic ambient air and physiological conditions in a novel particle deposition chamber (Savi *et al*, 2008). The cell cultures, representing the inner surface of airways and alveoli, were microdissected epithelia from pig tracheae and re-differentiated human airway epithelia both with established air liquid interface (ALI), porcine lung surface macrophages, the human bronchial epithelial cell line BEAS-2B, as well as the rat alveolar epithelial cell line R3/1. Cells were cultured on microporous filter inserts and exposed to the aerosol at ALI conditions for 1.5 hours (POA) and 2 hours (SOA), respectively. Control cell cultures were (i) exposed to particle-free air or (ii) left untreated in the incubator. Cellular responses were measured within 24 hours after exposure to the aerosol. Biological endpoint measurements included cytotoxicity, cell and tissue integrity, phagocytic activity of macrophages, release of inflammatory mediators such as interleukin-6 (IL-6), IL-8, IL-10, tumor necrosis factor alpha (TNF-α) and monocyte chemotactic protein-1 (MCP-1).

The results demonstrate that a single, short-term exposure of the various lung cell types to the aerosols at ambient-air concentrations of about 10^4 particles/cm^3 leads to only moderate cellular responses. However, there is evidence for i) different effects of POA and SOA and for ii) different effects of aerosols originating from diesel exhaust and wood combustion. Our data indicate that a short time exposure to realistic aerosol concentrations does not induce changes in cell and tissue integrity, but leads to subtle changes in cellular functions that are essential for lung homoeostasis. We found slightly increased cytotoxicity for the various cell cultures after exposure to SOA. In comparison to POA, the phagocytic activity of porcine macrophages was found to be decreased after exposure to SOA from wood burning, whereas it was increased after exposure to SOA from diesel exhaust (Fig. 1).

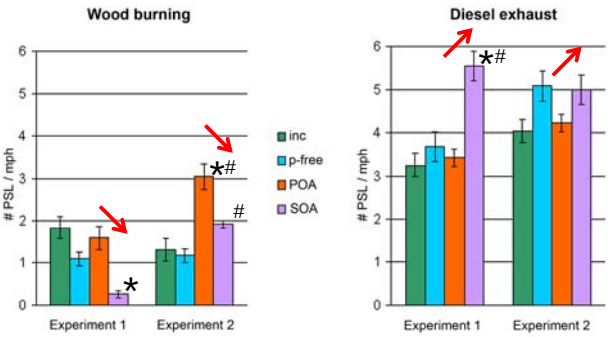

Figure 1. Clearance function of macrophages measured by the number of PSL particles associated per cell.
Means and SEM; $p < 0.05$ to *untreated cells (inc) and #cells exposed to particle-free air (p-free); n = 100 cells.
→ response to SOA compared to that after exposure to POA; SOA still contains some POA (~ 25% for diesel and ~ 30% for wood burning).

The analysis of the inflammatory mediators showed a general trend to increased release after the exposure to SOA; this effect was more pronounced for the diesel exhaust particles. This result is in line with our findings for the cytotoxicity.

In conclusion, our study shows that a single, short-time exposure to ambient concentrations of carbonaceous aerosols does not result in major cytotoxicity or release of inflammatory mediators. However, there are clear indications for subtle changes in cellular functions that are essential for lung homoeostasis, especially after the exposure to SOA from diesel exhaust.

General and PAH-mediated cytotoxicity in particulate matter from wood combustion

Due to ongoing discussions about risks for human health and European threshold values particulate matter emissions have gained in importance. The increasing use of renewable energy sources, such as wood, goes along with a higher burden of particulate matter, which has the potential to induce respiratory tract diseases in humans (Naeher, 2007; Pope, 2002). This study focuses on the toxicological characterization of particulate matter emerging from small scale wood combustion furnaces, investigating the direct cytotoxic effects as well as effects mediated by known carcinogenic compounds part of or adhering to the PMs, e.g. Polycyclic Aromatic Hydrocarbons (PAHs).

The physicochemical characteristics of PMs are assumed to be responsible for the direct (mechanical) toxicity of these dusts. In contrast PAH mediated toxicity is dependent on the bioavailability of PAHs for the cells exposed as well as their respective metabolic capacity for converting PAHS into high reactive intermediates. At present, potential PM toxicity assessment is based exclusively on PAH chemical analysis. The latter appears critical, as not all PAHs may be directly available to cells. Therefore additional *in vitro* assays as well as mechanistic studies are needed. Moreover addtl. pathways of action, beside xenobiotic metabolism and macromolecule interaction, e.g. membrane and nuclear receptor binding and activation, need to be taken into consideration. Indeed, the PAHs due to structural similarities with steroids, binding to the ligand binding domain of human steroid receptors is likely (Van Lipzig, 2004), thereby suggesting the potential activation of steroid receptor signal transduction pathways.

The 16 US EPA PAHs were quantified, via accelerated solvent extraction and adjacent GC-MS, in five particulate matter samples obtained from combustion events with variable conditions (e.g. complete and incomplete combustion). Cytotoxicity assays were performed in two model cell lines (A-549: human type II alveolar epithelial cells, THP-1: human monocytic cells, differentiated to macrophages), using for different PM concentrations and time points. A specific *in vitro* PAH transactivation assay (CALUX) was performed in order to investigate PAH bioavailability to the cells. Therefore, concentration-response curves were established with PM samples and with their respective organic extracts. To investigate possible steroid receptor binding and activation, specific androgen and estrogen receptor transactivation assays (PALM, MELN) are presently carried out (Balaguer, 1999; Freyberger, 2010).

No acute cytotoxicity was observed for PM samples, except for very high concentrations. The corresponding PAH transactivation assay (CALUX) demonstrated that some of the PAHs within the PM samples were bioavailable to the cells and provided for a good signal correlation between CALUX analyses and PAH chemical quantification. Indeed, the sample with the lowest concentration of PAHs revealed also the lowest response in the luminogenic signal, compared to samples with higher PAH amounts (Figure 1). However the signal intensity in the CALUX assay suggested a toxicity potential of individual or combinations of PAHs in the PM samples several fold above that indicated by mere PAH chemical quantification.

A Thermal Precipitator for Nanoparticle Cytotoxicity Screening

Dirk Broßell[1], Sabine Plitzko[1], Nico Dziurowitz[1], Erhardt Gierke[1], Volker Bachmann[1], Gunter Linsel[1], Nkwenti Azong-Wara[2], Christof Asbach[2], Heinz Fissan[2], Andreas Schmidt-Ott[3]

In vitro toxicity studies are becoming much more important due to increasing concerns about animal welfare and partly also due to higher costs of *in vivo* studies. We introduce a new device for *in vitro* cell exposure to nanoparticles for cytotoxicity screenings. The system is an attempt to solve one problem most *in vitro* toxicity studies encounter when trying to mimic *in vivo* inhalation studies, namely the lack of representativeness of the exposure to the particles (Teeguarden, 2007) and hence the resulting dose and dose rate. It is conceptualized as a toxicity screening device primarily indicating cytotoxic effects on the human respiratory tract.

The so called Cyto-TP is a thermal precipitator (TP) (Azong-Wara, 2009) for the deposition of airborne nanoparticles on living human epithelial lung cells at the air-liquid interface (ALI). The cellular response to ALI exposure seems to be similar to suspension exposure but occurs at doses significantly lower (Holder, 2008). Cellular response at ALI may be observable at exposure atmospheres with moderate particle number concentrations. The TP deposits particles very smoothly onto the cell surface and therefore does not damage the cells by impact. By using airborne particle exposure the surface chemistry, morphology and size of the nanoparticles do no change in contrast to the use of suspension exposure. Unlike in a similar concept using electrophoresis for particle deposition (Sillanpää, 2008), particles bear their natural charge level. These aspects contribute greatly to a higher representativeness of exposure mode.

The Cyto-TP consists of a hot plate (52°C) and a parallel cold plate (37°C) which hosts the cell cultures as shown in Fig. 1. The aerosol flows between the two plates and particles are deposited onto the cells by thermophoresis. Potential cell stress due to secondary effects is minimized with our device, so cellular response can be related more easily to the presence of nanoparticles in the exposure atmosphere. After exposure the cells can be placed inside a scanning electron microscope for analysis. Additionally CASY cell counting and analysing used to determine the ratio of living and dead cells.

The presentation will describe the first prototype of the Cyto-TP and its design and functionality along with a newly designed experimental approach for cytotoxicity screening. First results of the validation of the Cyto-TP approach with nanoparticles will be presented.

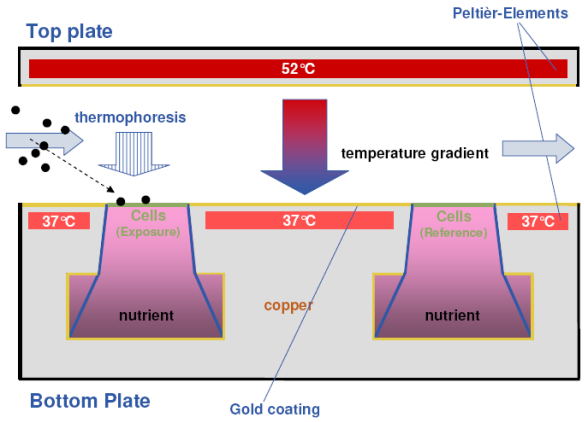

Figure 1. This is a concept sketch of the functionality of the Cyto-TP. The nanoparticles in a laminar flow are deposited onto the cells placed at the cold plate.

Session 9E: Aerosol-based Nanotechnology: Methods and Applications

From Embedded to Supported Metal/Oxide Nanomaterials: Thermal Behavior and Structural Evolution at Elevated Temperatures

S.B. Bubenhofer, W.J. Stark and R.N. Grass

Institute for Chemical and Bioengineering, ETH Zurich, Zurich, 8093, Switzerland
Keywords: flame spray pyrolysis, composite nanoparticles, particle formation and growth, modelling.
Presenting author email: s.bubenhofer@chem.ethz.ch

The relation between structure and function is of major importance at material interfaces which often excel in terms of chemical or physical effects. Therefore, multi-phase nanocomposites (e.g. core-shell, janus-shaped and carrier-supported noble metal nanoparticles) attract attention due to their possibility to contact two materials at the nanometer scale profiting from their highly increased interaction area (Kamat (2007)).

Especially at metal/oxide interfaces, accounting for a majority of heterogeneous catalysts, the structure-function relationship has been studied intensively. High temperature, dry aerosol processes (flame synthesis) are common for building such composites (Strobel and Pratsinis (2009)). But the formation of the key structural elements in such multi-component systems, depending on coagulation-order and solid-solid diffusion, is not fully understood yet (Rotzetter *et al* (2010)).

We therefore present a systematic material study on the morphological transition from metal embedded in oxide to metal supported on oxide nanocomposites with the model compound Pd/SiO_2 (Bubenhofer *et al* (2011)). Crystalline Pd encapsulated in silica nanoparticles are produced in a single step flame spray pyrolysis process. Nanometer scale transformation of this material to nanocrystalline Pd dispersed on the amorphous silica matrix was achieved by heating to elevated temperatures.

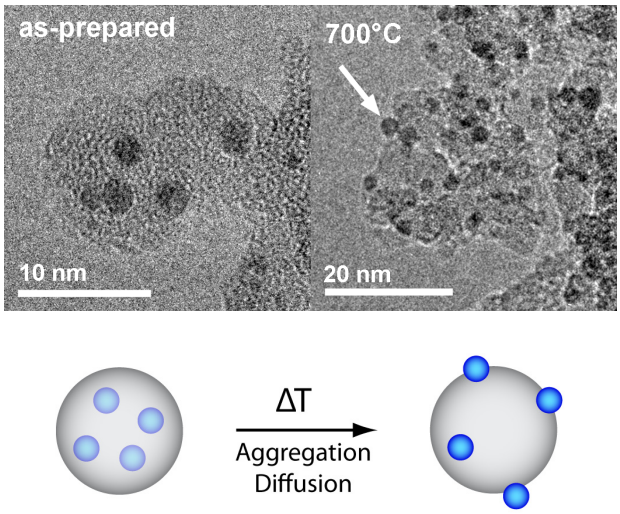

Figure 1. Morphological transformation of noble metal encapsulated in oxide nanoparticles to supported on oxide particles (2 vol% Pd with SiO_2 matrix).

A physical model based on Pd cluster diffusion and aggregation within silica spheres was derived to describe the transformation process, which gives an understanding of the influence of temperature, matrix viscosity, particle sizes and concentrations on this morphological transformation

The data is discussed in terms of aerosol formation mechanisms (consecutive vs. simultaneous coagulation) and compared to literature data on the high-temperature aerosol formation (Jensen *et al* (2000), Strobel and Pratsinis (2009)) of nanocomposites.

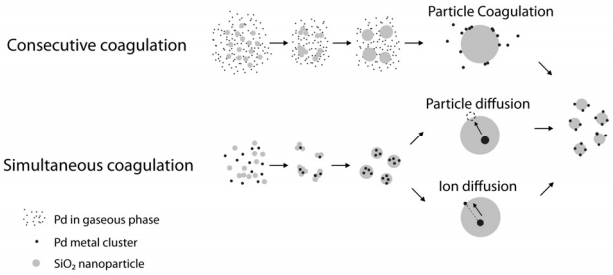

Figure 2. Possible 2-component nanocomposite formation mechanisms in flame spray synthesis.

Valuating the model and the discussed mechanism by tuning a parameter in the aerosol formation process, clearly shows, that the findings enable morphology predictions (core-shell vs. supported metal/silica particles) both in nanocomposite formation processes at elevated temperature (flame spray synthesis) and also during thermal evolution of multi-phase nanomaterials, determining their performance in e.g. catalysis or fuel cells.

Scaling of an aerodynamic lens for use in coating technology

D. Kiesler[1], T. Bastuck[1], F.E. Kruis[1] and M. Kennedy[2]

[1]Institute for Technology of Nanostructures and Center for Nanointegration Duisburg-Essen (CeNIDE), University Duisburg-Essen, Duisburg, 47057, Germany
[2]Federal-Mogul Burscheid GmbH, Burscheid, 51399, Germany
Keywords: aerodynamic focusing, coatings, deposition, inertial impaction.
Presenting author email: dennis.kiesler@uni-due.de

The embedding of nanoparticles in coatings produced by Physical Vapour Deposition (PVD) is complicated due to the fact that typical coating conditions employ high-vacuum (HV) conditions whereas the production of nanoparticles necessitates quasi-atmospheric conditions. This requires the separation of both processes and thus a transfer of the particles produced in a HV environment. An efficient tool to this purpose is aerodynamic focusing (Liu, 1995) which increases the particle concentration on the center of the flow and thereby reduces the particle losses upon the transfer in the HV. Existing aerodynamic lenses are however not designed to apply the higher flow rates characteristic for particle synthesis. The purpose of this work is to design, optimise and experimentally verify a high-flow rate aerodynamic lens system.

Using the aerodynamic lens calculator (Wang, 2005; Wang, 2006), a design was sought for allowing to focus 30-80 nm TiC nanoparticles in 5 slm argon, which is a factor 50 above the conventional flow rates in aerodynamic lenses. It was found that in the optimal lens configuration the required pumping capacity scales unfavourably with the inlet flow rate (Table 1). Due to this scaling a concept with multiple lenses is favoured.

Table 1. Comparison of aerodynamic lens systems with different flow rates.

Inlet Flow rate Q (slm)	**Pressure needed in Skimmer (Pa)**	**System lengh (m)**	**Min. pumping capacity (m^3/h)**
0.5	100	0.81	31.2
1.5	33	2.45	283.7
4.5	11	7.31	2533.7
Scaling with Q	**~ Q^{-1}**	**~ Q**	**~Q^2**

First a single aerodynamic lens for 0.5 slm Ar with 3 orifices was designed, built and optimized. While the aerodynamic lens calculator was a good starting point, further optimization especially for the last nozzle and the skimmer was needed. Figure 1 shows the simulated trajectories of 50nm Ti particles in the simple and in the the optimized nozzle. The simulations were done in Fluent™ 6.2. Due to small particle sizes and large pressure differences ranging from 10^5 to 10^0 Pa a user defined function calculating the local slip-correction-factor for the particle drag force and the Brownian random movement was developed.

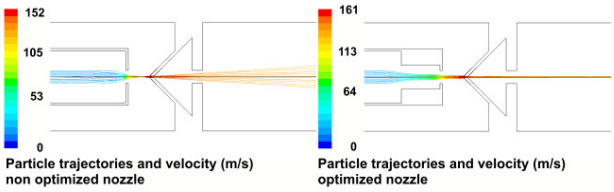

Figure 1. Simulation results for 50nm Ti particles in an non optimized acceleration nozzle (left) and optimized one (right). A tight particle beam can be formed

Pressure measurements allowed a good comparison between the lens designer, the CFD simulation and the experiment. In the experiment, TiC particles from an Mini-Arc-Reactor were used. Different skimmer-nozzle configurations and sample positions were tested (Figure 2). The particles could be deposited by inertial impaction even 500 mm after the skimmer having a spot diameter less than 20mm. The particle deposition efficiency was analyzed by gravimetric measurements. It could be shown, that under optimal conditions 70% of the particles entering the system were deposited on the Sample. The flow into the vacuum chamber was reduced from 0.6 slm at the lens entrance to 1.5 sccm. This means, that the particle concentration on the beam axis could be increased by a factor of 400.

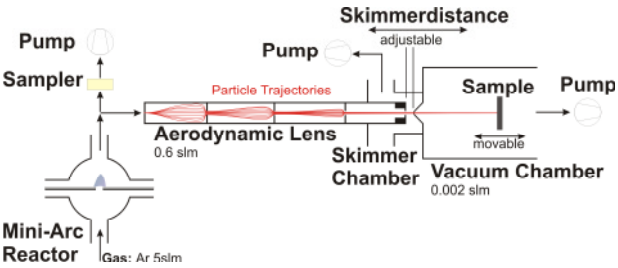

Figure 2. Schematic representation of the experimental setup.

This work was supported by the Deutsche Forschungsgemeinschaft in the framework of the collaborative research program “Nanoparticles from the gas phase” (SFB 445).

Use of aerosol-derived nanoparticles for the fabrication of polymer ultrafiltration membranes

Christoph R. Kellenberger, Norman A. Luechinger and Wendelin J. Stark

Department of Chemistry and Applied Biosciences, Swiss Federal Institute of Technology (ETH Zurich), Wolfgang-Pauli-Str. 10, HCI E 107, ETH Hönggerberg, Zurich 8093, Switzerland

Keywords: soluble nanoparticles, carbonate nanoparticles, polymer filtration membranes, polymer composite, ultrafiltration

Presenting author email: christoph.kellenberger@chem.ethz.ch

Polymeric ultrafiltation membranes are playing an important role in mass separation processes in many industrial sectors such as the chemical and biopharmaceutical industry and the water treatment and recovery industry. Commercial ultrafiltration membranes are nowadays produced by a technique called phase inversion. Therefore, a phase separation has to be induced in a previously homogeneous polymer solution by precise control of temperature, time and solvent to non-solvent ratio. This process unfortunately is limited by the number of parameters that have to be controlled simultaneously during production and by the broad pore size distribution that decreases the selectivity of the resulting membrane (Peinemann, Nunes, 2008).

We present a novel approach towards the production of ultrafiltration polymer membranes which are fabricated by a facile and fast procedure. This process is based on the use of soluble (degradable) carbonate nanoparticles (Huber 2005; Loher 2005; Grass 2005). The nanoparticles act as the pore template and the process can be applied on numerous polymers. Membranes can be fabricated by a simple two-step procedure. Basically, a polymer solution (polymer dissolved in a solvent) containing dispersed soluble nanoparticles is used as a starting material. This solution is roll-coated on a substrate (e.g. glass) and after evaporation of the solvent a solid polymer film (with incorporated soluble nanoparticles) is obtained. In a second step the polymer membrane is turned porous by simple dissolution of the soluble nanoparticle template in a mild acid. The pore formation of the resulting membrane is different to state-of-the art techniques. Here, the pore size and number of pores is exactly defined by the size and number of nanoparticles, as they serve as a direct template of the finally obtained pores. Therefore, the pore formation is very reliable yielding a narrow pore size distribution that guarantees the high selectivity of the membrane. Additionally, the soluble nanoparticle template dissolution in a mild acid is very fast (< 10s) which can be run at ambient conditions without the need for precise and simultaneous control of various process parameters.

The use of $CaCO_3$ nanoparticles (50nm in size) in a polyethersulfone (PES) or polysulfone (PSU) matrix led to the formation of a polymer membrane with a molecular weight cut-off (MWCO) of 1400kDa, whereas the use of $SrCO_3$ nanoparticles (17nm in size) in a PES matrix led to a MWCO of 150kDa. This demonstrates that the pore size of the filtration membranes can directly be tuned by the nanoparticle size. The MWCO of the according membranes was examined using a dextran rejection profile test that is widely accepted among membrane manufacturers (Tkacik, Michaels, 1991).

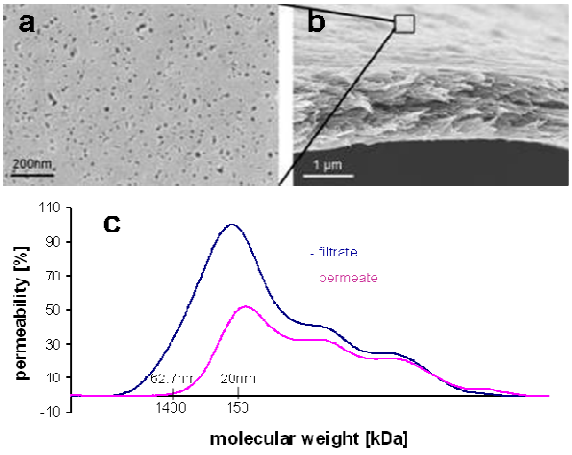

Figure 1: Top view on PES membrane with a MWCO of 150kDa (a). Cross section of the same membrane (b). Typical dextran rejection profile of a 1400kDa MWCO membrane (c).

A new measurement technique for the process monitoring of the catalytic activity of nanoparticles during their production process

N. Neubauer, M. Seipenbusch and G. Kasper

Institute for Mechanical Process Engineering and Mechanics,
Karlsruhe Institute of Technology (KIT), 76131, Karlsruhe, Germany
Keywords: process monitoring, online measurement, catalytic activity, palladium nanoparticles.
Presenting author email: nicole.neubauer@kit.edu

Introduction

For process monitoring and quality assurance integrated gas phase processes require online methods for the determination of the catalytic behaviour of the produced catalyst nanoparticles. In addition, an online technique capable of a substance-specific detection of catalytically active nanoparticles against a background of particles in workplace air is also still needed (Kuhlbusch *et al.*, 2009; Murashov *et al.*, 2009). For very active nanoparticles, such as platinum or nickel, the method of aerosol catalysis enables an online measurement of the catalytic activity of the particles (Weber *et al.*, 1999; Seipenbusch *et al.,* 2001). Less catalytically active nanoparticles, e.g. iron oxide, require an accumulation of nanoparticle material prior to catalytic investigations (Neubauer *et al.,* 2011). Therefore we studied a new measurement technique combining particle sampling on a substrate and the catalytic reaction into one instrument. In the following work the method capable of detecting the catalytic activity of nanoparticles and the achieved results are demonstrated.

Experimental

Catalytically active palladium nanoparticles generated by spark discharge were used as catalysts. The hydrogenation of ethene was chosen as a suitable catalytic test reaction which already runs at ambient air temperature.

In a first step the palladium particles are deposited on a substrate using either filtration or an impaction based process. After the particle deposition over a fixed time interval on a glass fiber filter or a glass impaction plate, the aerosol flow is cut. Both substrates can be heated so that – if the chosen catalytic reaction requires it - the temperature can be increased.

In a second step the deposited palladium particles are exposed over a defined time to the gaseous educts ethene and hydrogen (each 3.0, 50 vol-%) so that the catalytic reaction is initiated. The conversion of ethene to the gaseous reaction product ethane is detected by infrared spectroscopy (Bruker Vector 22).

Results

The concentration of the converted ethene was related to the mass of the accumulated palladium nanoparticles which was determined by gravimetry. For both deposition processes observation gives that the concentration of the converted ethene increases proportionally to the mass of the used palladium nanoparticles (cf. Figure 1 for deposition by filtration).

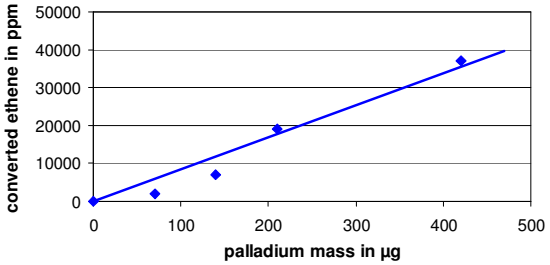

Figure 1. Calibration curve for the concentration of converted ethene vs. the mass of palladium nanoparticles deposited by filtration.

A lower detection limit of 120 ng can be extrapolated based on the curve linearity and assuming a measurement limit of 10 ppm of the ethene decrease by infrared spectroscopy. At aerosol concentrations of 1 mg/m^3 and a flow rate of 1 l/min a sampling time of only 8 seconds is sufficient to deposit a mass of 120 ng of palladium particles.

Conclusion

Small amounts of a palladium aerosol can be very rapidly detected on the basis of their catalytic activity. According to the estimated sensitivity of the used technique in the range of nanograms as well as the required sampling time, the technique can be considered a true real-time method for the specific determination of palladium nanoparticles.

Biological labels are used in bio-imaging and the ability to tag cells and biomolecules facilitates diagnosis and therapy. Even though organic dyes are used for such applications, their photobleaching inhibits their further employment. Quantum dots do not exhibit photobleaching and their emission color can be tuned by their size, however, their optical blinking and the high toxicity of their components restrict their use in bio-applications. An alternative strategy for such biolabeling applications are plasmonic nanoparticles. These particles can be detected under dark-field microscopy.

Hybrid magnetic/plasmonic nanoparticles possess properties originating from each individual material. Such properties are beneficial for biological applications including bio-imaging, targeted drug delivery, *in vivo* diagnosis and therapy. Limitations regarding their stability and toxicity, however, challenge their safe use[1]. Here, the one-step flame synthesis of composite SiO_2-coated Ag/Fe_2O_3 nanoparticles is demonstrated (Figure 1). The hermetic SiO_2 coating[2] does not influence the morphology, the superparamagnetic properties of the iron oxide particles and the plasmonic optical properties of the silver particles. It does prevent, however, the release of toxic Ag^+ ions from the nanosilver surface[3] and reduces the interaction field among the iron oxide particles, resulting in a stable over 2 days suspensions with no signs of agglomeration (flocculation) and sedimentation[4]. The feasibility of these multi-component nanoparticles with superior properties and performance is explored by their specific binding with live tagged cells, and the detection as well as magnetic manipulation of the latter is demonstrated. Therefore, the hybrid SiO_2-coated Ag/Fe_2O_3 nanoparticles do not exhibit the limiting physical properties of each individual component, while retain all the desired ones, facilitating their safe employment in such bio-applications.

Figure 1 shows a TEM image of the composite Ag/Fe_2O_3 SiO_2-coated nanoparticles. The silver nanoparticle (dark particle) is attached on the iron oxide core, and encapsulated by a nanothin silica layer of about 2 nm thickness.

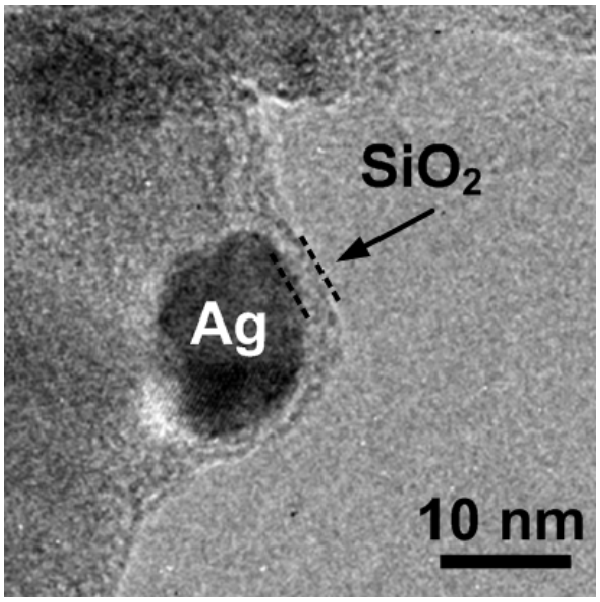

Figure 1. TEM image of the composite Ag/Fe_2O_3 SiO_2-coated nanoparticles. The silver nanoparticle (dark particle) is attached on the iron oxide core, and encapsulated by a nanothin silica layer of about 2 nm thickness.

Since carbon nanotubes(CNT) were introduced as gas sensors(Kong et al., 2000), many researchers have studied CNT-related gas sensors actively. It is known that bare CNT-based gas sensors are insensitive to CO and H_2(Kong et al., 2001) but sensitive to NO_2 and NH_3(Kong et al., 2000) at room temperature. Room temperature sensing can have the significant meaning in terms of lowering the consumption of electric power, simplifying the structure of sensor devices and being easy to fabricate a sensor device. To lower the working temperature down to room temperature, catalysts such as Pd and Pt are utilized with CNT to get a surface reaction with target molecules and a remarkable change of conductivity.

Here, we report on a crystalline shell-shaped carbon nanoparticle(SCNP) based gas sensor detecting CO and H_2 at room temperature without catalysts and even in an inert atmosphere. We utilized the crystalline SCNPs synthesized through continuous wave CO_2 laser irradiation on acetylene flow(Pikhitsa et al., 2005) without catalysts and patterned them by ion-induced focusing method into sensor devices.(Kim et al.,2006)

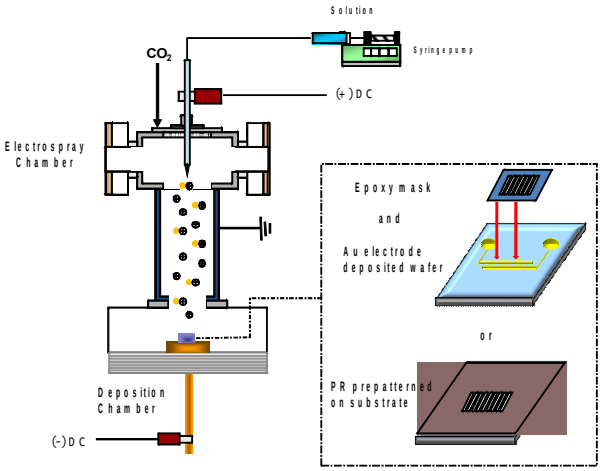

Figure 1. Schematic diagram of sensor fabrication setup

Ion-induced focusing approach was realized by electro-hydrodynamic atomization method, which needs charged aerosol form of SCNPs as can be seen in figure 1. To obtain charged SCNPs, well-dispersed solution of particles should be prepared. As-synthesized SCNPs have a hydrophobic nature, chemical treatment of SCNPs with nitric and sulfuric acid at 110° C was conducted.(Pikhitsa et al., 2005) Acid treatment can make the surface of SCNPs hydrophilic by attaching functional groups such as carboxylic and hydroxyl groups; it can separate SCNPs from each other and thus maintain the SCNPs to be well-dispersed in ethyl alcohol. Then, SCNPs were patterned on the substrates by ion-induced focusing method and the nanoparticle focusing mask.(Kim et al, 2006 and You et al, 2010)

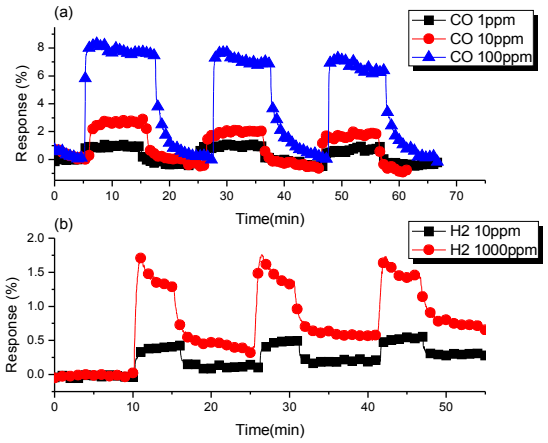

Figure 2. Gas sensor response for CO and H_2 gas

Figure 2 shows the gas sensor response for CO 1~100ppm and H_2 10~1000ppm measured at room temperature. In our preliminary study, the pristine SCNP based gas sensor shows insensitivity to CO and H_2 at room temperature. But chemical treatment can make the carbon sensor work at room temperature even at low concentration of CO and H_2 gas.

Session 9F: Charged Aerosols

Electrostatic controlled coating of particle surfaces with nanoparticles

S. Sigmund, M. Yu, J. Meyer, M. Seipenbusch, M. Wild and G. Kasper

Institut für Mechanische Verfahrenstechnik und Mechanik, Karlsruhe Institute of Technology, 76131 Karlsruhe, Germany

Keywords: Nanoparticles, charged particles, electrostatic particle coating

The process of electrostatic controlled coating of particles surfaces with nanoparticles has been investigated as a new, versatile process.

Because of their specific characteristics compared to bulk materials, nanoparticles obtain more and more attention in the field of particle technology, especially particles in size range below 10 nm. To take advantage of those characteristics, such as high catalytic or magnetic activity, isolated, un-agglomerated nanoparticles are required. To keep nanoparticles from agglomeration and to avoid high diffusional loss, one can generate a support particle coated with nanoparticles. Thus particle dynamics and powder flow properties are governed by support particle properties and that leads to a simplification in systems handling.

The process of surface coating is in our case an electrostatic controlled process. Support and coating particles are generated separately and charged oppositely before mixing for selective agglomeration. This method of electrostatic coating provides an alternative process route to other well known coating mechanisms, e.g. chemical vapour deposition. The electrostatic surface coating has several advantages: According to Zebel (1959) the bipolar coagulation between the positive support particles and the negative coating particles is accelerated compared to diffusive coagulation. Repulsive forces between unipolar charges decrease coagulation in each size range. In addition these repulsive forces should lead to a homogeneous allocation of the coating particles on the support particle surface. This method provides a highly controllable process and the possibility of selective agglomeration. Over changing the charging conditions, it is possible to generate tailored nanoparticle systems. Even though bipolar coagulation was investigated before (Maisels et al., 2000), the use of this method in particle coating is completely new. Previous works (Alonso et al., 2005) also showed that there is a challenging task in charging nanoparticles in size ranges below 10 nm.

For experimental investigations SiO_2 monospheres with a diameter of d = 235 nm are used as support particles. These monospheres are suspended in water and dispersed in air. The platinum coating particles with a size of about 10 nm are generated by a glowing wire generator. After dispersing and charging, an SMPS System is used to determine the charge distribution of the support particles. Each support particle carries several 10 elementary charges. Then charged support particles are mixed with charged coating particles. After passing a mixing zone with a known residence time the charge distribution is determined again. Every agglomeration between the positive support particle and a negative coating particle equalizes one positive charge on the support particle surface. Further it is assumed that according to the enormous difference in size the agglomeration of coating particles does not change the support particle diameter. So it is possible to follow the process progress by comparing the charge distributions before and after mixing with coating particles. Beside the influence of concentration and residence time, several other parameters were investigated.

To investigate coagulation dynamics, a theoretical model was developed. This model permits to determine the charge distribution of support particles after a given residence time and thus the point of neutralisation of all charges on particles surface by bipolar agglomeration of coating particles. For this purpose equations were set up to calculate the change in particle concentration. Bipolar coagulation, self coagulation, particle loss by diffusion and electrostatic dispersion are considered in these equations. The equations are solved with sectional method.

The results from experimental measurements were compared to those from numerical calculations.

This project is part of the JointLab IP3, a joint initiative of KIT and BASF. Financial support by the ministry of science, research and the arts of Baden-Württemberg (Az. 33-729.61-3) is gratefully acknowledged.

Characterization of EHDA in the simple-jet mode

L.L.F. Agostinho[1,2], E.C. Fuchs[2], J. Wartena[1], C. U. Yurteri [1,2], J. C. M. Marijnissen [1,2]

[1]Faculty of Applied Sciences, Delft University of Technology, 2628 BL Delft, The Netherlands

Keywords: Electrospray, simple jet mode, water
Presenting author email: luewton.lemos@wetsus.nl

In the past few years electrohydrodynamic atomization (EHDA) has become a very important tool to atomize liquids. Its application ranges from medicine to agriculture (Geerse, 2003). The spray can be operated in different modes (Cloupeau *et al.*, 1994). The most explored one is the cone-jet mode due to its capability of producing small droplets with a narrow size distribution. But here we describe the characteristics of another mode, the simple-jet mode.

Water was sprayed using a nozzle-ring setup and it was atomized using three different flow rates (240, 360 and 480 mL/h). In some experiments NaCl (99% Sigma Aldrich) was added to the water to change its electric conductivity. High speed imaging was used to measure droplet size and size distribution as well as to characterize the liquid break-up. For the conditions applied in these experiments the results have shown that the generated droplet size is strongly influenced by the applied potential. Furthermore, the droplet average diameter can be smaller than the nozzle diameter. Figure 1 shows the influence of the applied potential on the spray characteristics for a constant flow rate of 240 mL/h.

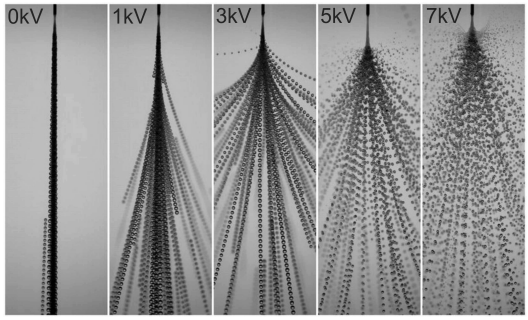

Figure 1: Simple-jet mode at different potentials and constant flow (240 mL/h). The potentials (written on the upper left corners) were applied on the ring while keeping the nozzle (0.41mm OD) grounded. Distance between the nozzle and the ring was kept constant at 2,5cm.

Just like in the cone jet mode, the jet break-up can happen in the varicose break-up and in the lateral kink break-up (whipping break-up) (Hartman, 2000). The ramified break-up was not seen within the experiments conditions. For a given configuration this transition depends on the applied potential difference. The transition between these two kinds of break-up can be explicitly seen in the current –potential difference diagram (Figure 2). Size and size distribution are influenced by these break-up mechanisms.

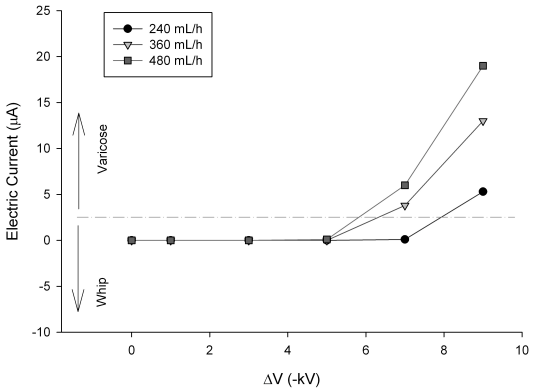

Figure 2: Applied potential against spray electric current for three different flows (240, 360 and 480 mL/h). The arrows and dotted line were arbitrary placed to show the varicose break-up and the whipping break-up regions.

This directly implies that current can be used to adjust the spray characteristics efficiently. The process energy balance also showed that EHD atomizers are more efficient than other atomization methods. Therefore, for applications which require high flows and droplets in the micrometer range, EHDA in the simple-jet mode is a promising technique.

Particle diagnostics and wave phenomena in complex plasmas

Complex (dusty) plasma is a mixture of micron-sized particles or grains with an ion-electron plasma. The grains (typically monodisperse plastic microspheres) collect ions and electrons and like floating Langmuir probes acquire large negative electric charges. They can be levitated and confined in a gas discharge. Due to collective interaction, the grains form crystal- or liquid-like structures. These structures can propagate linear (Samsonov 2005) and nonlinear waves, solitons (Harvey 2010), shocks (Samsonov 2003), and exhibit phase transitions. Since the characteristic time scale is determined by the large mass of the grains, the system is slow enough to observe with a video camera or with a naked eye.

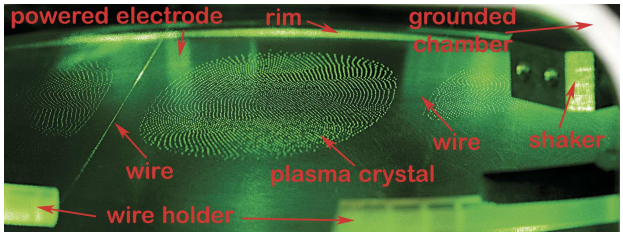

Figure 1: Monolayer complex plasma confined in an rf discharge.

The experiments were performed in a radio-frequency capacitively coupled gas discharge (Fig. 1). A monolayer of monodisperse microspheres was levitated and confined above a flat electrode 20 cm in diameter. The particles were illuminated with a sheet of laser light and imaged with a high speed (up to 2000 frames per second) video camera. The monolayer was excited with electrostatic pulses applied to wires stretched at or below the layer. We simulated complex plasmas using molecular dynamics code which solved the equations of motion for every grain by the 5th order Runge-Kutta method taking into account interaction of every grain with every other.

A range of interesting effects was observed. A vertical wave packet was excited. It propagated with a group velocity which was 100 times smaller than its phase velocity. Solitons and their interaction during a head-on collision were studied. It was found that a collision caused delay in propagation. Soliton steepening in an inhomogeneous lattice has been observed. The amplitude grew even in the presence of damping due to the gas drag. Shock waves were found to cause phase transitions.

Similar experiments were also conducted on board the International Space Station where three-dimensional complex plasma crystals and liquids were obtained. Crystals with different structures such a body centered cubic, face centered cubic, and hexagonal close packed were observed. Using a gas puff, shock waved were excited and propagated in a 3D complex plasma. The shock front remained remarkably smooth, with a microroughness of the order of the interparticle distance.

Video diagnostics is important for studying complex plasmas. Apart from 2D imaging, we performed 3D imaging with a laser tomography system (Samsonov 2008). A laser beam was expanded into a sheet with a raster optics and scanned using a pair of galvanometer driven mirrors. Each step was synchronized with the video camera. The system has been tested with the scanning speeds of up to 120 000 steps per second and up to 256 steps.

A range of software tools has been developed in order to identify particle positions and track their motion reliably. The tracking algorithms can include the physics of the process and can offer significant computational advantages over standard enumerative techniques. The developed algorithm is based on a state estimator which predicts the particle states (position, velocity and acceleration). The predicted positions are compared to the measured position and a weighted correction is applied using an Extended Kalman Filter. Here we use a simplified state estimator which takes into account only nearest-neighbor particle interactions. This reduces the computational time at the expense of the accuracy of the state estimation and particle tracks compared to a full N body simulation.

Contact charging of metal nanoparticles

S. Rennecke and A.P. Weber

Institute of Particle Technology, Clausthal University of Technology, Clausthal-Zellerfeld, 38678, Germany

Keywords: charge exchange, bouncing, inertial impaction.
Presenting author email: stephan.rennecke@tu-clausthal.de

When a spherical particle impacts on a rigid surface it may stick to it, or, if the impact velocity is sufficiently high, may rebound from the surface being resuspended in the surrounding gas. Furthermore a rebounding particle may gain an electric charge during contact, as a consequence of different work functions of particle and surface material. This process of dynamic contact charge transfer to the particle can be modelled by assuming the formation of a plate capacitor in the circular contact zone between the deformed sphere and the rigid surface, as shown by John et. al. (1980). Therefore, the functional dependence of the contact charge on the impact velocity gives a direct insight into the mode of deformation and the material properties of the particle, if the contact potential is known. In the present work the dynamic contact charging of metal nanoparticles is investigated in order to develop appropriate contact models describing the rebound and charging behaviour of nanoparticles.

For this purpose the contact charge q_c as a function of impact velocity has been determined experimentally using a single stage low pressure impactor. Spherical, size selected and singly charged metal particles in the size range from 20 nm to 100 nm were impacted on a smooth surface at process conditions far above the critical Stokes number for deposition. The onset of particle rebound and the mean charge of the particles after collision have been measured using an electrometer. The actual impact velocity of the nanoparticles has been determined numerically using the Statistical-Lagrangian-Particle-Tracking (SLPT) method (Yook et al., 2007). The setup allows defined collision experiments for impact velocities up to approximately 200 m/s.

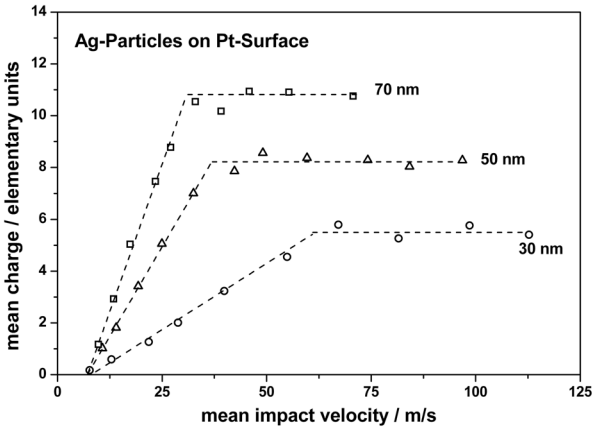

Figure 1. Mean particle charge as a function of impact velocity for silver particles of different size

The mean contact charge as a function of impact velocity for silver particles of different size is given in figure 1. When the threshold velocity for particle rebound is reached, q_c increases linearly with the impact velocity approaching constant values, that increase with particle size. The slope in the linear part is proportional to the square of the particle size. This behaviour is identical with the observation of Wang and John (1988) for the dynamic contact charging of conducting micrometer particles assuming complete plastic deformation, indicating that macroscopic deformation models are also valid on the nano scale.

The constant values reached at higher impact velocities have so far not been observed for micrometer particles. This may be explained with the much smaller capacity of a nano sized sphere, limiting the maximum transferred charge at a given contact potential. Therefore the actual contact potential can be calculated precisely for each measurement, being 0,46V, independent of the particle size, for the Ag-Pt interface, in the presented dataset.

The simultaneous characterization of the electrical properties of the interface allows a quantitative comparison of experiment and theory for the first time. Furthermore, as the contact potential is known, the maximum contact area of the deformed particle can be calculated. This allows an adaption of contact models, considering the unique properties of nanoparticles, such as the great importance of surface forces.

In this contribution the experimental data for the threshold velocity for rebound and the dynamic contact charge for different metal nanoparticles will be presented. Appropriate contact models for the quantitative description of the contact charge will be discussed.

Comparison of methods to achieve a stationary charge distribution

Lena Knobel[1], Hans-Joachim Schmid[1]

[1]Department of Mechanical and Environmental Process Engineering (MVU)
University of Paderborn, 33100, Paderborn, Germany

Keywords: charged particles, SMPS, aerosol measurement, stationary charge distribution

The common method to achieve a stationary charging distribution in an aerosol for nanoparticle classification using a differential mobility analyzer is a radioactive source. In recent years there has been an increasing attention to alternative solutions.

In this research the influence, which the methods have on the charge distribution, are investigated. Three bipolar charging methods are considered:

- Radioactive Source, ^{85}Kr (TSI)
- Soft X-ray photonionizer (PMT Partikel)
- Surface-discharge Microplasma Aerosol Charger (Tsukasa Sokken)

An experimental investigation showed that these chargers, as a part of a SMPS system, result in different particle size distributions for a given polydisperse testaerosol (see figure 1).

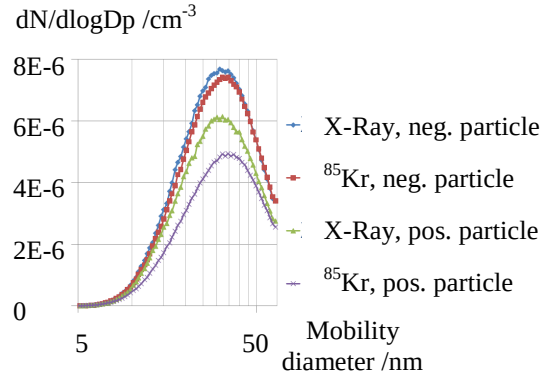

Figure 1. Mobility distribution by the different kind of chargers measured by a SMPS System

The charge probability of the particles depends on the ion mass and ion mobility. Positive and negative ions have different mobilities and masses due to different propensities to form water clusters. (Hoppel, 1990) As a result, a balanced bipolar ion environment leads to an asymmetrical charge distribution of the particles.

The common method to calculate the charge distribution, needed in order to determine the particle size distribution, is the Wiedensohler Approximation (Wiedensohler, 1987). This approximation is based on the Fuchs theory (1963). The ion mobilities, which represent fixed input parameters in this calculation, are determined experimentally using an Americium charger by fitting the results of the SMPS measurement to the Fuchs theory. The ion masses are additional fixed input parameters calculated by Wiedensohler. Lee *et al.* (2004) showed different ion concentration and mobilities produced by a radioactive source (^{241}Am) and a soft X-ray photonionizer. In this work the ion concentrations and mobilities, produced by the three chargers mentioned above, will be investigated.

Also the resulting particle charge distribution will be determined via a Tandem DMA setup. Figure 2 shows the part of the singly charged particles produced by the different chargers in comparison to the Wiedensohler Approximation.

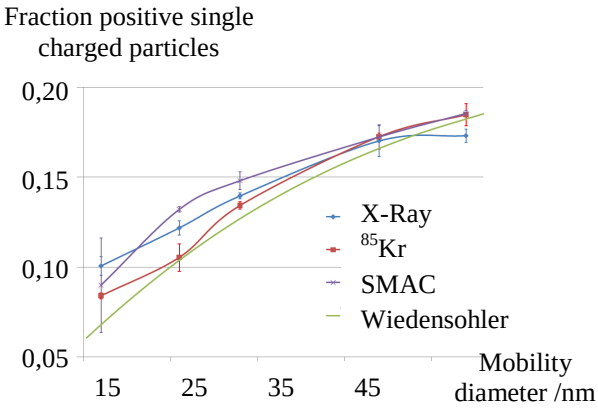

Figure 2. Fraction of positive single charged particles produced by the different chargers

Another effect on the charge distribution occurs downstream the chargers (Lee, 2004), (Hoppel, 1990). Ions leave the chargers together with the particles. Diffusion occurs as a function of the ion mobility, which is different for positive and negative ions. Therefore, the charging process is continuing with an imbalanced ion concentration for negative and positive ions downstream the chargers. Thus, the charge distribution reaching the DMA is not stationary anymore.

This effect is investigated experimentally and theoretically. The model considers the following ionic effects: recombination, diffusion and electrostatic dispersion.

A simplified procedure for particle charge distribution measurements and its application to the characterization of the annual DBD aerosol neutralizer

Wild, Markus[1], Meyer, Jörg[1] and Kasper, Gerhard[1]

[1]Karlsruhe Institute for Technology KIT, IMVM, Strasse am Forum 8, 76139 Karlsruhe, Germany

Keywords: Measurement (characterization), Dielectric Barrier Discharge; charged particles; TDMA.
Presenting author email: markus.wild@kit.edu

The annular dielectric barrier discharge aerosol neutralizer is a device designed to impose a Boltzmann charge distribution to airborne particles by electrostatic means. The device's performance in neutralizing aerosols is compared to a radioactive ^{85}Kr source. Amongst others, the particle charge distributions of sodium chloride particles ranging between 27-200 nm are investigated. The method of choice is a Tandem-DMA setup. The basic task is to determine the number concentration of differently charged particle fractions. Usually a rather complex curve fitting method is applied to evaluate the obtained data, see e.g. Stolzenburg and McMurry (1998). The evaluation process can be vastly simplified if some restrictions concerning the conduct of the experimental procedure are observed.

Therefore, a method to determine the aerosol concentration within a well defined interval of electrical mobilities – such as distinct peaks in a mobility spectrum illustrated in Figure 1– directly from a continuous DMA scan is described.

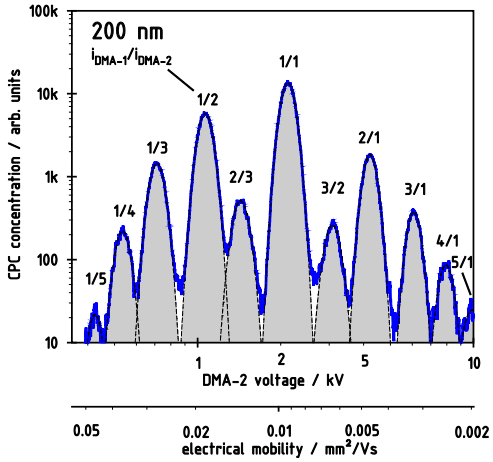

Figure 1. mobility spectrum of a pre-classified (200nm) and neutralized sodium chloride aerosol measured by a CPC after DMA-2 in a TDMA setup. i indicates the state of charge in DMA-1 and DMA-2, respectively.

The method is based essentially on moving the transfer function across the spectrum at such a rate that the time window during which particles of an arbitrary mobility can pass through the DMA remains constant during the scan. This implies a specific ramp function for the scan voltage, which we derive, thereby establishing a direct and simple link between the cumulative number of particles exiting the DMA while scanning across a peak, and the concentration enclosed within that mobility window at the inlet (see Figure 2). The method is an implicit part of the theoretical framework described by Wang and Flagan (1990). However, by relaxing the goal of deriving a complete size distribution in favour of the lesser requirement of measuring only the total concentration within certain, well defined bounds of mobility, one gains accuracy, sensitivity, and last not least convenience because there is no need for extensive post-processing of the data. The method is particularly suitable for measuring aerosol charging probabilities with distinct peaks in the mobility spectrum.

While the charged fractions of laboratory generated aerosols in the range of 27 to 200 nm are investigated with a TDMA set-up and the mentioned data evaluation procedure, the neutral fraction is measured by a separate measurement.

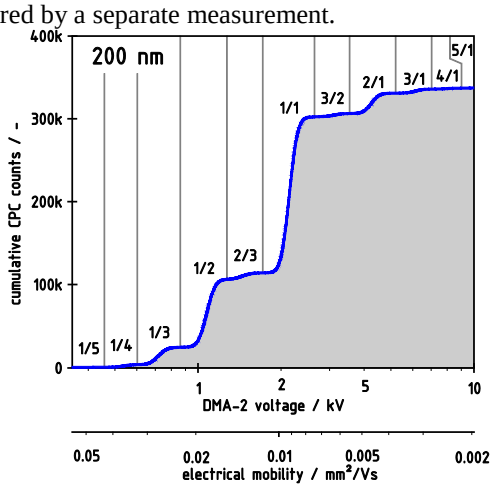

Figure 2. cumulative particle counts of the aerosol introduced in Fig. 1 when performing an up-scan using a logarithmic voltage ramp

The method was used to determine the performance of the annual Dielectric Barrier Discharge (aDBD) aerosol neutralizer in comparison to a common ^{85}Kr β-source. The obtained charge distributions resembled each other very well. The aDBD proofed to provide a promising alternative to the use of radioactive material and its well-known disadvantages in aerosol measurement technology.

Session 10A: Aerosols in Geoengineering / Aerosols in Global Climate Models

A New Hybrid Solver of Dissolution of Inorganics into the Particle Liquid Phase: Evaluation and Global Scale Implications on Aerosol Properties.

F. Benduhn[1,2], and K.S. Carslaw[1]

[1]Institute for Climate and Atmospheric Science, School of Earth and Environment, The University of Leeds, Leeds, LS2 9JT, United Kingdom.
[2]Now at: Department of Atmospheric Chemistry, Max-Planck-Institute for Chemistry, Mainz, Germany.
Keywords: Atmospheric aerosol, Aerosol modeling, Inorganics, Aerosol dynamics.
Presenting author email: francois.benduhn@mpic.de

A new hybrid solver of dissolution of inorganics into the aerosol liquid phase has been developed. With respect to former solutions (Capaldo et al., 2000) the solver follows a novel approach as decision is being made onto which parts of the aerosol size spectrum are assumed to be in equilibrium and which parts are assumed to be in transition. Decision criteria include mass fractionation as well as prospective equilibration time considerations. In addition special care was taken to keep computation time as low as possible. As stiff dissolution considerably minimizes the integration time step of the transient solver, an additional decision criterion considering the mathematical stiffness was introduced. Under stiff conditions equilibrium is assumed and the composition is later corrected according to equilibration time considerations. The novel equilibrium solver follows both an analytical and a differential approach, depending on whether equilibration is chemically or mass fractionally driven, respectively. Transient dissolution is based on the method detailed in Jacobson (1998).

The solver has been implemented into the modal version of the aerosol global transport model with combined chemistry GLOMAP/TOMCAT (Spracklen et al., 2005). Under its current version the solver allows for the concurrent dissolution of HNO_3, HCl and NH_3. Dissolved matter is allowed to interact with sulphuric acid and sea salt, which is assumed to be composed of sodium chloride and sodium sulphate. Liquid phase equivalent ions encompass NO_3^-, Cl^-, SO_4^{2-}, HSO_4^-, NH_4^+, Na^+ and H^+. Chemical ion interaction, as given by the particle liquid water content, sulphuric acid dissociation and the surface partial pressure of the dissolvable species, is assessed according to the method detailed in Topping et al. (2009). Dissolution may be set to occur into the four soluble modes (nucleation, Aitken, accumulation, and coarse). The solver may be run in the full equilibrium, the hybrid and the pseudo-equilibrium regime mode. The latter one stands for equilibration with ulterior composition adaptation according to evaluated equilibration time (see above). In the box model version the solver may also be run in full transition, serving as benchmark for evaluation.

Box model tests show that the hybrid solver catches the transient behavior of dissolution for both acidic and sea salt particles very closely for situations of low to moderate stiffness, of up to say 1-10 ppm atmospheric concentration of dissolvable species depending on the aerosol load. Highly stiff conditions require the use of pseudo-equilibration. Under this circumstance the solver still catches aerosol composition quite well, especially if compared to the full equilibrium configuration.

Global runs were performed in the hybrid, the full equilibrium, as well as the pseudo-equilibrium mode, and compared to runs without dissolution. Sensitivity tests with respect to the sticking efficiency were also done. At this moment global runs were performed for HNO_3 and NH_3 dissolution only. The solver proved to associate accuracy with computational efficiency with dissolution using approximately 10% of total computation time. Results show the relevance of the transient behaviour of dissolution for aerosol composition and its interaction with aerosol microphysical properties via particle size. When set to full equilibrium, the coarse mode tends to take up the bulk of the dissolvable matter due to the size discrepancy with the competing nucleation, Aitken and accumulation modes. In the hybrid mode, the coarse mode is mostly set into the transient regime, leaving much more matter available for the smaller modes whose surface to volume ratio is higher. Depending on atmospheric composition the smaller modes are thus allowed to reach the stiff regime, under which circumstance sulphuric acid, nitric acid and ammonia interact efficiently to lead to the formation of liquid phase ammonium sulphate and ammonium nitrate thus entailing considerable increase in particle size and consequent modifications of the cloud condensation number. The influence of the sticking efficiency is shown to be secondary to negligible only as modes in the transient regime are usually not in the molecular regime due to their size.

Convective processes involve strong vertical motions locally and may cause heavy precipitation and damages. Recent studies have found that global warming causes more flooding, but the precipitation extremes exceed the expectations from temperature changes in observations and IPCC climate models. Here we investigate convective cloud precipitation in response to warming environments using a cloud model with detailed microphysics and aerosol treatments (Yin et al., 2005; Cui et al., 2006). Our simulations show that precipitation increases more than 22% with per 1K warming and accordingly increased moisture (Fig. 1). Our results demonstrate that liquid cloud drops grow to larger sizes during the warm-rain process, and more large drops freeze and become graupel particles, which, when falling below 0°C level, melt and produce more precipitation. In a warming atmosphere without increasing moisture content, convective clouds only develop to mid-troposphere with little precipitation. We also show that precipitation increases with warming temperatures for different aerosol loadings, with more precipitation in a clean environment. We anticipate more studies on the precipitation response to global warming in organized convective systems in the future. Furthermore, it is suggested that climate models should have detailed treatment of mixed-phase microphysics.

Weak response of CCN to changes in DMS flux: implications for the CLAW feedback in current climate assessments

M. T. Woodhouse[1], G. W. Mann[2], K. S. Carslaw[1] and O. Boucher[3]

Keywords: dimethyl-sulphide, CCN, climate effect, CLAW
Presenting author email: m.woodhouse@see.leeds.ac.uk

The CLAW hypothesis (Charlson et al., 1987) relates the production of dimethyl-sulphide (DMS) in the surface ocean by phytoplankton to the optical properties of clouds via the first and second aerosol indirect effects, thereby proposing a climate feedback. The CLAW feedback has been the subject of much investigation over the last two decades, but only recently have aerosol models with detailed aerosol microphysics become available.

Presented here are simulations in the UK Met Office HadGAM atmospheric general circulation model where the flux of DMS to the atmosphere from the oceans is perturbed. The impact of these DMS flux perturbations on aerosol when simulated by two different aerosol schemes is investigated. One aerosol scheme carries only mass in several aerosol types, each with a prescribed size distribution, and is typical of most aerosol schemes used in recent global climate assessments (e.g. IPCC AR4). The second aerosol scheme (UKCA-mode, Mann et al., 2010) uses a two-moment approach transporting number and mass in several size modes, allowing particle number to be conserved and growth to be simulated.

The response of CCN to changes in the flux of DMS is quantified as $\Delta CCN/\Delta Flux_{DMS}$, and termed CCN sensitivity.

The more detailed two-moment aerosol scheme predicts a very weak CCN response to changes in DMS flux, or a very low CCN sensitivity (Figure 1). This suggests that the CLAW feedback is either very weak, or negligible. The simpler mass-only aerosol scheme predicts a larger response of CCN to DMS changes. The greater response in the mass-only aerosol scheme is believed to be incorrect, due to the very limited representation of aerosol microphysics within the scheme. These results have significance for the representation and quantification of the CLAW feedback in current climate assessments, suggesting that the strength of the feedback may be over-estimated by simple aerosol schemes.

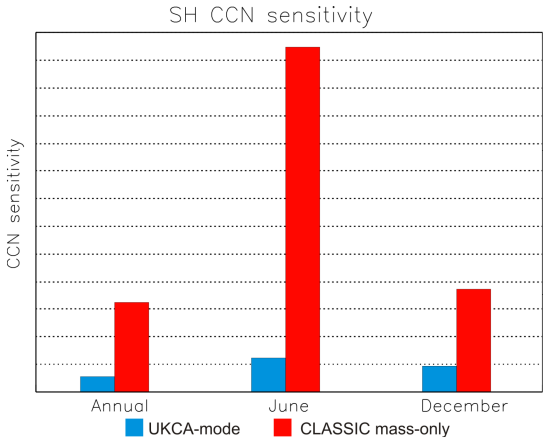

Figure 1 Comparison of CCN sensitivities calculated from DMS flux perturbations in the microphysical aerosol model UKCA-mode and the mass-only aerosol model CLASSIC.

Estimating the radiative impacts of biogenic secondary organic aerosol, their variation with location and climate, and the implications for climate geoengineering

C. E. Scott, P. M. Forster, K. S. Carslaw, D. V. Spracklen and S. R. Arnold

Institute for Climate and Atmospheric Science, School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, UK

Keywords: forest, biogenic particles, climate change

Presenting author email: pm08c2s@leeds.ac.uk

The possibility that cuts in greenhouse gas emissions do not occur on a timescale that prevents a dangerous level of temperature increase has prompted research into alternative means by which the Earth's radiative imbalance may be redressed. Such mechanisms, involving the deliberate modification of parts of the Earth system, may broadly be classified as climate 'geoengineering' schemes. The aim of this work is to evaluate the potential for reduced deforestation and increased afforestation, as such a geoengineering scheme, to offset a portion of the anticipated future climate change.

In addition to the implications for the carbon cycle, a number of biogeophysical and biogeochemical side-effects also determine the overall climatic impact of a forest; changes to surface albedo, evapotranspiration, sensible heat transfer, wind patterns, chemical emissions, cloud cover and precipitation will all contribute. Previous modelling studies, examining the biogeophysical side-effects, have concluded that the net climatic impact of a forest is latitude dependent. At high latitudes where the presence of trees obscures highly reflective snow, the net climate effect is warming. In tropical regions, the presence of forests generates an additional negative radiative forcing due to increased evapotranspiration efficiency and surface roughness that is sufficient to negate the effect of decreased albedo.

However, these studies did not consider the impact of forests on local atmospheric chemistry. Vegetation emits a number of biogenic volatile organic compounds (BVOCs) e.g. isoprene, monoterpenes and sesquiterpenes, which may undergo photochemical oxidation by the hydroxyl radical (OH), ozone (O_3) or the nitrate radical (NO_3). The resulting oxidation products may then participate in organic aerosol production, either through the nucleation of new particles, or by condensation onto existing particles, facilitating their growth. Whilst experimental constraints limit practical measurement of the composition of the smallest particles, inclusion of a "nucleating organic" term in the particle formation rate equation has been shown to give better model agreement with formation rates derived from smog chamber experiments (Metzger *et al*., 2010).

The resulting secondary organic aerosol (SOA) may either affect the climate *directly* through the reflection of incoming shortwave radiation, or *indirectly*, via their action as cloud condensation nuclei (CCN). Local CCN concentrations influence the microphysical and radiative properties of clouds, via their effect on cloud drop number concentrations (CDNC). Whilst CDNC over polluted regions tends to be updraft limited, aerosol concentrations have been shown to provide the limiting factor in pristine regions (Poschl *et al*., 2010). Using an aerosol microphysics model (GLOMAP), Spracklen *et al.* observed a simulated doubling of regional CCN concentration when comparing the presence of boreal forests to Arctic tundra, resulting in a radiative forcing of between -1.8 and -6.7 $W.m^{-2}$ of forest (Spracklen *et al*., 2008).

Here, we extend this work by using a pseudo-coupled framework of models to simulate the change in aerosol and cloud properties under idealised deforestation and afforestation scenarios. The Community Land Model (CLM) is used to prescribe the changes to forest cover, whilst the Community Atmosphere Model (CAM) and GLOMAP (mode) are used to simulate the atmospheric chemistry and aerosol processes resulting from the altered BVOC emission. Climatic variables, such as atmospheric carbon dioxide concentration, temperature and solar radiation, are changed sequentially in order to determine the sensitivity of this system to potential future climate changes. Radiative forcings are then calculated using an offline radiative transfer code.

In June 2009 the Sarychev volcano located in the Kuril Islands to the northeast of Japan erupted explosively, injecting ash and an estimated 1.2 ± 0.2 Tg of sulphur dioxide into the upper troposphere and lower stratosphere, making it arguably one of the 10 largest stratospheric injections in the last 50 years. During the period immediately after the eruption, we show that the sulphur dioxide (SO_2) cloud was clearly detected by retrievals developed for the Infrared Atmospheric Sounding Interferometer (IASI) satellite instrument and accurately modelled by simulations using a nudged version of HadGEM2 (Figure 1).

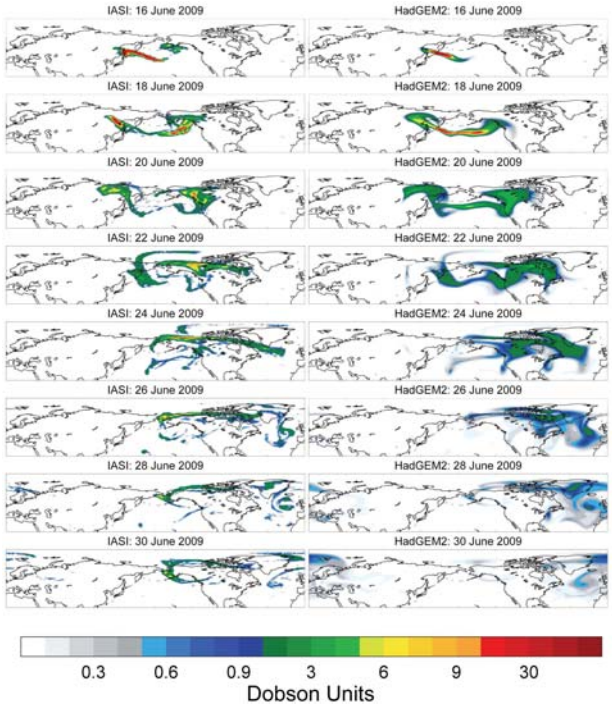

Figure 1. The evolution of plumes for (left) IASI and (right) HadGEM2 for the period 16–30 June 2009.

The resultant stratospheric sulfate aerosol was detected by the Optical Spectrograph and Infrared Imaging System (OSIRIS) limb sounder and CALIPSO lidar. Additional surface-based instrumentation allows assessment of the impact of the eruption on the stratospheric aerosol optical depth. The model simulations and OSIRIS measurements (Figure 2) suggest that in the Northern Hemisphere the stratospheric aerosol optical depth was enhanced by around a factor of 3 (0.01 at 550 nm), with resultant impacts upon the radiation budget.

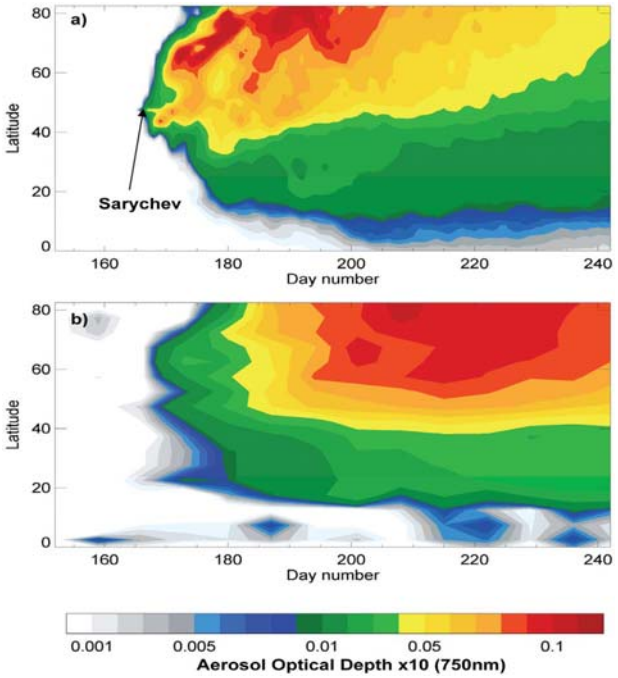

Figure 2. Time versus latitude plots of the aerosol optical depth at 750 nm from (a) HadGEM2 and (b) OSIRIS.

The simulations indicate that, in the Northern Hemisphere for July 2009, the magnitude of the mean radiative impact from the volcanic aerosols is more than 60% of the direct radiative forcing of all anthropogenic aerosols put together. Modelling the eruption of Sarychev also serves to increase confidence in the model representation of transport and the sulphur cycle which has potential consequences for solar radiation management geoengineering proposals.

Session 10B: Remote Sensing of Aerosol Properties

The FAAM volcanic ash flights in May 2010: results from the lidar, the CAS, and ARIES

The Facility for Airborne Atmospheric Measurements (FAAM, http://www.faam.ac.uk/) performed a series of flights during the eruption of the Eyjafjallajökull in spring 2010 with its BAE146 research aircraft.

Volcanic ash layers were observed using an on-board elastic backscatter lidar operating at 355 nm, which allowed detailed mapping of the plumes. Using the method by Digirolamo *et al* (1994), the lidar ratio (extinction-to-backscatter ratio) has been determined for a number of selected vertical profiles where signal from Rayleigh scattering could be well identified from regions both above and below the ash layer. The lidar ratio was found to be equal to 60 ± 13 sr (average and standard deviation for all the selcted profiles during the May 2010 flights). As not all lidar profiles could be analysed in this way, the mean lidar ratio has then been applied to the whole dataset, using the method by Fernald (1984) and Klett (1985) to infer the aerosol extinction coefficient and aerosol optical depth (AOD).

A flight on 4 May overpassed the ground-based lidar in Aberystwyth a few times. This provided ground truth validation of the on-board lidar and of its data inversion procedure. The ash layer during this flight was found to be in patches of short horizontal extent, and moreover patches of enhanced backscatter from non-ash aerosol were also identified, and found in proximity to the ash patches. Ash and non-ash were distinguished based on their depolarisation signatures. Despite this strong horizontal inhomogeneity, the two lidars showed excellent qualitative and quantitative agreement.

Size-distributions were obtained *in situ* using a Cloud and Aerosol Spectrometer with Depolarisation (CAS-DPOL). Mie scattering computations using the observed size-distributions (corrected for refractive index) aided the determination of two important parameters for the interpretation of the lidar data: the fraction f_c of extinction in the coarse fraction, and the specific extinction $K_{\rm ext}$ of the coarse mode, identified with volcanic ash. The coarse mode extinction fraction ranged between 43% and 98%, whereas the specific extinction of the coarse particles ranged 0.3–0.7 m^2/g. These estimates were based on a refractive index of $1.52 - i0.00155$, and a particle density of 2.3 g cm^{-3}. These parameters enabled the mass concentration of volcanic ash to be estimated from the aerosol extinction coefficient derived by lidar.

Atmospheric radiance measurements above ash have also been made using the infra-red spectrometer ARIES (Airborne Research Interferometer Evaluation System). Radiative transfer computations using the lidar-derived profiles of aerosol extinction led to a very good reconstruction of the observed radiance spectra. Moreover, the spectral slope of the brightness temperatures in the 8 μm region was well correlated with the lidar AOD. The implications of this finding for the quantification of volcanic ash from satellite sensors in the infrared region will be discussed.

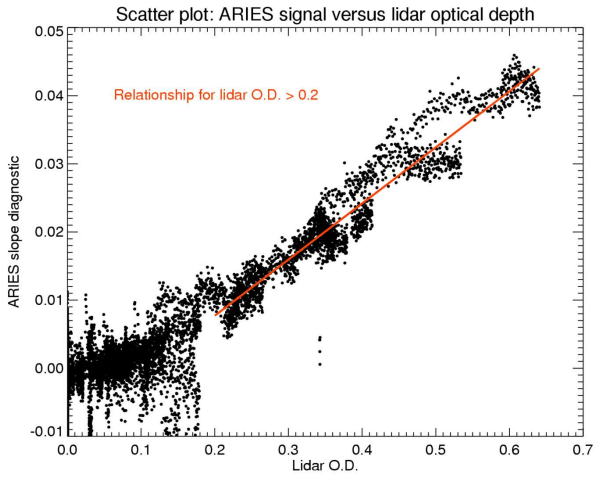

Figure 1: Correlation plot between the infrared brightness temperature slope in K/cm^{-1}, determined with spectrometer ARIES, and the AOD, determined by lidar on 17 May 2011.

Volcanic ash optical properties with an UV-depolarization Lidar

A. Miffre, G. David, B. Thomas and P. Rairoux[1]

[1]Laboratoire de Spectrométrie Ionique et Moléculaire, CNRS UMR 5579, Université Lyon 1, Villeurbanne, 69622, France

Keywords: remote sensing, depolarization, ash, light scattering matrix.

Presenting author email: miffre@lasim.univ-lyon1.fr

In this contribution, a ground-based UV-polarization Lidar is used to study the optical properties of tropospheric volcanic ash particles. Measurements have been performed during the mid-April 2010 eruption of the Eyjafjallajökull volcano (63.63°N, 19.62°W, Iceland) at Lyon (45.76°N, 4.83°E, France) at the border of the air closure traffic area. The volcanic origin of the observed air masses has been confirmed by 7-days air mass back-trajectories and FLEXPART ash particles numerical dispersion model. The measured UV-particle backscattering coefficient β_p is typically equal to 4.0 $Mm^{-1}.sr^{-1}$ and UV-depolarization ratios δ_p lie in the range from a few to 44 %. After long-range transport, the β_p and δ_p-variations are interpreted as variations in ash-mass concentrations. Moreover, a partition between spherical and non spherical particles is retrieved from both scattering and depolarization measurements.

Volcanic particles release gas and ash particles that can be transported over several thousands of kilometres and may remain in the troposphere for several weeks (Ovadnevaite *et al*, 2009). The physical properties of volcanic ash particles, such as size and shape, may change during advection. In this contribution, a UV-remote sensing experiment is performed to study the volcanic particles shape by measuring the ability of volcanic particles to depolarize UV-laser light. Scattering occurs from both fine and coarse mode particles, enhanced by our UV-light choice. Very sensitive (from a few to 44 %) and accurate (better than 30% at 4-km altitude) δ_p-measurements have been achieved by a new home-built depolarization Lidar detector, using two polarizing beam-splitter cubes to ensure a fully negligible cross-talk between parallel and perpendicular Lidar detector channels.

Vertical profiles of the parallel backscattering coefficient $\beta_{p,//}$ and depolarization ratio δ_p are displayed on figure 1, together with the relative humidity profile. A double-layering structure is observed, showing that, after long-range transport, the volcanic ash cloud is not homogenously spread in space as confirmed by 7-days back-trajectories and FLEXPART dispersion model. Despite long-range transport, the volcanic particles are still non spherical. Moreover, within our error bars, we attribute the highest observed δ_p-value of 44 % to volcanic ash particles, as it agrees with laboratory scattering matrix measurements performed on randomly oriented ash particles (Munoz *et al*., 2004). At lower altitudes, as RH increases, spherical sulphates particles growth lowers the observed depolarization ratios. Using δ_p(ash) = 44 %, we deduce the ash particles β_p-vertical profile from our depolarization measurements.
Using O. Munoz's volcanic ash particles optical parameters (2004) and applying optical scattering computations, ash particles concentration has been evaluated from β_p. Figure 1 displays the retrieved ash-mass concentration.

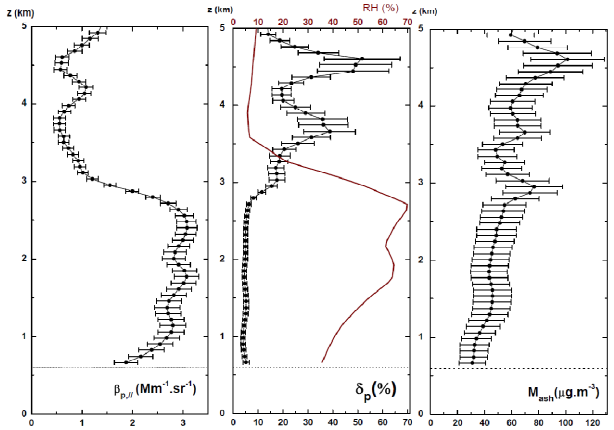

Fig. 1 UV-particle backscattering $\beta_{p,//}$, depolarization δ_p, relative humidity RH and retrieved ash-mass concentration vertical profiles on April 19th at 19 h UTC. The vertical resolution is 75 m.

Retrieved ash-mass concentrations are well below the limit value of 2 000 $\mu g.m^{-3}$ chosen for airport closures and compare well with numerical dispersion model. Hence, our methodology, which combines very sensitive and accurate scattering and depolarization measurements with a numerical dispersion model helps to retrieve the optical properties of volcanic ash particles. The presentation will point out this approach, and details the further retrieved partition between spherical (sulphates) particles and non spherical (ash) particles, obtained from optical simulation of spherical sulfates particles. This work is submitted to Atmospheric Environment's special issue on the Icelandic volcano.

We thank A. Stohl's group for providing FLEXPART numerical dispersion model. This work was supported by Région Rhône-Alpes and CNRS.

A general work focused on the study of Saharan dust intrusions is presented as a case study of air masses advected from the Saharan region to the Canary Islands and the Iberian Peninsula (IP). This work is divided in two parts in order to examine two relevant and different aspects of this study. Each one is separately submitted. This first one (Part 1) describes the dust detection, identification and vertical structure analysis by using AERONET data, lidar measurements and backtrajectory modelling. In the Part 2 the evaluation of potential dust impact on surface once that Saharan dust intrusion arrives at the Southern IP will be presented.

The observations were performed over three Spanish geographically strategic stations within the dust-influenced area along a common dust plume pathway monitored from 11 to 19 of March 2008. A 4-day long dust event (13-16 March) over the Santa Cruz de Tenerife Observatory (SCO), and a linked short 1-day dust episode (14 March) in the Southern IP over the Atmospheric Sounding Station 'El Arenosillo' (ARN) and the Granada station (GRA) were detected.

Meteorological conditions favoured the dust plume transport over the area under study. Backtrajectory analysis clearly revealed the Saharan region as the source of the dust intrusion.

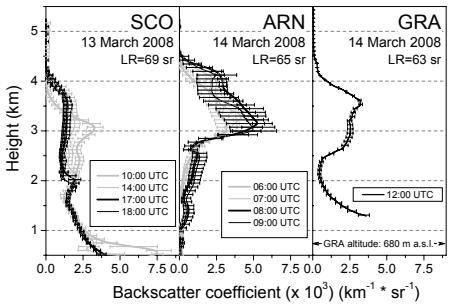

Figure 1. Height-resolved backscatter coefficients (1-h averaged profiles) under dusty conditions over SCO site (left), ARN (centre) and GRA (right) stations.

Under the Saharan air masses influence, AERONET Aerosol Optical Depth at 500 nm (AOD^{500}) ranged from 0.3 to 0.6 and Ångström Exponent at 440/675 nm wavelength pair ($AE^{440/675}$) was lower than 0.5, indicating a high load and predominance of coarse particles during those dusty events.

Lidar observations characterized the vertical structure of those dust plumes, identifying different aerosol contributions depending on altitude (see Fig. 1). In particular, the 3-km height dust layer transported from the Saharan region and observed over SCO site was later on detected at ARN and GRA stations.

No significant differences were found in the lidar (extinction-to-backscatter) ratio (LR) for dust particles over all stations. LR ranged from 60 sr to 70 sr during the main dust episodes. However, AERONET retrieved LR values for dust particles are underestimated, unless a dust more realistic model is used instead in the AERONET inversion algorithm (Müller *et al.,* 2010). These similar LR values found in all the stations suggest that dust properties were kept nearly unchanged in the course of its medium-range transport.

In this work we study the changes detected in the atmospheric aerosols over the city of Granada after the arrival of lofted aerosol layers associated to the eruption of the Eyjafjallajökull volcano in 2010. The analyzed events correspond to the last part of the volcanic event, May 2010, when volcanic plumes reached the Iberian Peninsula. The study has been developed at the Andalusian Center for Environmental Studies (CEAMA), located in South-eastern Spain in the urban area of Granada, a non-industrialized medium size city (37.18ºN, 3.58ºW and 680 m a.m.s.l.).

At the CEAMA a wide variety of instrumentation deployed for the characterization of the atmospheric aerosols is running in a continuous basis. Thus, remote sounding of the atmospheric aerosol is performed by a multi-wavelength Raman lidar system, included in EARLINET (Bösenberg et al., 2003). Furthermore, columnar aerosol properties are retrieved during the day by means of CIMEL CE-318, included in AERONET (Holben et al, 1998), while during the night the atmospheric column is monitored by the starphotometer EXCALIBUR (Pérez et al., 2010). Together with this remote sensing instrumentation a set of instruments is operated in the surface boundary layer to characterize the optical, physical and chemical aerosol properties by in-situ methodologies. Thus our station includes an integrating nephelometer (TSI-3563), a Multi Angle Absorption Photometer (MAAP), an Aerosol Particle Sizer (TISI-APS-322) and a Particle Soot Absorption Photometer (PSAP). Finally, sampling of PM10 and PM1 is simultaneously performed, to determine major and trace aerosol components.

During the first half of May 2010 a good number of simultaneous measurements obtained by the diverse instrumentation above mentioned were gathered. This has allowed for determining the mean features of the atmospheric aerosol during the two relevant periods when the volcanic aerosol plumes reached our station. During the first event, 5-8 May, the lofted aerosol layers subsided and were finally mixed with the PBL aerosols. Thus, the changes in the atmospheric column, integrated and resolved, where followed by appreciable changes in the aerosol properties measured at the surface boundary layer. Lidar retrievals allowed us to distinguish at least two different lofted aerosol layers, with rather low aerosol linear depolarization ratios, ~4-8%, and different values of lidar ratio and backscatter and extinction related Ångström exponent.

Starting on the evening of 7 May the mixing of the lofted aerosol with the urban atmospheric aerosols is reflected in the in situ instrumentation operated at the CEAMA. Thus, we evidenced an increase of submicron particles associated that leaded to increasing scattering, with an unusual single scattering albedo around 0.9 for our urban station. During this period filter sampling of atmospheric particles, segregated in PM10 and PM1, has been accomplished. The chemical analyses of these filters revealed that during these days the anthropogenic aerosols followed the typical weekend trend, with an evident reduction in nitrated, organic and elemental carbon and locally re-suspended mineral matter. On the contrary we evidenced an increase in n-sss sulphates that according to the previous statements must have a non-anthropogenic origin.

During the second event, 11-13 May, lofted aerosol plumes coming from Iceland presented larger aerosol depolarization ratios, over 20%, and smaller backscatter related Ångström exponent, around 0, than in the previous event. Thus suggesting the arrival of volcanic plumes enriched in volcanic ashes. During this second event there were no evidence of mixing of the lofted aerosol plumes and the planetary boundary layer.

This study evidences the interest in combining different techniques to reach a more complete picture of the atmospheric aerosols.

In the field, aerosol in-situ measurements are often performed under dry conditions (relative humidity RH<30–40%). Since ambient aerosol particles experience hygroscopic growth at enhanced RH, also their microphysical and optical properties – especially the aerosol light scattering – are strongly dependent on RH. The knowledge of this RH effect is of crucial importance for climate forcing calculations or for the comparison of remote sensing with in-situ measurements.

Here, we will present results of an optical closure study performed within the Cloud and Aerosol Characterization Campaign (CLACE 2010) carried out at the Jungfraujoch (JFJ, 3580 m asl) and at the Kleine Scheidegg (KLS, 2060 m asl) in Switzerland during July 2010.

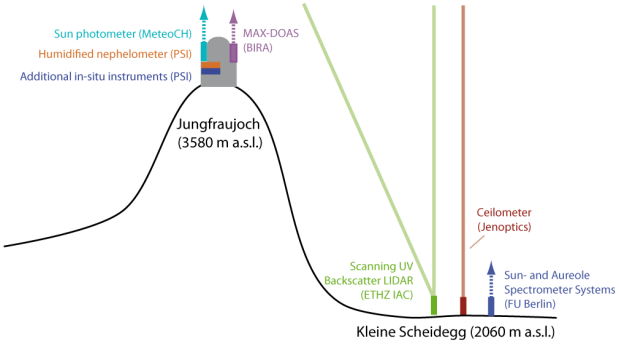

Figure 1: Set-up for optical closure study during CLACE 2010

The aerosol scattering coefficient was measured dry and at predefined RH conditions with a humidified nephelometer (WetNeph, Fierz-Schmidhauser *et al*., 2010) together with other continuously running aerosol measurements e.g. for characterizing the aerosol size distribution, the aerosol absorption, etc. at the JFJ. At the JFJ a MAX-DOAS (multi-axis differential optical absorption spectroscopy) retrieved aerosol extinction profiles (Clémer *et al*, 2010). Approximately 1500 m below the JFJ at the KLS a variety of remote sensing instruments were installed. A scanning backscatter LIDAR (light detection and ranging, by Leosphere Inc.) measured the aerosol backscatter signal together with a ceilometer (CHM 15K by Jenoptik) at 355 nm and 1064 nm, respectively. In addition, the sun and aureole spectrometer system FUBISS-ASA1 and ASA2 (Asseng et al., 2005; Zieger et al., 2007) measured among other variables the aerosol optical depth (AOD) and the slope of the phase function in the forward scattering region (aureole index) at various wavelengths in the visible and near infrared spectrum (see Fig. 1 for an overview of the set-up).

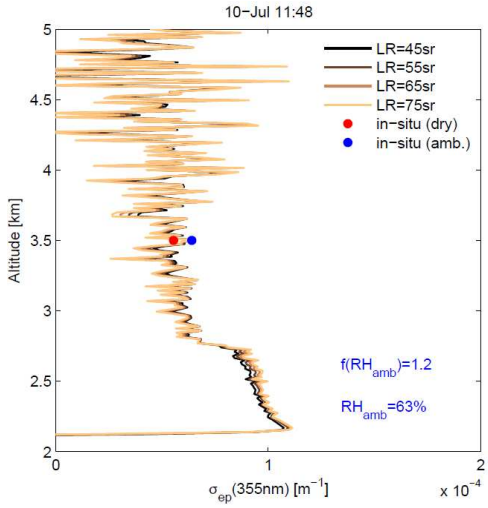

Figure 2: Example of the aerosol backscatter profile (at different LIDAR ratios LR) compared to the dry and ambient in-situ measurement at JFJ (bullet points). On the 10th of July a strong Saharan dust event was present at the JFJ.

An example of the results is seen in Fig. 2, where the aerosol extinction σ_{ep} profile as measured from KLS is shown during a Saharan dust event together with the corresponding in-situ measurements from JFJ.

This paper presents one-year dataset of Raman lidar measurements conducted at the South African EUCAARI (The European Project on clouds, aerosols and climate) site Elandsfontein (Laakso *et al.*, 2010). Previous lidar measurements have been sparse on the African continent, especially in the Southern areas.

The measurement site is located on the eastern part of Highveld, approximately 200 km east of Johannesburg at a hilltop about 1750 meter asl. Additional instrumentation provided aerosol absorption and scattering, chemical composition, number size distribution (10 nm – 10 µm), aerosol optical depth (AOD), trace gases (SO_2, O_3, NO_x, H_2S) and basic meteorology. The region has significant anthropogenic emissions especially from coal-based power production, petrochemical industry and further away, the megacity of Johannesburg. Other important sources are frequent savannah fires, especially during the dry season (June-October) and some local biofuel burning.

The lidar measurements were started on the 13th December 2009 and were stopped at the end of January 2011. The instrument in use was a seven-channel Raman lidar called "POLLY^{XT}–POrtabLe Lidar sYstem eXTended" (Althausen *et al.*, 2009). The output of the instrument includes vertical profiles of the particle backscattering coefficient at three wavelengths (355, 532 & 1064 nm) and of the particle extinction coefficient at two wavelengths (355 & 532 nm) for the whole troposphere. The vertically integrated extinction coefficient gives the AOD. In addition, such size/composition-dependent, intensive particle quantities as the Ångstrom exponents, the lidar ratio and depolarisation can be determined. The height and the evolution of the boundary layer and night-time residual layer can be defined together with the height and thickness of different cloud and aerosol layers. The depolarisation channel (355 nm) of the lidar enables us to separate spherical and non-spherical particles. Thus, we are able to identity dust particles and estimate the ratio of ice crystals and water droplets in clouds. The vertical resolution of the system is 30 meters.

The typical backscattering and extinction profiles and other properties for the seasonal aerosol will be calculated. The evaluation of planetary boundary layer (PBL) will be defined.

The local summer (Dec-Feb) had most distinct PBL evolution on most days. A very shallow aerosol layer was observed during the night and an increase up to 2-3 km during the day on average. The maximum layer thickness was about 5 km. This period was the cloudiest period of the year and in contrast, winter (Jun-Aug) was almost totally cloud free. Strong and complex multilayered structure of the aerosol was observed throughout the year, most frequently in autumn (Mar-May). Winter and partly spring (Sep-Nov) showed mostly a stable aerosol layer up to 1-3 km height. Furthermore, the diurnal variation was the weakest in winter.

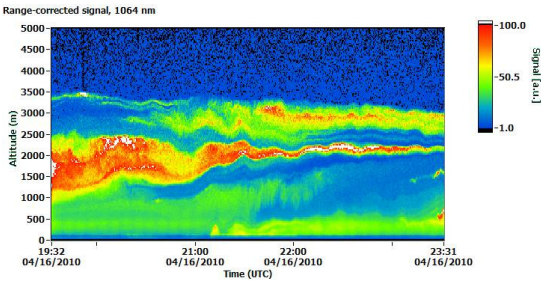

Figure 1. Multiple aerosol plumes. Four-hour time series of backscatter signal at 1064 nm from April 16th, 2010 at Elandsfontein.

Presenting author email: cristina.gutierrezcanas@ehu.es

Combined cycle power plants fuelled by natural gas are more versatile than those powered by coal or oil and, thus are becoming the key trade factor –in a daily basis- by the electric market due to the variability of renewable generation. This turns in a higher frequency of shutdowns/start-ups than foreseen by design. Transients are characterized by higher emissions of gases (CO and NO_x), but also for ultrafine and fine carbonaceous particles as a result of changing combustion conditions. Although the structural properties of flame generated soot and diesel exhaust soot (Tree *et al*, 2007; Miller *et al*, 2007; among others) have been studied intensively, investigations of soot from utility boilers have been mainly conducted on size distribution and elemental analysis. Fingerprinting the contribution of soot from natural gas combustion is possible through the identification of its nanostructure, from amorphous to graphitic and fullerenic. The characteristics of the internal carbon lamella comprising a soot primary particle are collectively called the nanostructure (Vander Wal *et al*, 2010). Soot nanostructure depends strongly on the fuel identity and synthesis conditions, such as burning temperature, residence time, fuel properties and fuel oxygen ratio, and the nanostructure in turn affects the oxidation reactivity of the soot. Chemically, soot can be distinguished by both elemental composition (trace metals) and surface functional groups.

Here are presented the results of soot characteristics along the transients of a natural gas, combined cycle, power plant. Each gas turbine is of 250 MW nominal capacity. Experiments include the follow-up of gaseous emissions (FTIR, Gasmet Oy) as well as aerosol measurement and sample collection. This has been done by means of an ELPI (Dekati, Ltd.) used both as an aerosol analyzer, providing near real-time size distributions (20 s averaging time) and as a sample pre-separator allowing soot characterization. Samples have been analyzed by TEM/SAED and image analysis (frequency plots of common morphologies versus particle size, primary particle size and number of particles in aggregates/agglomerates). TEM analysis focus on physical characteristics of carbon layers and their arrangement.

Functionalized graphitic structures have been observed around the characteristic mode of 330 nm at high NO_x. Partial oxidation of the soot by NO_2 results on oxygenated functional groups –phenolic, carbonyl and to a less extent carboxylic acid groups. Soot with well-defined graphene planes is less susceptible to oxidation. MWCNTs and fullerenic structures at high CO, up to 300 nm aerodynamic size). Non carbonaceous structures, such as metal or combined agglomerates were not observed. A few (less than 1.5% in number) carbon agglomerates decorated with metal nanoparticles were observed. During startup and shutdown periods, size distributions present a characteristic mode at 330 nm but differ in a secondary mode at 140 nm probably associated with a transient of high NO_x in the early stages of startup. In the case of shutdown, a secondary and less intense mode is consistently present at 83 nm.

A fast shift towards supermicron size ranges is characteristic of the later stages of start-up. The aggregates within this coarse fraction, in excess of 2 μm, can contain >1000 primary MWCNTs or multiconcentric fullerenic structures. These results are in accordance with the description (Homann,1998) of the pathways to large particles in flames.

Optimization of Dust Collectors in Incineration Plants to control Fine Particulate, Dioxins and NOx by using ePTFE Membranes and Catalytic Filtration Technologies

J. Ebert, G. Pranghofer and O. Petzoldt

W. L. GORE & Associates, Industrial Dry Filtration, Putzbrunn, D-85639 Germany
Keywords: Dust Removal, Filtration, Membrane, Fine Particles, Dioxin, NOx.
Presenting author email: Ole.Petzoldt@wlgore.com

Introduction

Fabric Filters are state-of-the-art to control dust emissions from incineration and other industrial processes. Two types of filtration processes are currently used in particulate filtration. Depth filtration (usually referred to as conventional filtration), and Surface filtration. Conventional filter bags require the accumulation of a dust cake inside the cross section of the fabric to be sufficiently efficient. Over time that blocks the filter and reduces its permeability. Surface Filters don't need that so-called seasoning.

Membrane Filtration

Membrane ePTFE filters, patented by W. L Gore & Associates, operate with a different filtration principle. The filter media is a microporous film of expanded Polytetrafluoroethylene, laminated to a backing material. (Figure 1).

Figure 1 PTFE Membrane Filter laminate.

In a surface filtration system the dust is collected on the membrane's surface which is a chemically inert, non-sticking material. The ePTFE membrane shows almost a 100 % efficiency to capture particulate, practically independent from the particle size, a high chemically resistivity and it is operational to 260°C with surges to 285°C. The results of the performance of membrane filters in incineration plants will be provided, including retention rates of PM 2.5, Dioxins, Heavy Metals and, in combination with sorbents, of acidic components in compliance with European Regulations.

Dioxins

Dioxins (PCDD/F) are the most toxic man made substances, emitted in gas and solid phase during incineration of waste. The permissible dioxin emissions in most industrial nations is less than 0.1 ng (I-TEQ)/Nm^3. The common system to remove dioxins is installing an injection process for powdered activated carbon; other alternatives are non-flammable additives and catalytic technologies.

Catalytic Filtration

Gore developed the REMEDIA D/F catalytic filter system. Catalytic filters consist of an ePTFE membrane that is laminated to a catalytically active felt, manufactured from ePTFE fibers which contain V_2O_5/TiO_2. Particles are captured on the membrane and dioxin/furans are catalytically destroyed within the felt (Figure 2).

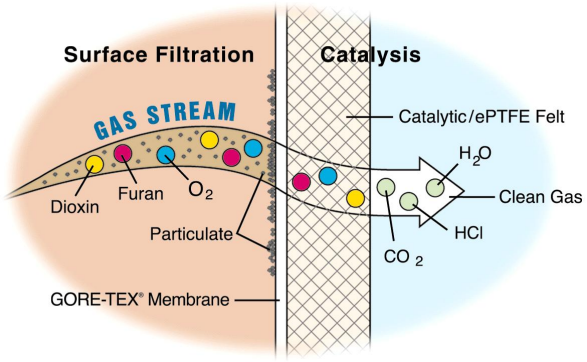

Figure 2 REMEDIA D/F Catalytic Filter System.

The catalyst fiber, which makes up the support felt, promotes the oxidation of dioxins and furans to form CO_2, H_2O, and traces of HCl. In typical industrial facilities, the system is operated at temperatures of 180°C to 250°C. The filter velocity is approximately 1 $m^3/m^2/min$, which is the usual range for cloth filters.

The system is globally used in municipal, hazardous and medical waste incinerators, crematoria, metallurgical plants and various other industrial high temperature processes. Some examples and results will be shown in the presentation

NOx

Currently Gore is developing a catalytic filter system to reduce NOx from Flue gases. Tighter regulations for NOx emissions (< 100 mg/m^3) today and in future, not only for waste incinerators but also for power plants, cement kilns, steel plants and other industrial processes, require efficient catalytic technologies to convert NOx into Nitrogen. As an alternative to ceramic catalysts, catalytic filter bags can be used. The technology and first results from pilot and full scale plants will be discussed in the presentation.

Hybrid filtration and catalytic control of toxic pollutants from a 1.2MW waste biomass cofiring boiler

Keywords: Abatement strategies, heavy metals, filtration, electrostatic precipitators, PCDD/Fs
Presenting author email: david.sanz@ciemat.es

The control of toxic trace pollutants from combustion sources requires enhanced and selective mechanisms of both separation and abatement. In this work, the performance of a line (Fig. 1) combining enhanced surface filtration together with catalytic, and thus selective abatement is presented. So-called "hybrid filters" combine electrostatic precipitation and surface filtration in different arrangements (Miller, 2003). We present the performance of a pilot scale hybrid filter as the core of a process line, treating 1000 Nm^3/h of flue gases from a 1.2MW fluidized bed boiler. Moreover, the media substrate is chemically active for it contains a catalyst for PCDD/Fs destruction (Fritsky, 2001). REMEDIA™ bags consists of an ePTFE membrane laminated over a catalytic felt substrate. Targeted chemical conversion implies an operation temperature of about 200ºC.

Biomass wastes will be burnt in a fluidised bed boiler. Samples will be taken upstream and downstream the filter (Figure 1) to determine the removal efficiency of dioxins, heavy metals, particulate matter and trace gases.

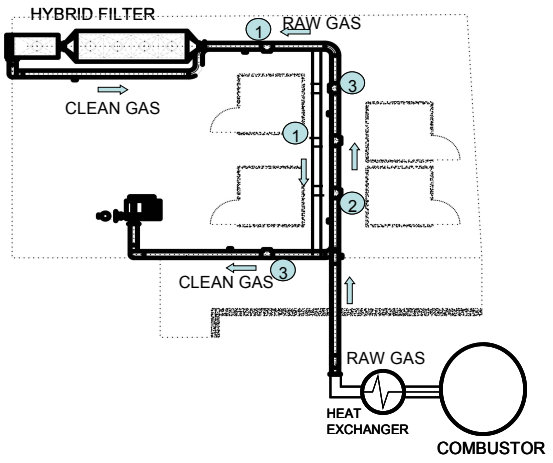

Figure 1. Validation test line lay-out. Sampling ports for aerosols (1), dioxins (2) and gases (3)

Fuel screening has been made on the basis of chloride and heavy metals content (Figure 2). Ash content, humidity, calorific value and elemental composition (C, N, S) were also determined. Municipal sewage sludge and animal meal show higher chloride and mineral content. Heavy metals content of sludge is the highest, except for titanium. Olive tree pruning residue has the second highest content in copper, due to phytosanitary treatments. Copper is relevant to PCDD/Fs formation because of its catalytic promotion of PCDD/Fs and its presence within the penetration window of conventional electrostatic precipitators (Peña, 2009).

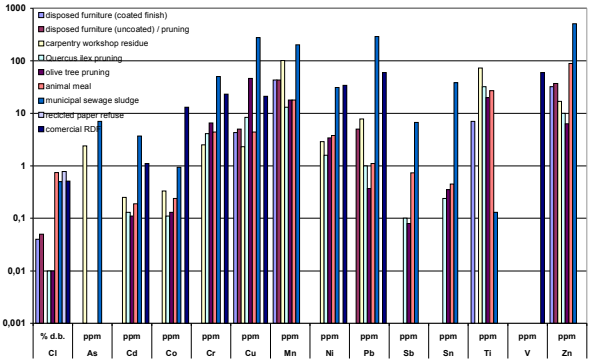

Figure 2. Chloride (%) and heavy metal (ppm) content of potential test fuels.

A test matrix was planned, focusing on the more relevant operating conditions: gas flow rate, temperature and applied voltage to the ESP. Two different fuels are used in the tests, a mixture of municipal sewage sludge/olive tree prune and refuse from recycled paper. Experimental results include: emission dynamics and its relationship with operating conditions, physicochemical characterization of fine and ultrafine particles as well as determination of trace gases concentration. Fractional efficiency of the hybrid filter and conversion of PCDD/Fs will be discussed as dependent on fuel quality and operating conditions. The feasibility of advanced control technologies for trace and toxic pollutants will be demonstrated on the basis of these findings.

Authors are thankful to Minestery of the Environment and Rural and Marine Affairs of Spain for funding of this work. Thanks are also given to ASERMA (Asociación de Recuperadores de Madera) and Energía Oriental S.A. for facilitating samples of potential test fuels.

In the past (Lorentzou *et al*, 2009), we have introduced a Multi-Functional Reactor (MFR) prototype, suitable for the abatement of the gaseous and PM emissions of the Diesel engine. In this work, the performance of MFR prototypes under both conventional and advanced combustion engine operating conditions is presented. The MFR comprised two novel aspects: a system design which exploits internal heat recovery and a multifunctional catalyst able to enhance the direct soot oxidation rate (i.e. through oxygen transfer) and the indirect (NO_2-assisted) soot oxidation rate as well as to promote CO and HC oxidation.

The MFR demonstrated faster thermal response and more even in-filter temperature distributions during regeneration conditions compared to a standard filter. The employed catalyst synthesis and application technology consisting of a combination of aerosol based and wet chemistry techniques enabled the increase in the direct soot oxidation activity and filtration efficiency with respect to a reference state-of-the-art (SA) DPF. The pressure drop during soot loading was kept at comparable to the SA DPF level. Moreover, the MFR demonstrated significant HC/CO oxidation activity while minimizing the NO_2 emissions during conventional combustion conditions.

An aging procedure was applied on the MFR (equivalent to 100,000 km of normal vehicle driving). This did not result in losses in its catalytic activity and filtration efficiency. It caused an increase in the filter pressure drop by nearly 20 % mainly due to ash particles accumulation. MFR simulation results indicated that significant economy can be achieved with respect to the fuel consumption related to filter regeneration (up to 45.2 % during NEDC driving conditions). This gain comes from the fact that the developed catalyzed filter can be sufficiently regenerated at lower temperatures (550 ^{o}C) than the SA DPF. Besides the fuel consumption gain, there are additional advantages such as less engine wear due to in cylinder oil-dilution during fuel post injection as well as enabling filter regeneration at lower engine load conditions. Significant fuel savings were also realised during alternative to NEDC driving cycles (Figure 1).

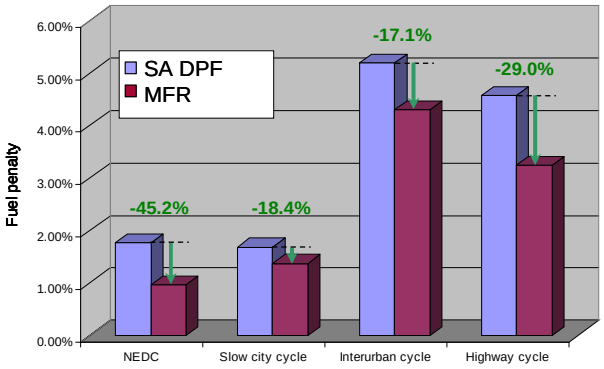

Figure 1. Calculated fuel penalty due to filter regeneration for different driving cycles.

The MFR was also tested under Homogeneous Charge Compression Ignition (HCCI) engine operating conditions. The MFR revealed equivalent performance under both conventional and HCCI engine operation conditions with respect to filter pressure drop, filtration efficiency and regeneration performance. The microstructural properties of the soot cake evolved at either conventional or alternative combustion conditions were equivalent. The catalyst soot oxidation activity was not affected by the applied combustion type either. This came into contrast with the fact that soot analysis from both types of combustion revealed differences with respect to the soot particles' micro-structure and easy of oxidation. The HCCI soot, with increased hydrogen content compared to the conventional soot, is oxidized at lower temperatures under TGA conditions. Moreover, HCCI engine operation resulted in soot particles that in some cases are quite different than the conventional soot particles demonstrating a core with a distinguished outer shell structure. These core/shell particles were the first to be eliminated during oxidation. Raman analysis, on the other hand did not quantified any significant differences in the degree of structural organization of the samples. As a conclusion, the possible differences recognized by TEM and TGA analysis did not seem to result in any performance differences at the catalyzed monolith scale.

Session 10D: Turbulent Aerosol Transport and Exchange / Transport and Transformation

Vertical transport of aerosol particles in the marine boundary layer near Barbados

B. Wehner, F. Ditas, A. Wiedensohler, H. Siebert

Leibniz Institute for Tropospheric Research, 04318 Leipzig, Germany

Keywords: nucleation, turbulence, vertical profiles

The number concentration of aerosol particles is highly variable in different layers of the boundary layer and the overlaying free troposphere. Vertical transport of particles is mainly caused by atmospheric turbulence which might be also relevant for the transformation of aerosol particles as well as new particle formation. To quantify the turbulent transport, measurements of particle number concentrations and vertical wind speed are required. The temporal resolution of available instrumentation defines the minimum of turbulent structures which can be resolved.

In contrast to wind speed measurements, where a high temporal resolution up to 100 Hz can be achieved by commercially available instrumentation, measurements of the particle number concentration with a higher resolution than 1 Hz are still rare. Thus, a new fast mixing-type CPC (FCPC) with a temporal resolution of approximately 20 Hz (Wehner et al., 2010) was constructed. This instrument has been installed on the helicopter-borne platform ACTOS (Siebert et al., 2006). ACTOS is equipped with instrumentation to measure standard meteorological parameters with a high temporal resolution as well as cloud and aerosol microphysics.

Here, measurements from the CARRIBA (Clouds, Aerosol, Radiation and tuRbulence in the trade wInd regime over BArbados) experiment in November 2010 will be presented. Within the campaign 17 research flights in the cloudy and cloud-free marine boundary layer have been performed.

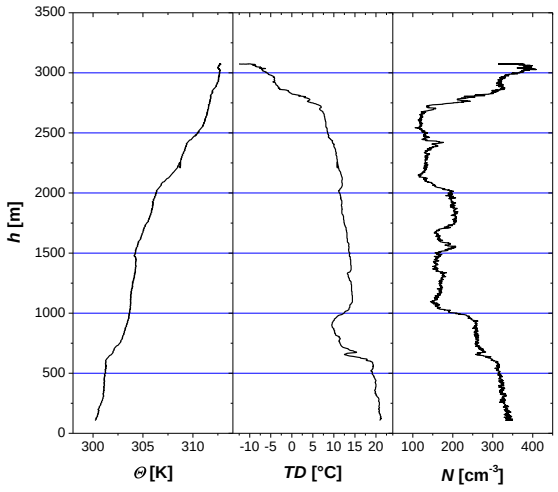

Figure 1: Vertical profiles of the potential temperature Θ, the dewpoint temperature *TD*, and total particle number concentration *N* during ascent on November 21, 2010.

Figure 1 shows a vertical profile of potential temperature Θ, dewpoint temperature *TD*, and particle number concentration *N* measured on November 21, 2010 under cloud-free conditions. The profile of Θ illustrates a slight inversion at about 600 m, but also in higher altitudes regions with a slightly positive gradient of Θ, e.g. at 2500 m can be detected. The corresponding profile of *N* also shows the presence of different layers characterized by different particle number concentrations.

In addition to the vertical profile several horizontal legs were flown in different heights. As an example, Fig. 2 shows the fluctuations of particle number concentration during a horizontal flight leg in a height of about 100 m with meter resolution which is unique for airborne measurements so far.

Together with the measurements of vertical wind speed fluctuation, these observations will allow us to make the first direct estimates of the vertical turbulent flux of aerosol at different heights in the marine boundary layer by applying the so-called "eddy covariance method".

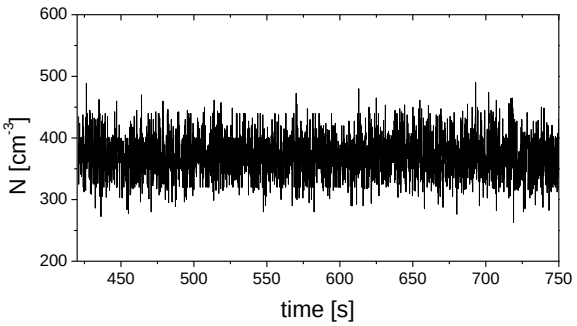

Figure 2: Time series of variation of particle number concentration with a 10-Hz resolution during a horizontal flight leg at around 100 m above sea surface.

Analysis of particles and CO_2 fluxes in an urban area: correlation with traffic rate and micrometeorology

D. Contini, A. Donateo, C. Elefante, F. M. Grasso

Institute of Atmospheric Science and Climate (ISAC-CNR), 73100, Lecce, Italy
Keywords: eddy-correlation, urban pollution, aerosol flux, CO_2 flux
Presenting author email: d.contini@isac.cnr.it

The study of urban aerosol and carbon dioxide sources is important for their potential effects on health and climate. The aim of this work is to quantify and parameterise the particle number and the CO_2 fluxes through the analysis of correlation with traffic rate, atmospheric stability and friction velocity. This could help to improve how the urban sources are included in air quality and climate models. Further, the differences in the dynamics of CO_2 and particles will be investigated.

A micrometeorological station was located on the corner of a roof of a school at 14m (above street level) on the town of Lecce (Italy) at 40°21'18" N - 18° 9' 59" E. Instruments were located above a four-lane road with relatively high traffic rate (T_R, up to 2400 vehicles/hr). The station included a Gill R3 ultrasonic anemometer, a CPC (Grimm 5.403), a CO_2/H_2O fast open-path detector (LIcor-LI7500), a thermo-hygrometer (Rotronic MP100) and a telecamera. All instruments were synchronously operated by the PC that also provided control of the telecamera used for counting vehicles passing in the main road using a motion detection software. The accuracy of the measurement of T_R was +/- 10%. Aerosol was sampled through a 2.5m inlet (26 mm in diameter with a 45 l/min flow-rate). Calculation of losses indicate that the system was able to detect particles in the size range between 9nm and 1000nm with a first-order time response of about 1.3s.

Post-processing of data was performed on 30mins averages in the streamlines reference system. Correction of high frequency losses have been performed as in Contini et al (2010). The median correction is 29% (Inter-quartile range 25-75, IQR=19% - 40%). Non stationary data were removed corresponding to 9.2% for both aerosol and CO_2. Data in the wind direction sector between E and SW were removed to limit the interference of the school building. In this sector, the site was characterised, using Digital Elevation Model described in Di Sabatino et al (2010), in a radius of 1km covering all footprint for fluxes and most of the footprint for concentration, by buildings with an average height of 7m +/- 4.6m. Globally the building covers 35% of the area.

Significant differences were observed in fluxes between weekdays (average 28200 vehicles/day) and weekend (average 25600 vehicles/day). In weekdays diurnal hours (06am-21pm) median aerosol fluxes (F_P) was 99127 $cm^{-2}s^{-1}$ (IQR=65207 – 133762 $cm^{-2}s^{-1}$) and median CO_2 flux (F_C) was 0.00086 $gm^{-2}s^{-1}$ (IQR=0.00049 – 0.00149 $gm^{-2}s^{-1}$). In nocturnal hours and weekend the median F_P was 26731 $cm^{-2}s^{-1}$ (IQR=7555 - 60201 $cm^{-2}s^{-1}$) and median F_C was 0.00022 $gm^{-2}s^{-1}$ (IQR=0.00022 – 0.00044 $gm^{-2}s^{-1}$). There is a clear correlation between fluxes and T_R (as shown for Fp in Figure 1). The relationship between F_P and T_R is almost linear (in the range of T_R analysed); similar results were obtained for CO_2 with $F_C=4.51\ 10^{-7}\ T_R$ ($R^2=0.938$). Overall there is a low correlation between F_P and F_C (for 30 minutes averages the Pearson coefficient is 0.56). Specifically Fp and Fc have a different diurnal pattern with Fc presenting a low flux in the middle of the day likely as a consequence of photosynthesis. This is evident also on correlation of concentration fluctuations that have a typical pattern with a decrease of correlation around midday and an increase of correlation at the rush hours (maximum of T_R). The emission ratio F_P/F_C has a median value of $9.16*10^{11}$ particles/g (IQR= $9.16*10^{11}$ – $1.60*10^{12}$ particles/g). The normalised flux F_P/T_R shows a clear increase when the friction velocity increases; further, there is a correlation with stability parameter $\xi = (z-d)/L$ showing an increase going from stable to neutral and unstable conditions. These correlations will be investigated and compared with results obtained in other cities (Dorsey et al., 2002; Jarvi et al., 2009).

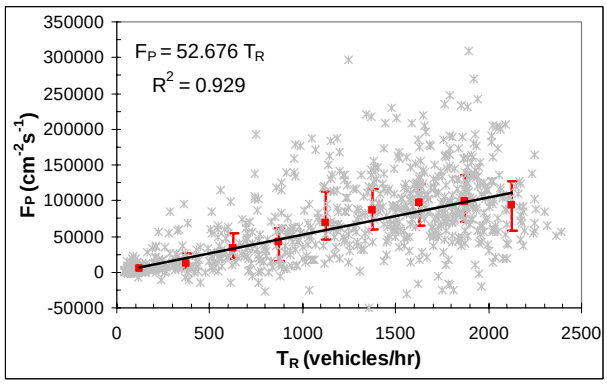

Figure 1. Aerosol fluxes against traffic rate. Red squares are median values calculated in bins of 250 vehicles/hr and error bars represent the IQR.

Highly size resolved particle fluxes over an urban area

M. J. Deventer, F. Griessbaum and O. Klemm

Climatology Working Group, University of Münster, 48148 Münster, Germany
Keywords: fluxes, turbulence, urban aerosols, size distribution.
Julian.Deventer@uni-muenster.de

Cities are both sources and sinks for atmospheric aerosol particles. The input of particulate material from the regional background is mostly established through aged accumulation range particles. The emissions originate from combustion processes, yielding large numbers of nano-sized particles, and from re-suspension of coarse particles from the urban surfaces. Size-resolved measurement of turbulent particle fluxes by using the eddy covariance technique is an appropriate tool to study these bi-directional fluxes. A preliminary study showed that emission of ultrafine particles may co-occur with deposition of particles in the micrometer range. This is equivalent to the simultaneous occurrence of positive (upward) number fluxes and negative (downward) mass fluxes (Schmidt and Klemm, 2008).

For this study, we employ two fast aerosol particle spectrometers, a Ultra-High Sensitivity Aerosol Spectrometer (UHSAS) covering the size range between 60 nm and 1 µm diameters, and a Passive Cavity Aerosol Spectrometer Probe (PCASP-X), ranging from 0.1 µm to 10 µm diameter, both from Droplet Measurement Technologies, Boulder, CO, USA. The instrument combination covers the entire size range in over 100 size bins. This will allow the detailed study of aerosol dynamics within the urban boundary layer. Processes are analyzed in combination with the exchange fluxes of sensible heat, water vapor, and carbon dioxide (CO_2).

The measurements are conducted at a 65 m high telecommunication tower in the city of Münster (population ~ 275.000), NW Germany. The tower has been extensively evaluated on its flow distortion effects on turbulent flux measurements (Griessbaum and Schmidt, 2009), by using the large eddy simulation (LES) code Gerris (http://gfs.sourceforge.net/). The well defined site (Schmidt and Klemm, 2008, Schmidt et al., 2008, Dahlkötter et al., 2010) is influenced by traffic, industrial sources, vegetation, and long range transport.

The presentation will show results of highly size resolved turbulent particle flux measurements, obtained during the 2011 field campaign.

This work is supported by the Deutsche Forschungsgemeinschaft (DFG) under grant KL 623 / 12-1.

Transport and mixing of aerosols due to highway-generated turbulence

M. Gordon[1], R.M. Staebler[1], J. Liggio[1], J. Brook[1], S.-M. Li[1], J. Wentzell[1], C. Mihele[1], G. Lu[1], and P. Lee[1]

[1]Air Quality Research Division, Environment Canada, Toronto, Ontario, M3H 5T4, Canada
Keywords: Traffic emissions, Turbulence, Aerosol measurement, Air quality
Presenting author email: mark.gordon@ec.gc.ca

Primary and secondary aerosols from traffic emissions can have a considerable impact on local and regional air quality. Often, the inventories which provide emissions input for the air quality models rely on laboratory testing of individual vehicles under non-ambient conditions. However, on the sub-grid scale, turbulence induced by both highway structure and traffic flow will modify the gradient of aerosol concentration and influence particle evolution. This may lead to rapid changes in the aerosol size distribution in the first few seconds after emission. These effects are missing from air-quality models, and a careful analysis of field data is necessary to quantify their impact.

A study of the sub-grid evolution of aerosols (FEVER; Fast Evolution of Vehicle Emissions from Roadways) was conducted in the Toronto area in the summer of 2010. The study included mobile measurements of turbulence using two sonic anemometers and an aircraft turbulence probe (AIMMS-20, which also measured GPS and inertial motion sensing), particle size distributions with a Fast Mobility Particle Sizer (FMPS), aerosol composition with an Aerodyne aerosol mass spectrometer (AMS), black carbon (SP2), VOCs (PTR-MS) and other trace gases. Stationary sites upwind and downwind of the highway measured wind speed, turbulence, particle size distributions with a Scanning Mobility Particle Sizers (SMPS), and traffic density, composition, and speed. On-highway measurements were also made to characterize the generation of turbulence according to vehicle type.

Turbulent kinetic energy (TKE) was measured with a stationary sonic anemometer located at the side of the highway. As wind changes direction, the time taken for an air parcel crossing the road to reach the measurement point also changes. Hence, the stationary measurements can demonstrate the reduction in TKE with increasing time from the road, as shown in Fig. 1. The mobile lab was driven perpendicular to the highway to sample air at varying distances downwind. TKE measurements from the mobile lab are compared to stationary TKE measurements in Fig. 1, demonstrating a good agreement.

Size distributions measured with an FMPS on the mobile lab were binned by time from the road, as shown in Fig. 2. These distributions demonstrate the dilution of the three modes with increasing time (and distance) from the highway. These results are taken from transects during a morning rush hour. Analysis of 23 other morning and evening rush-hours is currently underway to investigate the dilution rates of different modes and changes in particle diameter with distance from the highway.

These preliminary results demonstrate a strong enhancement of turbulence near the highway. On-road measurements and investigation of TKE as a function of traffic density and vehicle type suggest that the enhancement of turbulence is primarily due to heavy vehicles. This enhanced turbulence influences aerosol concentration, and may influence size and composition. Ongoing analysis is underway to parameterize highway-generated turbulence as function of traffic type and density and to investigate the effect of turbulence on the physical and chemical evolution of aerosols.

Introduction

In the case of an accidental or chronic atmospheric pollution by a nuclear plant, aerosols deposition transfer coefficients must be known. A major issue is to determine the impact of aerosols contained in the radioactive plume on urban areas. In dry atmospheric conditions, transfer coefficients are defined by the dry deposition velocities Vd ($m.s^{-1}$), the ratio between the aerosol vertical dry deposition flux ($particles.m^{-2}.s^{-1}$) and the concentration of aerosols ($particles.m^{-3}$; Seinfeld and Pandis, 1998). Dry deposition velocities are dependent on atmospheric turbulent conditions and surface roughness. Actually, for urban surfaces, only a few dry deposition velocities were measured, in field or in laboratory environments. Moreover, existing data are not linked with atmospheric conditions (Fowler *et al*, 2009). Therefore, it is important to improve the knowledge and the models on urban areas.

The aim of this wind tunnel study was to quantify, experimentally, dry deposition velocities for a submicron aerosol on three different urban surfaces, for three different wind speeds (U_{ref}). We measured also air turbulence intensities and friction velocities U_* in the wind tunnel.

Test equipment and methods

Experiments were conducted in April 2010 in the IRPHE closed-circuit wind tunnel (8.7 m x 0.7 m x 0.3 m). Dry deposition has been studied successively on glass, cement facing and synthetic grass with U_{ref} equals to 1.3, 5.0 and 10 $m.s^{-1}$. The bottom of the tunnel was totally recovered with each type of studied surface to develop the characteristic boundary layers. Deposition velocities were measured at three distances from the tunnel entrance (1, 5 and 7 m). A monomodal polydisperse submicron fluorescein aerosol, representing the accumulation mode of the atmospheric aerosol, was generated and injected in the wind tunnel (Maro *et al*, 2010). Spectrofluorimetric measurements of deposited aerosols on squares of each urban-type surface gave deposition fluxes. Spectrofluorimetric measurements of aerosols taken on filters gave aerosol concentrations in the wind tunnel.

Turbulence intensity, friction velocity and air velocity measurements were made by hot wire anemometry at three distances (1, 5 and 7 m) for each type of surface and at the three flow velocities U_{ref}.

Results and discussions

Friction velocity increased with wind speed and surface roughness. This study showed a significant increase of the deposition velocity with the surface roughness and with the wind speed (figure 1). But the increase due to surface roughness was much more important than the increase due to wind speed.

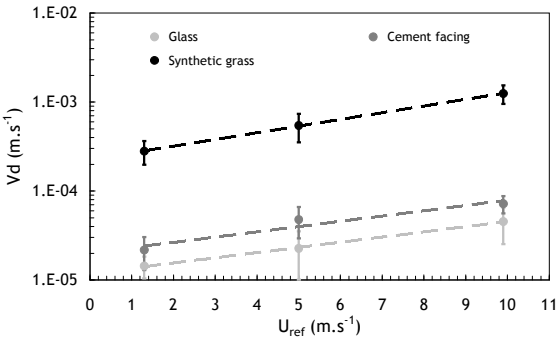

Figure 1. Dry deposition velocity Vd function of air flow velocity U_{ref}.

We found also that the ratio between deposition velocity and friction velocity on each surface was not constant (Table 1).

Table 1. Mean Vd/U_* ratio function of substrate

Substrates	Vd/U_* ($.10^{-3}$)
Glass	0.05 ± 0.05
Cement facing	0.11 ± 0.05
Synthetic grass	1.2 ± 0.3

These experiments in wind tunnel are the first step of a future study on the dry deposition in urban areas. The next step will be *in situ* experiments to take into account all the atmospheric parameters existing in urban environments.

Session 10E: Spark Generators for Nanoparticle Generation

Generation of Au-Ge nanocomposites by spark discharge

S. Kala, F.E. Kruis and R. Theissmann
Institute for Nanostructures and Technology, Faculty of Engineering Science and Center for Nanointegration Duisburg-Essen (CeNIDE), University of Duisburg-Essen, Duisburg, 47057, Germany
Keywords: composite nanoparticles, aerosol generation
Presenting author email: shubkala@gmail.com

Spark discharge has been succssfully applied to generate metallic nanoparticles (Schwyn et al., 1988). However, this technique is not fully explored to synthesize metal-semiconductor (M-S) nanocomposites, which is indeed a challenging task. M-S nanocomposites allow to manipulate the physical, chemical, optical and mechanical properties of the resultant material via an interaction between metal and semiconductor atoms. Optical coupling of semiconductor nanoparticles with metal nanoparticles can be a viable route to modify the spectral features of semiconductor nanoparticles or vice versa. For example, surface plasmon resonance of Au nanoparticles can be utilized to enhance the emission of semiconductors nanoparticles (Bassu et al., 2010).

In this study, the ability of the spark discharge technique to prepare M-S nanocomposite is demonstrated. To prepare M-S nanocomposite, conditions of electrical breakdown are created between Au, which is connected to high voltage supply with positive polarity and Ge, which is grounded. Electrical breakdown between Au and Ge, which act like anode and cathode, respectively, occurs at ~ 4kV. On electrical breakdown, both Au and Ge evaporate and which on subsequent cooling in the carrier gas (high purity N_2) form a mixture of Au and Ge nanoparticles by nucleation and condensation. The size-distribution of the generated mixed particles is monitored by a scanning mobility particles sizer on varying the carrier gas flow rate (1-10 slm) and charging current (1-10mA), leading to spark frequencies between 8 and 120 Hz. As the cathode material experiences more erosion, therefore, in the generated mixture the atomic percentage (at.%) of Ge must be larger than Au. However, on changing the spark frequency from 8 to 120 Hz, atomic ratio of Au:Ge is found to be vary largely from 2:98 to 70:30 in the generated mixtures (shown in Table 1), as measured by energy dispersive x-ray spectroscopy. The large change in the at.% of Au in the generated mixture with the increase in spark frequency is found to be due to voltage reversal during discharging.

Table 1. Atomic percentage of Au and Ge in the AuGe mixture generated at different charging current/spark frequencies

Current (mA)	Spark frequency (±error)	Atomic %	
		Au	Ge
1	8 (±4)	2.20	97.80
2	21 (±8)	3.29	96.71
5	55 (±10)	16.96	83.04
7	74 (±10)	30.09	69.91
10	120 (±5)	70.02	29.98

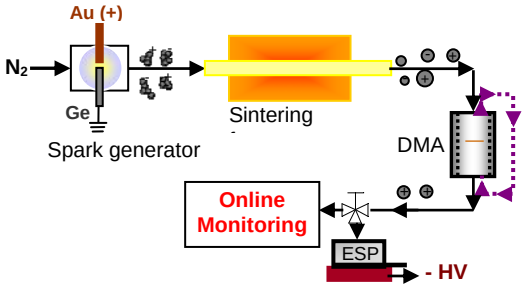

Figure 1. Schematic representation of different components utilized to prepare AuGe nanocomposites.

To convert the AuGe mixture into more defined composite nanoparticles, additional sintering and size-selection steps have been included, as shown in Figure 1. AuGe mixture generated (with carrier gas flow of 2 slm) at 55 and 74 Hz spark frequencies are first sintered at 900°C then size fractionated by a differential mobility analyzer (DMA) (with sheath gas flow of 20 slm). Size-selected nanocomposites of mobility diameter of 20 nm prepared with a frequency of 55 Hz, revealed that AuGe alloy nanoparticles of sizes 1-6 nm are embedded in the Ge matrix (Figure 2(a)). The size of the embedded AuGe alloy particles in the Ge matrix is found to increase up to 10-20 nm as shown in Figure 2(b), if prepared with a frequency of 74 Hz.

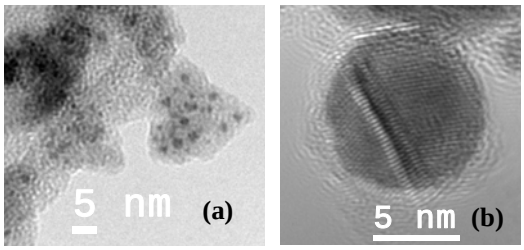

Figure 2. HRTEM images of synthesized AuGe nanocomposites prepared at spark frequencies of (a) 55 and (b) 74 Hz.

Due to the huge economic and environmental rewards, one major goal in catalysis related research is to create cheaper catalysts. As catalysis happens on the surface of the catalyst, one possible way to realize this would be to dilute the more expensive active material with a less costly one, providing that the active material stays at the surface. This could be achieved by using a material which is less prone to interact with the reactant gases, such as a cheaper noble metal. In most catalysts, the active material is dispersed in a high area complex oxide support as nanoparticles. In order to maintain the high activity, it would be necessary to ensure that the active material is at the surface of the nanoparticle.

In the present contribution we investigate whether this approach towards cheaper catalysts is viable. We report on our findings from attempts to produce PdAg alloy particles using aerosol generation and deposition. The use of PdAg is motivated by the fact that Pd segregates to the surface in the presence of a reactive gas while Ag segregates in ultra-high vacuum (UHV) and that Ag is considerably less expensive than Pd.

Agglomerate PdAg nanoparticles were generated by a commercial spark discharge generator, using one Pd and one Ag electrode. In order to enable size-distribution measurements, reshaping of the agglomerate particles, and controlled depositions of the produced particles, the spark generator was connected to an aerosol nanoparticle system (Messing *et al.*, 2009; Messing *et al.*, 2010). This system includes a neutralizer, a tandem-DMA setup for size selection and size distribution measurements, a compaction furnace for reshaping of the particles and an electrostatic precipitator for controlled deposition of the particles. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), x-ray energy dispersive spectrometry (XEDS) and high pressure x-ray photoelectron spectroscopy (XPS) have been carried out to thoroughly characterize the PdAg particles.

TEM images reveal that most particles are single crystalline, with a thin amorphous shell. From XEDS the composition are measured to approximately 75 atomic% Pd and 25 atomic% Ag. In Figure 1 Ag $3d_{5/2}$ core level XPS spectra from the PdAg particles are compared to the corresponding spectra of a $Pd_{75}Ag_{25}$ (100) single crystal and a (110)-oriented Ag crystal. The Ag $3d_{5/2}$ binding energy for the nanoparticles compares well with the bulk contribution for $Pd_{75}Ag_{25}$ (100) which in turn is shifted by 0.5eV relative to the bulk value in pure Ag. From this observation, we therefore conclude that the PdAg alloy particles consist of a proper alloy and not Ag and Pd in separate phases. In addition, corresponding Pd 3d spectra strongly indicate that the active Pd is present at the surface of the PdAg particles in the presence of reactant gases.

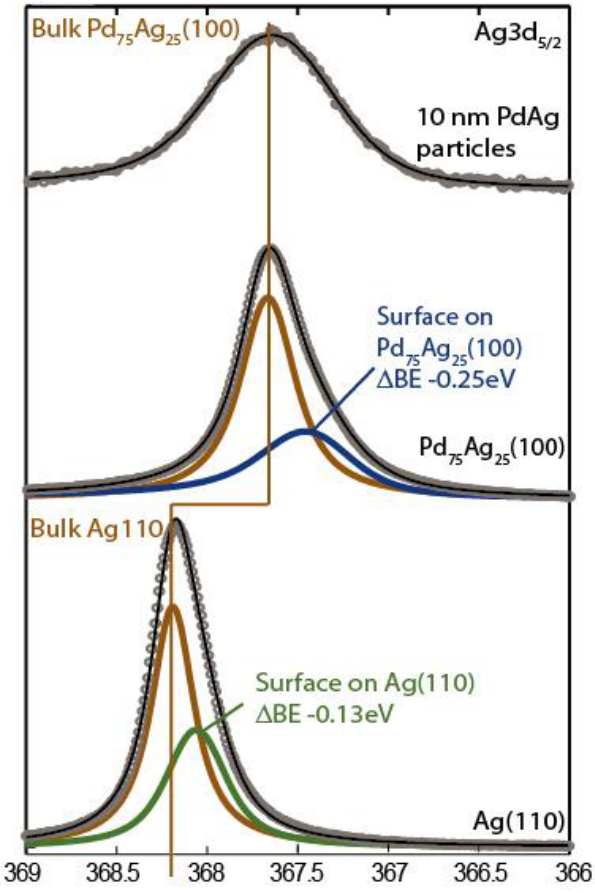

Figure 1. Ag $3d_{5/2}$ core level spectra from Ag(110), $Pd_{75}Ag_{25}$(100) and the aerosol PdAg particles.

Direct Synthesis of Magnesium Hydride using Spark Discharge

Presenting author email: t.v.pfeiffer@tudelt.nl

Magnesium hydride is a promising cheap hydrogen storage material, with a high gravimetric storage capacity. A major drawback is the high stability of magnesium hydride, which leads to high desorption temperatures. A possible solution to this problem could be the use of the orthorhombic γ-MgH_2 phase, which shows a desorption temperature 64 K lower than the regular β-MgH_2 (Huot, 2001). However, this particular metastable phase typically only forms at pressures in excess of 8 GPa and disappears after dehydrogenation, which so-far limits its usefulness in automotive applications.

Spark discharge is an aerosol-based nanoparticle production method, in which target electrodes are ablated by repetitive capacitive high-voltage discharges. The formed vapour rapidly condenses in a flow of inert gas to form nanoparticles. The high quench rates on the order of 10^7 K/s allow for the formation of non-equilibrium phases or amorphous structures. This research aims to provide a means of producing nanoparticulate metastable hydrides in aerosol form.

Experimental

Hydrided magnesium nanoparticles were synthesised *in situ* by the spark discharge method. Two magnesium electrodes were used in a flow of Ar containing 5% H_2 (figure 1). To limit oxidation, the setup is built using UHV-grade components, and water and oxygen are removed via absorbent columns. With this method it is possible to produce Mg nanoparticles with reversible hydrogen storage properties and limited MgO formation, as described in detail by Vons (in press).

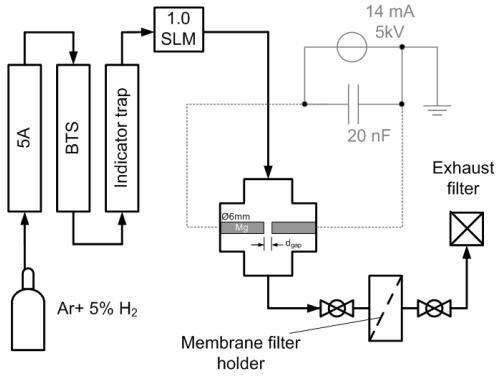

Figure 1. Spark discharge setup.

Structural analysis of the as-produced powders was performed using XRD and TEM. The hydrogen storage properties were evaluated using Thermal Desorption Spectroscopy and Sievert's analysis. The maximum temperature was set to 473 K in order to limit re-crystallization within the sample.

Results

XRD of the as-produced powders shows a strong amorphous signal, and further small broadened peaks corresponding to the Mg, MgO and β-MgH_2 phases. After 21h of desorption, the hydride phase is fully replaced by metallic magnesium.

During TEM imaging, the particles change shape and size, probably due to dehydrogenation caused by the electron beam. In addition to the highly agglomerated primary particles typically observed in spark discharge, large (~100nm) continuous domains are formed. There is no evidence of core-shell structures as reported by Förster (2010) for copper in mixtures of nitrogen and hydrocarbons, indicating that a different mechanism for particle formation is at play here.

Hydrogen desorption tests were performed directly on the powders, without any prior activation or charging steps. The desorption rates are surprisingly high for the low temperatures used, despite the absence of a catalyst. The cycling behaviour is currently under investigation. The hydrogen content of the as-produced powders ranges from 0.05-0.7 H/Mg. No suitable explanation for the observed variation in the hydrogen concentrations has been found so far.

Conclusion

Magnesium hydride nanoparticles were synthesised at atmospheric Ar/H_2 pressure from metallic magnesium using spark discharge. The uncatalyzed as-produced metal hydride is mostly amorphous, and can be dehydrogenated at temperatures below 473 K.

Self-charge Distribution of Nanoparticles Generated by Spark Discharge

K.Barmpounis[1,2], T.V. Pfeiffer[1], V.A.Vons[1], G. Biskos[1,2], A. Schmidt-Ott[1]

[1]Department of Chemical Technology, Delft University of Technology, Delft, 2628-BL, The Netherlands
[2]Department of Environment, University of the Aegean, Mytilene, 81100, Greece
Keywords: Spark discharge, charge distribution.
Presenting author email: K.Barmpounis@tudelft.nl

Introduction

Spark discharge generators are widely used for a controllable and stable production of high-purity aerosol nanoparticles (Schwyn, 1988). The mechanism of particle formation is an evaporation/condensation type process based on a capacitive spark discharge between two target electrodes. The energy contained in the capacitor is discharged in μs time fractions, resulting in localized rapid heating of the electrode surface. Material evaporating from the electrode surfaces is immediately quenched in a flow of inert carrier gas. As the temperature of the vapours decreases downstream the spark discharge region, they coalesce to form atomic clusters that grow to bigger primary particles.

Plasma created in the spark contains charge carriers that determine the charging state of the produced particles. While little is known about the mechanics of the charging process, it appears to favour the charging of small sub-10 nm particles as compared to the Boltzmann equilibrium distribution (Tabrizi 2008). Knowledge of the charge distribution is of great importance because combination of spark generators with mobility classifiers can lead to the production of well-defined nanoparticles. In this work, we report measurements of the charge distribution of Mg particles, produced by a spark discharge generator.

Experimental

Particles from the spark generator are produced in carrier gases of different purity. In the first case (low-purity system), Ar 5.0 is used to run the generator directly from the bottle. In the second case (high-purity system), the Ar 5.0 gas is purified by passing it first over an A4 water-absorbing molecular sieve and an oxygen-absorbing copper catalyst.

Measurements of the charge distribution of the generated particles are performed using a Tandem Differential Mobility Analyzer (TDMA) (Rader and McMurry,1986) coupled with a condensation particle counter (CPC) and an aerosol electrometer (AEM). Particles from the spark generator are passed through the 1st DMA and then through a Kr-85 neutralizer before measuring their mobility distributions by the 2nd DMA and the CPC. Charge distributions on particles of different size are then determined by comparing the mobility distributions with and without the Kr-85 neutralizer**.**

Results

Size distribution measurements of particles produced from Mg electrodes in the high-purity system showed a higher production of positively than negatively charged particles (cf. Fig. 1). Depending on the capacitor charging current, the ratio of positive versus negative particles varied from 8 to 17. For Mg particles generated in the low-purity system this ratio was found to be approximately equal to unity (data not shown here).

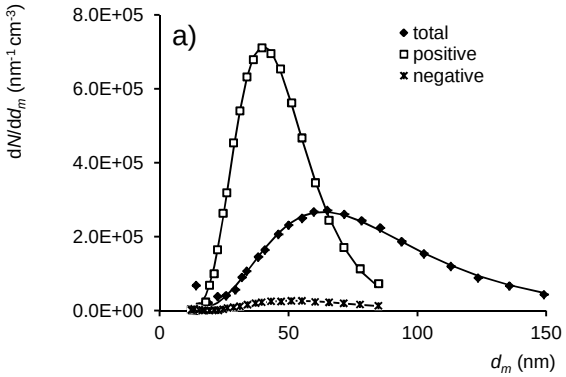

Figure 1. Positively and negatively self-charged Mg particles in purified gas and the total size distribution measured with a neutralizer, at a capacitor charging current of 9 mA. Lines represent lognormal fits to the data.

The high ratio of the positive to negative particles, in the case of high-purity system, can be explained by the absence of water and O_2 molecules. In low-purity gases these molecules capture free electrons, forming negative charge carriers which contribute to the formation of negative particles. In low-purity gases, less electrons are captured by these electronegative species, and the high electron mobility coupled to the electric fields present in the spark generator result in significant losses of electrons to the walls of the system. Hence less negative charge carriers are present in the charging process, leading to smaller amounts of negatively charged particles. Ongoing TDMA measurements aim to determine in more detail the charge distribution of Mg particles produced by the spark discharge.

During the last decade there has been an explosion in novel applications and products based on nanoparticles. Although the belief in the great potential of nanoparticles is strong, major concerns with respect to their toxicology have been frequently discussed lately. It is well known that the properties of a specific nano-sized material are different from the properties of the same material in bulk form, and therefore toxicology regulations often based on mass might not be relevant for nano-sized materials. In order to improve the understanding of nanotoxicology and to learn how to handle nanoparticles in a safe way it is of utmost importance to use highly characterized nanoparticles for toxicology investigations.

In the present contribution we describe a route to generation and deposition of very well characterized nanoparticles with respect to size, shape, mass, surface area and crystal structure. The nanoparticles were generated by spark discharge and fed into an aerosol nanoparticle system setup (Messing *et al.*, 2009) for on-line characterization, reshaping and deposition. Tandem differential mobility analyzers (DMA) coupled to an electrometer was used for mobility diameter and number concentration measurements. The particle mass was measured with a DMA-aerosol particle mass analyzer (DMA-APM) coupled to a condensation particle counter (CPC). An electrostatic precipitator was used for controlled particle deposition onto lacy carbon film coated Cu transmission electron microscopy (TEM) grids as well as directly into protein solutions. Primary particle size as well as particle shape and crystal structure were evaluated by TEM. Particle surface area was calculated from the measured primary particle size combined with either the DMA-APM measurements or the idealized aggregate theory (IA) approach. Finally the deposited mass and surface area dosages were calculated for deposition in an air liquid interface (ALI) chamber (Savi *et al.*, 2008) or the alveolar region of the respiratory tract.

Gold particles were used to demonstrate the capability of the setup, although particles of other materials can easily be produced by changing the electrode material in the spark discharge generator (Tabrizi *et al.*, 2009). From the measurements and calculations it is clear that a high enough mass and surface area reported for onset of inflammatory response can be reached in the ALI chamber, if a deposition time of roughly two hours is used. A further key aspect of the setup is the possibility to use a sintering furnace to reshape the as-produced agglomerate particles (Figure 1). By using this approach particles of the same number concentration and mass, but with clearly different surface area can be deposited. This provides for a direct comparison of toxicological response upon surface area, a feature that is believed to play a major role in nanoparticle toxicity. Finally, Dynamic Light Scattering (DLS) showed that when gold particles were deposited into protein solutions, the suspensions were stable for several days, which is promising for future studies.

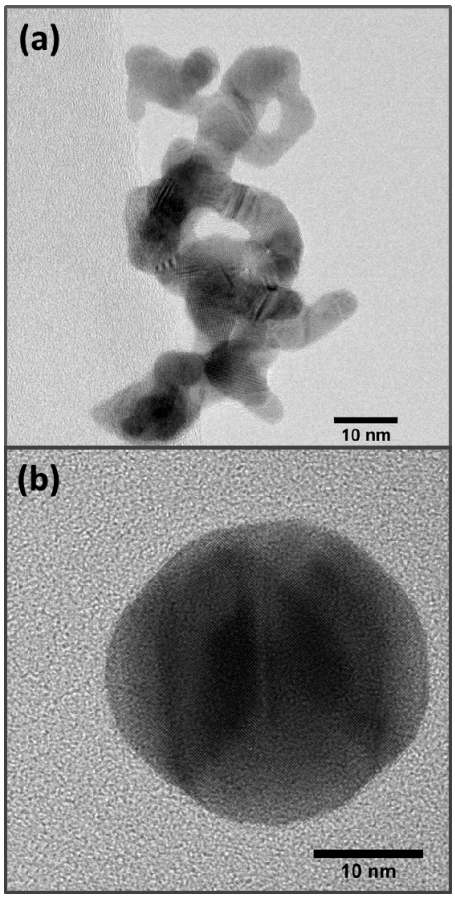

Figure 1. Gold nanoparticles of the same mass (0.24 fg) (a) before and (b) after reshaping. The mobility diameter decreased from 60 to 31 nm upon reshaping.

Session 10F: Modelling Aerosol Formation

H^2O: A new model to predict secondary organic aerosol formation

F. Couvidat[1], Y. Kim[1], K. Sartelet[1] and C. Seigneur[1]
[1]CEREA, Joint Laboratory École des Ponts ParisTech/EDF R&D, Université Paris-Est, 77455 Marne la Vallée, France
Keywords: Aerosol model, Modelling (regional), SOA (Second. Organic Aerosols)
Presenting author email: couvidaf@cerea.enpc.fr

A new secondary organic aerosol (SOA) model H^2O (Hydrophilic/Hydrophobic Organic), which is based on the model developed by Pun *et al.* (2002) is presented and evaluated with measurements over Europe. This model treats the formation of SOA by condensation on an organic phase or an aqueous phase. It distinguishes two kinds of surrogate species: hydrophilic species (which condense preferrentially on an aqueous phase) and hydrophobic species (which condense only on an organic phase). These surrogates species are formed from the oxidation in the atmosphere of Volatile Organic Compounds (VOCs) by radicals (HO, NO_3) and ozone. These VOCs are either biogenic (isoprene, monoterpenes and sesquiterpenes) or anthropogenic (mainly aromatic compounds).

This model includes many processes. It takes into account the effect of NO_X on SOA formation, the dissociation of acids into an aqueous phase, oligomerization of aldehydes, non-ideality of the particulate phase and hygroscopicity of organics.

The H^2O model was used to calculate SOA concentrations over Europe in summer when SOA concentrations are higher. An investigation was realized to find the most important processes for SOA formation. Taking into account the hydrophilic properties of SOA, oligomerization, and the explicit representation of high-NO_X and low-NO_X gas-phase chemical regimes (the extend of this process depends on the gas-phase chemistry model used, different models give different concentrations of radicals). The table below shows the impact of these processes on SOA concentrations.

Processes added	SOA increase
Representation of NO_X regimes	30 to 120%
Hydrophobic and hydrophilic species	46%
Oligomerization of aldehydes	60%

Table 1: Increase of SOA concentrations due to specific processes.

The following table shows the contribution of the main precursors to SOA formation. The biogenic compounds are found to be responsible for the formation of most regional SOA (around 93%) whereas the anthropogenic compounds are found to be a minor contributor. However, anthropogenic compounds have a higher impact in urban areas.

Precursor	Contribution to SOA
Isoprene	34%
Terpenes	59%
Anthropogenic compounds	7%

Table 2: Contributions of main precursors to SOA formation over Europe in summer.

The mean SOA concentration in summer 2001 was found to be around 1.8 $\mu g.m^{-3}$ but SOA concentrations were up to 10 $\mu g.m^{-3}$ in some areas. Concentrations are higher where biogenic emissions of terpenes and isoprene are higher (south and east of Europe).

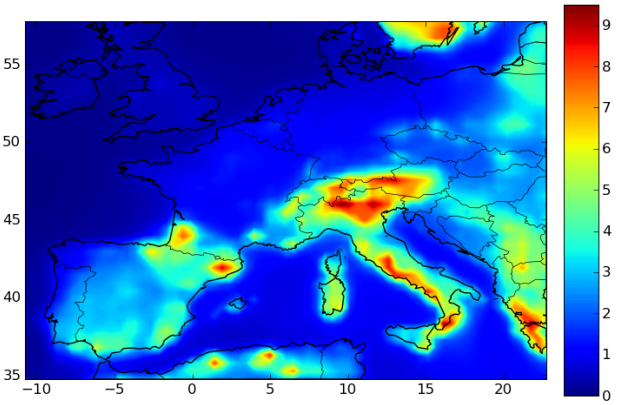

Figure 1: SOA concentrations ($\mu g.m^{-3}$) over Europe in summer 2001.

To test the H^2O model, a simulation over a whole year is conductive and calculated concentrations are compared to measurements.

This work was funded in part by ADEME, the French Agency for the Environment and Energy Management.

Environmental impact of aviation-produced aerosols: Towards alternative fuels

Rojo, Carolina[1], Vancassel, Xavier[1] and Ponche, Jean-Luc[2]

[1]Department of Physics and Instrumentation, ONERA, 92322, Châtillon, France
[2]LMSCP, University of Strasbourg, 67482, France
Keywords: aircraft plumes, biofuels, particle formation and growth, organics, soot particles.
Presenting author email: carolina.rojo@onera.fr

Environmental impact of anthropogenic emissions and their influence on global warming have become one of scientists' main interests. In this context, aviation plays an important role. Indeed aviation emissions (mainly carbon dioxide, water vapour, nitrogen and sulphur oxides, and soot) are responsible of new particle formation in the aircraft plume, including contrails, and therefore contribute to an increase of the radiative forcing and to the deterioration of local air quality (Lee D.S. *et al.*, 2009).

Use of alternative fuels would help limiting the impact of aviation-produced aerosols. There are currently several alternative fuels being tested to suit aviation regulations and infrastructure (Rahmes T. *et al.*, 2009). Globally, the combustion exhaust tends to present much lower sulphuric acid, aromatics and soot number concentrations (Timko *et al.*, 2010).

Comprehensive studies have already been made on aerosol emissions in aircraft plumes for standard Jet A1 kerosene (*e.g.* Kärcher, 1998, Yu *et al.*, 1999) but few studies are available for alternative fuels, thus a number of uncertainties remain. Indeed use of alternative fuels, reducing simultaneously aromatic and sulphur content, can lead to antagonist effects, having unexpected consequences.

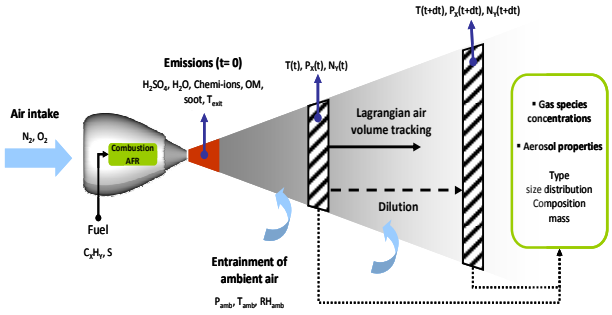

Figure 1. Scheme of the modelised aircraft plume.

The emissions of an aircraft flying with alternative fuel can be simulated by a coupled microphysical-chemical-dynamical trajectory box model (figure 1). Our model which describes the expansion of the jet plume and the evolution of the produced particles has already been tested for standard kerosene. A sensitivity study is carried out, using different fuel sulphur contents, soot particle number and organic concentrations, to simulate the combustion of an alternative fuel. Improvements are currently being made concerning the behaviour of particles in a mixture with a smaller amount of soot, a lower sulphuric acid content and different organic composition, especially regarding droplet freezing and hence contrail formation.

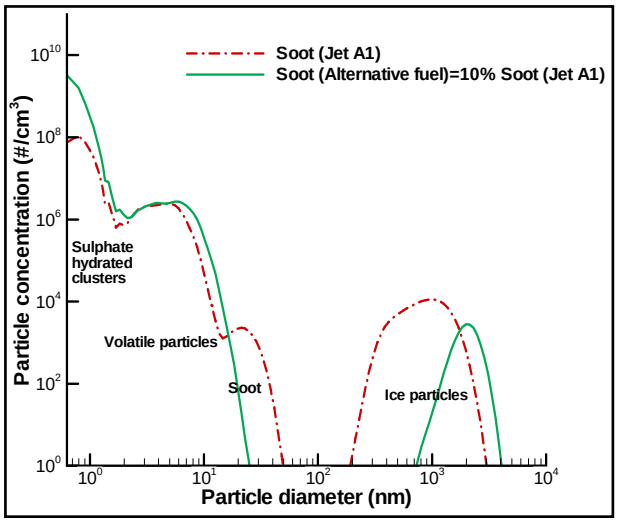

Figure 2. Simulated size distributions of particles in the aircraft plume at ~125 m behind the plane with standard fuel (red dashed) and alternative fuel (green solid).

In figure 2, the influence of soot particle initial number density on contrail formation is depicted for two types of fuel. For a typical jet A1, ice particle size (only formed by heterogeneous freezing) peaks at 1 micrometer at 0.5s in the plume, which corresponds to typical fresh plume contrails. When simulating the combustion of an alternative fuel, we used a reduced soot emission index, by 90%. For such a case, the ice crystals size distribution exhibits a maximum size close to 2 micrometer. This effect is mainly due to the enhanced amount of condensable material available for each crystal.

These differences in the condensation trails have an impact on the radiative budget of the atmosphere. The calculation of the optical depth of the two different contrails could clarify which fuel contributes the most to global warming. But reducing soot initial concentrations at the nozzle exit may promote other ice nucleation paths and homogeneous freezing must be revised.

Automatic classification of new particle formation events

H. Junninen[1], M. Paramonov[1], A. Hirsikko[1], M. Dal Maso[1], M. Kulmala[1]

[1] University of Helsinki, Department of Physics, P. O. Box 48, FI-00014 UHEL, Helsinki, Finland

Keywords: nucleation mode, number size distribution, automatic classification
Presenting author email: Heikki.junninen@helsinki.fi

Regional new particle formation (RNPF) appears with great regularity during the day time and very rarely, if ever, during the night. In order to observe particle formation and subsequent growth up to 100nm the air masses have to remain the same for a long time (up to 12 hours). For this reason one can analyze the continuous data a day at a time and classify days as RNPF event days and non-event days. Dal Maso et. al. (2005) developed a classification method for classification of days. The method is based on visual observation of size distributions, in order reduce subjective aspect of the result the analysis are performed in group of 3-4 persons. While being a powerful method, it is still subjective and very difficult to adapt to different group of people and to get comparable results, say between two different research groups. To address this problem a new automatic classification algorithm was developed.

The method is based on self-organizing map. Self-organizing map (SOM) is the most popular unsupervised artificial neural network algorithm. It solves difficult high-dimensional and nonlinear problems and makes projection into a low-dimensional space while keeping most of the information (Kohonen 1995).

For the RNPF classification algorithm we taught SOM (Figure 1) with different teaching data. For the final classification of unknown day we search for the best matching unit (SOM neuron with smallest Euclidean distance) from each SOM. From the best matching unit statistics on testing data we get the probability for the day to belong to a class event, non-event or undefined.

For teaching the algorithm we used 11 year aerosol size distribution data measured in Hyytiälä, Finland and 3 years in Värriö, Finland. Both places are located in rural background area and consequently the model works only for rural stations.

Data was divided randomly into 3 parts, teaching (3/5), validation (3/20), and testing (1/4) data. Over-fitting of the algorithm was avoided by monitoring errors in both, teaching and validation data.

The new algorithm performed well compared to traditional classification method. The days with RNPF-event are clearly different from all other type of days and the performance of the new algorithm is the best for these days. 92% of RNPF days were classified similarly by the two methods. Less than 1% of the event days were classified as non-event days and <8% as undefined days. When verifying the misclassified days manually we found that these misclassified days were problematic also for human to classify. These days were on the edge of being in one or in other class.

The biggest disagreement between methods was found in the class of undefined days. This class is actually left over class and not a real class, it contains great number of different type of days and there is no clear feature to describe this class.

When testing the model classification robustness from different sampling site, we found that for same type of sites the performance is equally good. However, if testing site has type of RNPF event that are totally missing from teaching data the algorithm has problems to classify these correctly.

In the presentation the algorithm description and performance in different stations will be discussed in details.

Keywords: aerosol modelling, size distribution, number concentration, nucleation, emissions.

Presenting author email: c.reddington@see.leeds.ac.uk

We use the global aerosol microphysics model, GLOMAP (Spracklen *et al.*, 2005) and observations made during the EUCAARI field campaign in May 2008 to better understand how primary particle emissions and secondary particle formation influence particle number concentrations in the European boundary layer (BL), and how the influence varies across the particle size distribution. Observations are available from the DLR Falcon 20 aircraft and from 15 field sites in the EUSAAR and GAW networks, and include measured non-volatile and total particle number size distributions.

In large-scale models there is considerable uncertainty associated with parameterisations for secondary particle formation and for the prescribed emission size distribution of primary particles, leading to uncertainties in predicted total particle and cloud condensation nuclei concentrations (Merikanto *et al.*, 2009). Here, we test four different parameterisations for BL nucleation including the activation and kinetic mechanisms (e.g. Sihto *et al.*, 2006), and two newly developed organic vapour mechanisms (Paasonen *et al.*, 2010). We also test different assumptions for the emission sizes of carbonaceous aerosol from Dentener *et al.* (2006) (AEROCOM) and Stier *et al.* (2005); varying by a factor of ~2 (hence a factor ~8 difference in the emitted number concentrations for fixed mass).

The AEROCOM size assumptions may be too small to be appropriate for a large-scale model as used here, but lead to best agreement between modelled and observed number concentrations of particles >50 nm dry diameter (N_{50}). In an experiment without BL nucleation, the normalised mean bias between modelled and observed N_{50} at the field sites is small (-5%). The aircraft observations confirm these findings; measurements of non-volatile and Aitken-mode particle concentrations in the BL agree best with the model when we assume small emission sizes. An hourly time series analysis shows that at roughly half the field sites the difference between modelled and observed N_{50} is statistically insignificant at the 99% confidence level. We find that, although BL nucleation increases simulated N_{50} over Europe by ~10–50% (depending on the mechanism and assumed emission sizes); the contribution is difficult to detect within the uncertainty of the observations and assumptions about primary emissions. To partly resolve this, we have implemented a new emission inventory (Denier van der Gon *et al.*, 2010) based on emitted particle number concentrations and size rather than mass.

For particles <50 nm, the difference between model number concentrations and the observations is statistically insignificant at 7 sites only if some form of BL nucleation is included. However, the agreement between hourly time series of modelled and observed nucleation events in this period is poor, and precludes any attempt to identify the best nucleation mechanism from such a short dataset.

This work was supported by funding from the EU's 6th Framework Programme project, EUCAARI.

Organic aerosol (OA), although a significant component of submicron particles throughout the world, is poorly simulated by predictive models. Current CTMs consistently underpredict OA mass concentrations at the surface during summertime conditions. Chemical transport models have traditionally treated POA as non-volatile and non-reactive and SOA as semi-volatile products of VOCs' oxidation (Kanakidou et al., 2005). However, several recent studies have shown that POA is semi-volatile while SOA can be seriously underpredicted by models that use traditional SOA precursors and do not take into account further oxidation of these compounds.

In this study we applied PMCAMx-2008, a 3-D CTM, to the European domain, in order to simulate the OA formation during the months of May 2008 and February 2009. PMCAMx-2008 includes the recently developed volatility basis set framework to describe OA absorptive partitioning by organizing the total OA mass into surrogates along an axis of volatility (Donahue et al., 2006; Stanier et al., 2008). We evaluated the performance of the model against AMS measurements taken during the above periods from various sites in Europe. The model predictions were compared against the Positive Matrix Factorization analysis of AMS observations.

PMCAMx models the processes of horizontal and vertical advection, horizontal and vertical dispersion, wet and dry deposition, gas phase chemistry, inorganic aerosol growth, aqueous phase chemistry and SOA formation and growth. The modeling domain covers a 5400 × 5832 × 6 km region in Europe with 36 × 36 km grid resolution.

Figure 1 shows the PMCAMx average predictions over the month of May 2008 for total ground OA mass concentration. The model predicts that fresh primary OA (POA) is a small contributor to organic PM concentrations in Europe during late spring, and that oxygenated species (oxidized primary and also biogenic secondary) dominate the ambient OA.

Sensitivity runs were also conducted to test the response of the predicted OA concentrations over Europe to i) a temperature increase of 2.5 and 5 K, and ii) 5 different emission reduction scenarios.

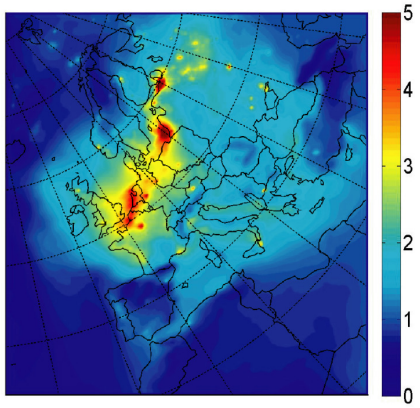

Figure 1. PMCAMx predicted average ground total OA concentrations (μg m^{-3}) for May 2008.

Assuming a uniform temperature increase of 2.5 and 5 K the model predicts significant increases of the OA during May due mainly to the increase in biogenic VOC emissions. The fresh POA is predicted to decrease due to evaporation, while the anthropogenic secondary OA to increase due to acceleration of its chemical production. The net increases are up to 25% of OA for a 5 K temperature increase. During the winter the situation is different because the OA is predicted to decrease for warmer conditions. This is due to the small biogenic SOA contribution to OA and the dominance of fresh POA during this cold low-photochemical activity period.

Presenting author email: christoph.winkelmann@pmi.com

Many applied problems in fluid mechanics have a multi-scale character due to physical processes evolving at many different time and/or length scales. Examples range from turbulent flows with different length scales to chemically reacting and multi-phase flows with various time scales. In most applied flow problems, resolving all scales in space and time present in a flow is not computationally feasible. For the non-resolved time-scales, e.g., time scales on which nucleation of over-saturated vapors is occuring, suitable models can be developed.

In general, the nucleation time-scale can be some orders of magnitude smaller than the timestep of the fluid simulations. To demonstrate this, we focus on aerosol flows in a rather simple geometry, but with an abrupt phase change caused by an immediate cooling of hot vapors that triggers creation of the aerosol droplets. The flow cooling is introduced by a rapid change of wall temperature in the considered pipe geometry as seen in Fig. 1(a). Consequently, an aerosol is formed from the hot vapors which are initially in the gas phase (Fig. 1(b,c)).

In our model, the aerosol is simulated in an Eulerian frame exploiting the computational efficiency of such approach. The formation of aerosol droplets is described by classical nucleation theory. Models for coagulation of, condensation to and evaporation from the droplets are included. In addition to the flow equations for mass, momentum and energy conservation, equations for the aerosol mass and number load are solved. In this method of moments approach, the diameter of average mass of the evolving aerosol can be easily determined. In order to account for the omitted time scales in the nucleation process, a sub-timestep model has been developed and included in our simulation to allow for computations at reduced computational effort. The accuracy of the obtained flow solution with this coarse-graining of the aerosol creation process is one of the key objectives for investigations presented in this work.

Our aim is to provide a simple computational framework for testing and analyzing aerosol models. In the literature only a modest number of detailed numerical experiments are available for aerosol generation processes by nucleation in flows of condensable vapors. Here, we consider the generation of an aerosol by a rapid cooling of hot vapors in laminar flow (Nguyen *et al.*, 1987).

We use the setup and flow parameters described by Nguyen *et al.* (1987) and consider a pipe flow with prescribed axial wall temperature profile starting from the temperature of hot saturated vapors of dibutyl phthalate and changing rapidly to room temperature within a short downstream distance (Nguyen *et al.*, 1987; Pyykönen and Jokiniemi, 2000). The aerosol model is implemented as an extension to the open-source software OpenFOAM®, which provides sufficient flexibility for consideration of geometrically more complex flow domains.

Our focus lies on two important aspects. First, the analysis of the time resolution at which the simulations need to be performed in order to obtain accurate results at minimal computational cost. For this, a set of simulations is carried out with different time-step sizes in order to investigate the accuracy and necessity of sub-time step modeling. Second, the validation of the method with experimental data available in the literature.

The extension of this work to multi-component aerosol formation and turbulent flow is ongoing.

Plenary 5:

Global aviation and particulate matter: from climate impact to volcanic ash and back

by Andreas Petzold

Global aviation and particulate matter: From climate impact to volcanic ash and back

Andreas Petzold
DLR, Institut für Physik der Atmosphäre, Oberpfaffenhofen, 82234 Wessling, Germany.

Keywords: aviation particulate matter, aviation climate impact, volcanic ash, mineral dust.
Presenting author email: andreas.petzold@dlr.de

Rationale: The relationship between airborne particulate matter (PM) and aviation is manifold. It extends from the impact of aviation PM emissions on cloudiness and on climate in general, to the impact on local air quality and human health. However, aviation PM does not only affect the atmospheric aerosol budget, but airborne PM also may have a strong impact on aviation by causing hazards to cruising aircraft. The entire research area is highly interdisciplinary, including measurement technology aspects, as well as studies on PM impact on aircraft engines and airframes, and using a network of civil aircraft as routine measurement platform for the aerosol in the global upper troposphere and lowermost stratosphere (IAGOS: In-service aircraft for a global observing system; www.iagos.org/). The plenary will give a broad overview of various research activities going on in this field. In the following recent highlights from different disciplines are briefly summarised.

Impact of Aviation on Climate: Aviation is considered one major source of PM at cruise altitude (9 – 13 km above sea level), causing significant climate effects via contrails and cirrus clouds forming on these particles. After a decade of intense research on PM emissions from aircraft gas turbines, their physico-chemical properties, and their impact on global climate, IPCC dedicated an entire report to this topic (IPCC 1999).

Although emission of PM from aircraft engines is now reasonably well understood, e.g., (IPCC 2007; Schumann et al. 2002), the development of current-technology measurement methods for engine certification is an ongoing task requested by the International Civil Aviation Organisation (ICAO). First results from extensive method intercomparison studies were published recently (Petzold et al. 2011).

In the past 5 years the research focus has shifted to effects of PM emissions at ground level on local air quality and human health. NASA has supported a whole series of experiments on aircraft PM emissions (APEX 1 – 3; (Wey et al. 2007)). Climate effects from contrails and in particular from cirrus clouds forming from persistent contrails are still in the focus of research. Very recently, Burkhardt and Kärcher (2011) estimated the net forcing effect of contrail cirrus, comprising not only young or line-shaped but also aged, irregularly shaped contrails, and including resulting changes in cirrus cloudiness to about 31 mWm^{-2}. They conclude that the net radiative forcing due to contrail-induced cloudiness constitutes one of the largest single aviation-related radiative forcing components.

PM Impact on Aviation: On April 14th, 2010, the eruption of the Eyjafjallajökull in Iceland and the accompanying cloud of volcanic ash forced most countries in northern Europe to shut their airspace between April 15-20, grounding more than 100,000 flights and an estimated 10 million travellers. This event has revealed to which extent our society and our economy relies on the availability of a safe and efficient air transport system and how volatile it still is facing the complexity of atmospheric conditions.

In the aftermath of the airspace closure it turned out that a quantitative knowledge of the exposure of aircraft encountering fine or coarse volcanogenic particles and gases in the atmosphere is still very limited. Furthermore, there are strong analogies between the issues and hazards associated with aircraft passage through volcanic ash and mineral (desert) dust clouds. Natural hazards that can severely impact the air transport system also include icing and dense clouds of ice crystals. The European project NEWAC (New aero engine core concepts: www.newac.eu/) forms the current framework for the more technically oriented research while the upcoming EU activity WEZARD (Weather hazards for aviation, start scheduled for July 2011) combines technology oriented research, atmospheric science, and measurement technology.

Both fields of research merge in the efforts of developing simple sensors for routine measurements of potentially hazardous situations on board of civil aircraft. These efforts rely extensively on the progress and experience gained in IAGOS, which was originally developed for atmospheric observation.

Session 11A: Biomass Burning

Comparison of qualitative and quantitative approaches for source apportionment of PM at urban and rural alpine sites.

Detailed knowledge about the sources of PM is mandatory for the enforcement of efficient PM reduction measures. Source apportionment of PM can be achieved by using qualitative and quantitative approaches with off-line PM sampling. Qualitative methods are based on the study of chemical profiles or ratio-ratio approaches (Robinson *et al.*, 2006). Different quantitative methods exist, notably two modeling methods: the Molecular Marker - Chemical Mass Balance (MM-CMB) and multivariate statistical models such as Positive Matrix Factorization (PMF). The mono-tracer method using organic carbon, levoglucosan and elemental carbon (EC) concentrations, or the isotopic carbon signature (^{14}C) can also be used.

Qualitative and quantitative methods (mono-tracer method, MM-CMB and PMF) of source apportionment were applied for PM samples collected in summer and winter seasons in urban background and rural alpine sites both in France (Grenoble and Lescheraines) and in Switzerland (Zurich and Magadino). At these sites topographic and meteorological conditions can lead to high pollutant concentrations. PM was characterized for a large array of chemicals including molecular speciation of organic matter, trace elements, metals and ionic species (about hundred compounds).

PM in alpine valleys is emitted to a large part by residential heating particularly biomass burning. Biomass burning was found to account for 42% of PM in Grenoble during winter (Favez *et al.*, 2010) and for 41% of the organic aerosol (OA) in Zurich (Szidat *et al.*, 2006). Vehicular emissions can also be important source of aerosol. Therefore, a proper apportionment of direct and indirect vehicular emissions and the emissions from biomass burning is an important issue for these sites. Because it is dependent of local sources and practices (e.g. type of burned wood), the use of adjusted methodologies and combined approaches is advantageous in order to obtain the best estimates.

Chemical marker profiles and the ratio-ratio approach using Polycyclic Aromatic Hydrocarbons, EC and hopanes (markers for direct vehicular emissions) allow the determination of source profiles for use in CMB (choices of type of wood burned or vehicular fuel type). Organic marker concentrations are used in order to validate the obtained PMF factors for each site.

Estimated contributions from biomass burning (BB) and direct vehicular emissions (DVEH) to OA in winter by the mono-tracer method and the MM-CMB model are found to be in good agreement (Fig. 1). Average source contributions were calculated for 30 samples per site in France and 10 samples per site in Switzerland. The obtained source contributions will also be compared with PMF model results for source contributions to PM in each season.

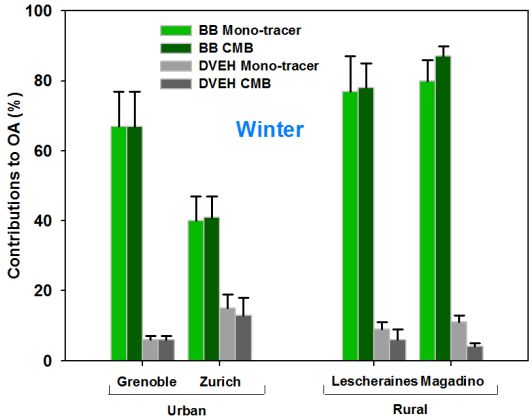

Figure 1. Wood burning contribution estimations to OA in winter in urban and rural sites by mono-tracer method and by MM-CMB.

C. Piot thanks the Region Rhône-Alpes for her PhD grant. Campaigns in France were supported by the FORMES program MEDAD Primequal Predit (Grant N°0001135) and by the Particul'Air program ADEME. The authors would like to thank staffs from ASCOPARG and AIR-APS for their support during the field campaigns. The activities at the Swiss sites were supported by the Competence Center Environment and Sustainability of the ETH Domain (CCES-IMBALANCE) and by the Swiss Federal Office for the Environment (FOEN).

Biomass burning is an important source of atmospheric trace gases and particulate matter, which impact air quality and climate. However, the effect of biomass burning on regional and global scale is still poorly quantified due to various uncertainties in the assessment, including analytical limitations, lack of representative source profiles and poor description of potential degradation of molecular source tracers during atmospheric transport. A major component of fine particles from biomass combustion is levoglucosan (LG), accompanied by its stereoisomers, mannosan (MN) and galactosan (GL). Due to reasonable atmospheric stability during long-range transport, levoglucosan has been used as marker for biomass burning processes. Increasing effort has recently been put into the quantification of levoglucosan and other anhydrosugars in biomass burning aerosols. Recently, stable carbon isotope measurements have emerged as a powerful tool to characterize source emissions and ambient aerosols influenced by biomass burning (Huang et al., 2006) and secondary formation processes (Fisseha et al., 2009).

Here we present a newly developed method for compound specific isotopic measurements of anhydrosugars in biomass burning aerosol filter samples by employing Thermal Desorption – 2-Dimensional Gas Chromatography – Isotopic Ratio Mass Spectrometry (TD-2DGC-IRMS). This method combines the advantages of thermo-extracting analytes from filter samples with the improved separation of polar components by two-dimensional GC (Ma et al. 2010). It was successfully applied to determine the isotopic composition of levoglucosan, mannosan and galactosan in a standard mixture. The obtained $\delta^{13}C$ values showed good agreement with the isotopic measurements of the bulk anhydrosugars, carried out by elemental analyser-isotope ratio mass spectrometry (EA-IRMS) (Table 1).

The biomass burning source samples analyzed with our new method were collected in the Pearl River Delta of China. The measured samples originated from different types of burning (open or in domestic stoves) of various plants, including rice straw, peanut and mulberry shrubs, China fir and Chinese red pine (softwood), chestnut and schima superba trees (hard wood). The burning in domestic stoves was defined by a mixture of smoldering and flaming stages, while flaming at higher temperatures was the dominant stage in case of open burning. Figure 1 shows an example chromatogram obtained for Chinese red pine. Generally, the softwood samples showed the highest LG $\delta^{13}C$ values of -23.19‰ to -21.52‰. $\delta^{13}C$ values for mannosan and galactosan could only be measured from softwood and ranged from -23.22‰ to -22.42‰ (MN), and -24.93‰ to -24.76‰ (GL). Levoglucosan generated from the combustion of grasses and shrubs showed $\delta^{13}C$ values of -25.69‰ to -24.33‰. Similar LG $\delta^{13}C$ values of -26.62‰ to -24.73‰ were measured for hard wood samples. Scrutinizing the influence of different combustion types on isotopic composition, open burning produced a lower $\delta^{13}C$ value for levoglucosan than domestic stove burning. For rice straw LG $\delta^{13}C$ values were found to be -26.32‰ and -24.33‰, respectively.

Table 1. The $\delta^{13}C$ values of levoglucosan, mannosan and galactosan measured by TD-2DGC-IRMS and EA-IRMS methods (n: number of measurements).

Compound		TD-2DGC -IRMS	EA-IRMS
Name	Chemical Formula	$\delta^{13}C$/‰ (n=5)	$\delta^{13}C$/‰ (n=3)
Levoglucosan	$C_6H_{10}O_5$	-23.59±0.19	-23.75±0.09
Mannosan	$C_6H_{10}O_5$	-24.50±0.22	-24.77±0.02
Galactosan	$C_6H_{10}O_5$	-26.79±0.16	-26.67±0.01

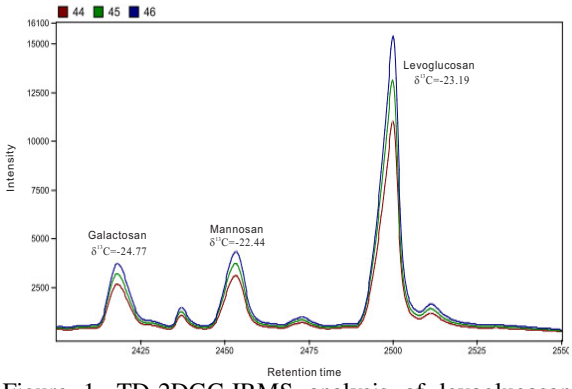

Figure 1. TD-2DGC-IRMS analysis of levoglucosan, mannosan and galactosan in softwood burning aerosol. Signals of CO_2^+ (m/z 44, red), and isotopologues on m/z 45 (green), and m/z 46 (blue) are shown.

The $\delta^{13}C$ data will be discussed together with organic speciation information, including ambient anhydrosugar concentrations, obtained by high-performance anion exchange chromatography (HPAEC) (Sang et al. 2011). Selected results from compound specific $\delta^{13}C$ analysis of ambient filter samples will be presented. These will be interpreted in the context of isotopic information from source samples with respect to main sources of biomass burning aerosols in urban and rural sites of the Pearl River Delta of China in 2009 and their atmospheric processing.

Keywords: biomass burning, fireplace, woodstove, $PM_{2.5}$, GC-MS, organic tracers.

catiagoncalves@ua.pt

This work provides detailed information on organic composition of smoke particles from residential combustion of the most prevalent Portuguese woods in an attempt of contributing with new data for source apportionment methodologies. In Portugal and other Mediterranean countries, there is a lack of information concerning the characterisation of particulate emissions from biomass combustion systems.

This new research extends to eight the number of biomass fuels studied and try to understand the differences that the burning appliance (fireplace versus woodstove) and the combustion temperature (cold and hot start) have on emissions. *Pinus pinaster* (Maritime pine), *Eucalyptus globulus* (eucalyptus), *Quercus suber* (cork oak), *Acacia longifolia* (Golden wattle), *Quercus faginea* (Portuguese oak), *Olea europea* (Olive), *Quercus ilex rotundifolia* (Holm oak) and briquettes produced from forest biomass waste were used in the combustion tests.

The burning tests were carried out at the Portuguese combustion facility, at the University of Aveiro (Fernandes, 2009).

Determinations included particle mass emission factors, the determination of its carbonaceous content (OC and EC) by a thermal optical technique (Alves et al., 2010) and detailed identification and quantification of organic compounds by gas chromatography–mass spectrometry (GC model 6890, quadrupole MSD 5973 from Hewlett-Packard and GC Trace Ultra, quadrupole DSQ II from Thermo Scientific).

Results suggest that fine particle emission factors from the woodstove were lower than those from the fireplace (Figure 1). For both combustion appliances, the OC/EC ratio is higher in cold start tests, except for some species, such as pine, eucalyptus and briquettes that behave differently in relation to OC emissions. The major organic components in particles from biomass burning were anhydrosugars, in particular levoglucosan, acids and aliphatic compounds. Retene was the dominant aromatic hydrocarbon found in the softwood smoke, whilst it was present at very small levels in the hardwood combustion emissions. Guaiacyl, like vanillic acid, and synapyl compounds were identified in softwood smoke, whereas hardwood burning contributed mainly to the formation of syringyl compounds, such as syringic acid. Stigmasterol was only present in the smoke of hardwood species; thus, this compound may be pointed out as a potential tracer for smoke from deciduous trees. β-sitosterol has a great expression in the smoke of softwood species.

The smoke composition varied widely depending on fuel type, burning appliance and combustion temperature.

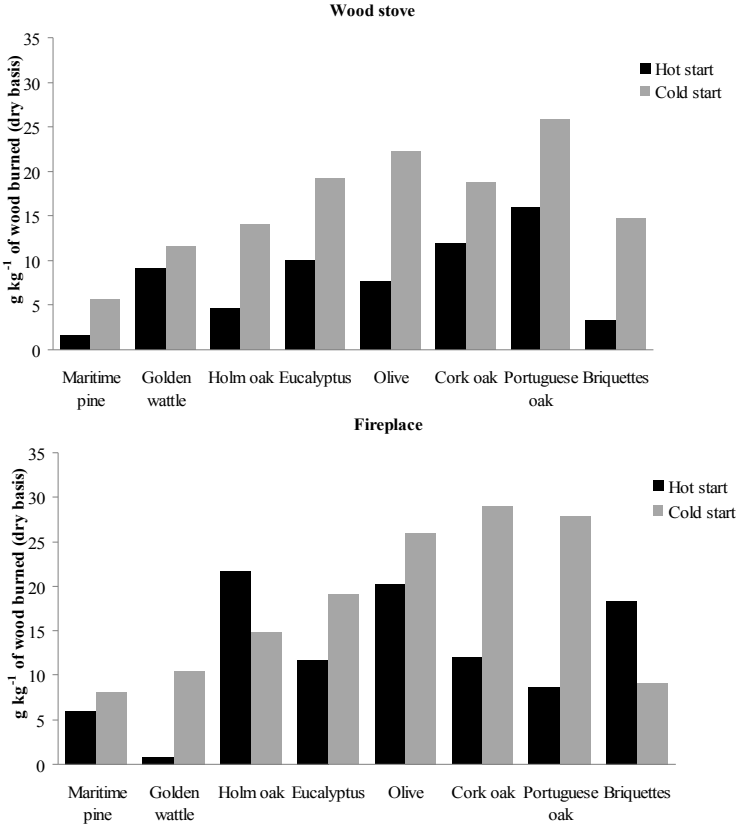

Figure 1 – $PM_{2.5}$ emission factors.

The impact of wood combustion on chemical composition of ambient aerosol during winter time was investigated. Sampling was done at the aerosol characterization site of the Helmholtz Zentrum München in Augsburg, Germany.

The campaign in 2010 represents a winter period strongly influenced by residential heating (15th to 19th February). The aerosol characterisation site is an urban background site which is not influenced by direct emissions of traffic or residential heating next to the area. The buildings in the neighbourhood are mainly supplied by the district heating network. To observe intraday course of concentrations of particulate organic matter filter sampling of PM_1 was done on an hourly basis for a period of four days. Moreover routine $PM_{2.5}$ sampling by daily collecting of ambient air on quartz fibre filters has been done at this sampling site.

A new developed method for analysing organic matter, the In-situ Derivatisation Thermal Desorption (IDTD) followed by Gas Chromatography Time-Of-Flight Mass Spectrometry (GC-TOF-MS), was applied for analysis of these samples.

Despite of contrary weather during four days of hourly sampling a strong influence of wood combustion activities was clearly visible. The heating activities were focused on the evening hours. The accumulation of emissions of wood combustion resulted in increasing concentrations of wood combustion aerosols in the city. High concentrations of organic marker substances like levoglucosan with a maximum at about midnight were observed. Maxima of levoglucosan prevailed for several hours. The highest average of the day (640 ng m^{-3}) was found on the 18th of February within the days of hourly sampling. The highest maximum values were shortly before and after midnight between the 17th and 18th of February (1400 ng m^{-3}) (figure 1).

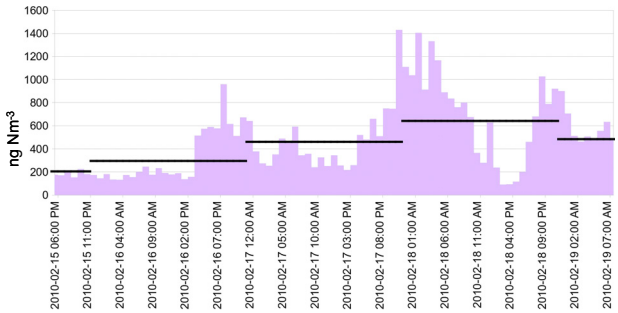

Figure 1. Urban background concentrations of levoglucosan: $PM_{2.5}$ values as 24-hours-means (bars) and intraday values of PM_1 (vertical bars)

The main driving factors for increased nightly concentrations were the unfavourable dispersion conditions (low mixing layer heights and wind speeds). In addition we assume that increased emissions from smouldering phases with low air supply at the end of heating events ("the last log of the day") contributed also to the observed variation in time.

A series of experiments with a log wood stove have shown that a smouldering phase of ten minutes during a burn-off of 45 minutes is responsible for two-fold higher values of total suspended particles (TSP) mass and especially levoglucosan when regarding chemical composition. Although concentrations of levoglucosan were found to be even higher at the inflaming someone can estimate that smouldering phases were also responsible for the observed values during night. Figure 2 shows the characterisation of a heating event typical for an evening leisure time in winter. The heating event is separated into four periods. The inflaming process showed high emissions of organics. Afterwards two reloads of logs were sampled. Emissions of PM and organics were lowered significant. The third reload is characterised by a smouldering phase with high emissions of PM and organics. Especially levoglucosan and the oxidised PAH 9H-fluoren-9-one were strongly influenced by inflaming and a smouldering phase during the combustion of the third reload. Whereas benz[a]pyrene was not affected in the same magnitude.

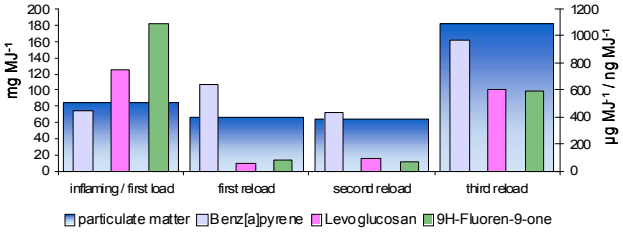

Figure 2. Typical leisure time log wood combustion event over three hours. Wood stove fired with beech log wood. Combustion time for each load was 45 min. Left y-axis: particulate matter [mg MJ^{-1}], right y-axis: benz[a]pyrene [ng MJ^{-1}], levoglucosan [µg MJ^{-1}], 9H-fluoren-9-one [100 µg MJ^{-1}] (units refers to introduced energy contained in the fuel)

Presenting author email: harri.portin@fmi.fi

During June-August 2010, intensive forest fires took place in the Western Russia, near Moscow. The smoke from the fires and associated aerosol particles had a considerable effect on air quality, causing adverse health effects. Characteristics of smoke and aerosol particles are also interesting from the atmospheric point of view. Smoke particles have often distinct optical properties compared to other particles, and have a significant impact on earth's radiation balance (Reid *et al*, 2005)

The smoke drifted long distances with air masses, and in several occasions, it could be observed in the city of Kuopio, Eastern Finland, where the Puijo observation tower is located. A long-term measurement station for aerosol-cloud interactions and aerosol properties is located on the top of the tower (Leskinen *et al*, 2009). The station is equipped with instruments capable of determining the physical and optical properties of the aerosol particles in detail. We have also used some remote sensing data and data from city of Kuopio air quality measurement sites.

On two days, 29.7. and 8.8, the presence of smoke could be seen from the data clearly and it even affected the visibility. In figure 1, time series of AOD from a local AERONET site and $PM_{2.5}$ from an air quality measurement site located in the city centre are shown. High AOD values and particle mass values clearly indicate the smoke presence. However, AOD is considerably lower in 29.7. compared to $PM_{2.5}$. This is likely caused by different vertical distribution; clearly elevated surface $PM_{2.5}$ was measured on both days, while column measurements of AOD suggest that the smoke plume was much thicker on 8.8.

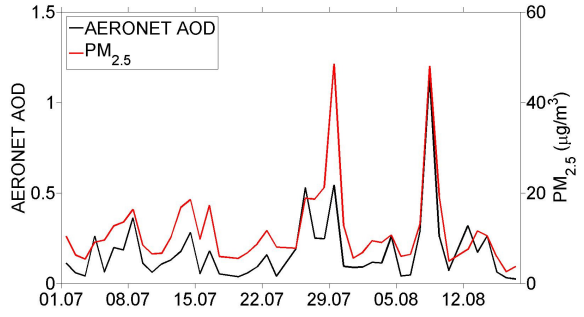

Figure 1. Time series of AERONET AOD and PM2.5 measured at Kuopio city centre. The two concentration peaks are on 29.7. and 8.8.

To better distinguish the characteristics of smoke and related aerosol particles, we made a comparison between smoky and clean conditions. Clean data for the comparison was chosen with the help of 120 hour back-trajectories calculated with FLEXTRA and satellite data from FIRMS Web Fire Mapper (http://firefly.geog.umd.edu/firemap/). Secondly, data from Puijo station was checked for any signs of smoke, such as large particle size and high black carbon content. We then calculated average values of the most important parameters from the clean air data and from the data collected during 29.7. and 8.8.

In table 1, mean values of total particle number concentration (N_{tot}), geometric mean diameter (GMD) and black carbon concentration (BC) from Puijo station for clean and smoky conditions are shown, together with the carbon monoxide (CO) data from an air quality site at the city centre. CO is of particular interest, since it's commonly used as one of the main indicators of biomass burning emissions (Stohl *et al*, 2007). Except for total particle concentration, the effect of smoke can clearly be seen in all parameters. Particles are twice as large on average and BC and CO experience a 12-fold and 8-fold increase, respectively.

Table 1. Average values of some of the most important parameters for clean and smoky air.

	clean	smoky
N_{tot} (cm^{-3})	2540	3380
GMD (nm)	76.3	158
BC (ng/m^3)	98.7	1230
CO ($\mu g/m^3$)	41.1	334

Presenting author email: misv@mail.ru

The extremely hot and dry weather conditions without precipitation in the European part of Russia in summer 2010 stimulated intensive and prolonged forest and peatbog fires. The most intensive smoke events in Moscow took place during the first decade of August. In the present paper, the results of the measurements of aerosol characteristics in Moscow and the Zvenigorod Scientific Station (ZSS) of IAP RAS, located at 60 km to the west from the centre of the city are analyzed.

Aerosol optical properties in the atmospheric column were measured by two AERONET CIMEL photometers installed at the ZSS and at the Meteorological Observatory of the Moscow State University (MO MSU). Optical characteristics of the near-ground aerosol at Zvenigorod were studied by means of polarimeter PhAN. Aerosol mass concentration in Moscow was recorded with TEOM instruments operated by the Mosecomonitoring network.

Smoke events in 2010 were characterized by very high maximal levels of the aerosol loading in the atmosphere. Maximal observed values of the aerosol optical thickness at the wavelength of 500 nm (AOT500) was about 4.5 both in Moscow and Zvenigorod. It is approximately 1.5 times greater than observed during previous intensive fires in 2002. In August, monthly mean AOT was about 4 times higher than the climatic value for this period in Moscow. Daily mean AOT500 values at the two sites are presented in Figure 1 along with the water vapor content. Maximal recorded values of PM10 in Moscow reached 1.6-1.7 mg/m^3. Such levels of aerosol pollution have never been observed previously.

Qualitative aerosol characteristics were also distinct from those in background conditions. AOT did not correspond to the Angstrom's law. Spectral dependence of AOT can be described (in logarithmic scale) by the second order polynomial with the local Angstrom's exponent increase with wavelength. In the period of fire events, the negative values of the degree of linear polarization of the light, scattered at the angle of 90°, was for the first time observed in field measurements. A tendency of the decrease in the degree of the linear polarization with the growth of the smoke pollution was revealed. This is an evidence for the growth of the particle effective radii with the increase of the turbidity of the atmosphere.

The results of the inverse problem solution by the method proposed by Dubovik and King (2000) showed that smoke aerosol in Moscow in 2010 was relatively weakly absorbing. Single scattering albedo at 440 nm varied in the limits of 0.94 - 0.98 during the period from August 1 to August 10. These values are close to the estimates for the aerosol from peatbog and forest fires in 2002 (Chubarova et al., 2009). Aerosol size distributions are characterized by the enhanced relative contribution of the fine fraction in the total aerosol volume content.

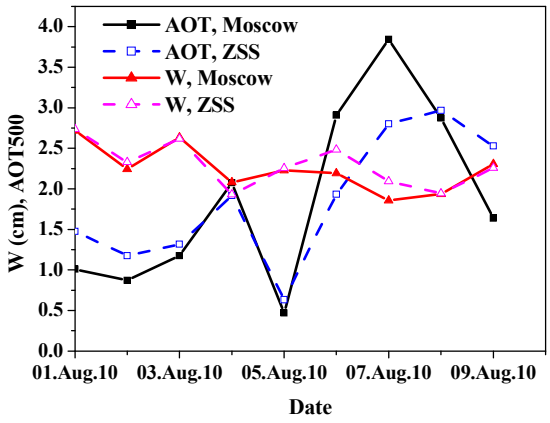

Figure 1. Daily mean aerosol optical thickness at 500 nm (AOT500) and water vapor content at the two measurement sites.

A significant increase in AOT causes a strong attenuation of shortwave irradiance. During the maximum aerosol loading observed on August 7, 2010, the loss of global shortwave irradiance (0.3-4.5 μm) was about 50-60%, while the loss in UV irradiance reached 75-90%.

Session 11B: Chemical and Physical Properties of SOA

Modelling the sensitivity of aerosol properties to variations in key inputs:- 1) vapour pressures; 2) non-ideality; 3) hydrolysis of acid-anhydrides

Introduction

Atmospheric aerosols have significant but highly uncertain impacts upon both the climate and human health. Gas to particle mass transfer of semi-volatile components, and the production of secondary organic aerosol (SOA), is an important factor in determining the evolving chemical composition of aerosol particles and is necessary for predicting their loading and composition. However the atmosphere contains many thousands of organic compounds, all of which can potentially condense and contribute to the mass of the aerosol; and even a basic identification of organic compounds in particulate matter is incomplete. To aid in the modelling of SOA formation, explicit hydrocarbon oxidation mechanisms (known as Direct Chemical Mechanisms or DCMs) that track the oxidative degradation of volatile organic compounds (VOCs) all the way through to carbon dioxide and water have been developed over a number of years. The DCM used in this work is the Master Chemical Mechanism (MCM, Jenkin et al., 2003) .

The Model used for Predicting SOA Formation

SOA formation is modelled using SOAF-POC (SOA Formation by the Partitioning of Organic Compounds) which couples the output of the MCM (molecular structures and atmospheric concentration for 2742 organic compounds) to a partitioning model (a variation on the Pankow model) with vapour pressures and non-ideality calculated using a series of automated estimation methods based upon the parsing of the molecular structures (see poster "Development of chemical informatics tools for calculating fundamental properties of atmospheric aerosol components" by M H Barley et al., this conference).

206 MCM scenarios were used in this work. The key inputs to the MCM model (NOx, Anthropogenic VOCs and Biogenic VOCs) were varied over 6 orders of magnitude (from 0.001 to 1000 times average UK inputs). For each scenario partitioning calculations were made for 24 different combinations of temperatures, %RH and involatile core mass. This presentation will investigate the dependence of key aerosol properties (condensed mass, average O:C ratio, average molecular weight, average contribution of specific functional groups, growth factor etc.) on vapour pressure values estimated by six different methods, non-ideality estimated by UNIFAC and the effect of hydrolysing all acid anhydrides in the MCM output. Some of these sensitivities have been previously investigated for sets of computer simulated compounds (McFiggans et al., 2010) but in this work the calculations are applied to atmospherically representative compounds from a DCM.

The base case (the partitioning calculations against which the other calculations were compared) used the 2742 molecules from the MCM without alteration, calculated vapour pressures using the boiling point and vapour pressure correlations of Nannoolal (referred to as the N/N-VP method), and assumed liquid phase ideality. Other calculations explored the impact of using other vapour pressure methods or including non-ideality. The results can be presented as a series of box-whisker plots which show, for all cases and scenarios (206 x 24), the impact of the changed input on the aerosol property compared to the base case value (see Figure 1)

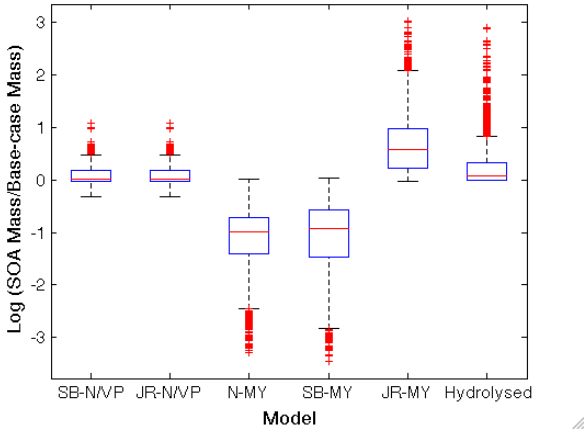

Figure 1. Box-whisker plot showing how changing the vapour pressure input data affects the SOA condensed mass. Base case is vapour pressure by N/N-VP, ideal liquid behaviour and no hydrolysis of anhydrides. SB and JR refer to boiling point estimation by Stein and Brown and Joback and Reid respectively, MY refers to the vapour pressure correlation of Myrdal and Yalkowsky. The sixth plot refers to the effect of hydrolysing all acid anhydrides, while retaining base case values for the other inputs.

According to the pseudo-ideal mixing assumption employed in practically all chemical transport models, organic aerosol (OA) components from different sources interact with each other in a single solution, independent of their composition. This critical assumption greatly affects modeled OA concentrations, but there is little direct experimental evidence to support it. A main experimental challenge is that OA components from different sources often look similar when analyzed with an aerosol mass spectrometer. We developed a new experimental method to overcome this challenge, using isotopically labeled compounds (^{13}C or D) and a High Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS).

Isotopic labeling changes the nominal mass-to-charge ratio (*m/z*) of a given fragment, but the added neutrons also increase the mass defect, which enhances the ability of the HR-ToF-AMS to distinguish different ions at the same nominal *m/z*. The ability of the HR-ToF-AMS to distinguish between isotopically-labeled and unlabeled organic fragments had not been investigated prior to this study. As such, an important part of this work was to develop the analysis method to separate isotopically labeled and unlabeled OA. The main scientific goal was to test the pseudo-ideal mixing assumption. We here tested this assumption for mixtures of secondary organic aerosol (SOA) formed from chemically dissimilar anthropogenic and biogenic SOA precursors.

We generated mixtures of SOA from isotopically labeled toluene and from unlabeled α-pinene and used the HR-ToF-AMS mass spectra to separate these different SOA types using a chemical mass balance. We evaluated the mixing behavior on a standard yield plot (Figure 1), which shows the α-pinene SOA mass yield (SOA formed divided by precursor reacted) as a function of the OA concentration. If the pseudo-ideal mixing assumption is valid and all OA in the system forms a single solution (the "ideal-mixing" case) the SOA mass yield of α-pinene should be a function of the total OA concentration in the system (blue symbols), consistent with equilibrium partitioning. If, on the other hand, the SOA formed does not form a single solution with the pre-existing OA (the "no mixing" case), the α-pinene SOA mass yield should be a function of only the α-pinene SOA (red symbols).

Focusing first on the final yields (large symbols) we observe that the results are consistent with pseudo-ideal mixing (the yields fall close to the expected yield line), and inconsistent with no mixing (the yields fall far from the expected yield line). This implies that, at equilibrium, the pseudo-ideal mixing assumption is valid for this system. The dynamic yields (small symbols) are clearly inconsistent with "no mixing", but they are also lower than expected for the ideal-mixing case. This is consistent with mass-transfer limitations during OA formation: there appears to be some delay between the condensation of organic vapors onto the pre-existing particles and the transfer of the organic species into the particle and equilibration with the bulk OA.

At equilibrium, our results suggest that semi-volatile OA components of different levels of oxidation form a single solution. More generally, anthropogenic and biogenic SOA appear to form a single solution. Therefore, the presence of anthropogenic SOA enhances the concentrations of biogenic SOA, which has important implications for environmental policy.

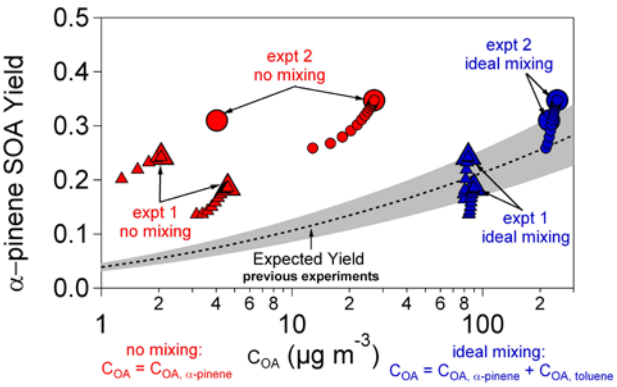

Figure 1. Evaluating the mixing behavior on a standard yield plot. The dashed lines are yield fits based on previous experiments; the shaded grey area is +/-20% of the yield fit, illustrating expected experimental variability. The final yields (large symbols) are consistent with equilibrium partitioning. Dynamic yields (small symbols) are consistent with mass-transfer limitations during OA formation.

Towards a better understanding of hygroscopic growth and cloud droplet activation of biogenic secondary aerosols

Buchholz, A.[1], Mentel, Th. F.[1], Rubach, F.[1], Spindler, C.[1], Tillmann, R.[1], Kleist, E.[2], Wildt, J.[2]

Presenting author email: a.buchholz@fz-juelich.de

Plant emitted volatile organic compounds (VOCs) are a major precursor of secondary organic aerosols (SOA), an important constituent of atmospheric aerosols. Knowledge of the microphysical properties (i.e. the hygroscopic growth and cloud condensation nuclei (CCN) activity) is important to understand the impact of aerosols on climate.

We used the Juelich Plant Atmosphere Chamber (JPAC) at the Research Center Juelich to investigate the microphysical properties of aerosols. SOA particles were produced from the ozonolysis and reaction of OH radicals with the complex VOC mixture emitted from trees typical for the boreal forest. Below 100% relative humidity (RH) the hygroscopic growth factor (GF) of the aerosol particles was determined depending on particle size and RH with a Hygroscopicity Tandem Differential Analyzer. Above 100% RH the activation point was measured depending on the super-saturation (SS=RH-100%) and the size of the dry particle by combination of a CCN-Counter (DMT) and a SMPS/CPC system. The chemical composition of the particles was determined with a High Resolution ToF AMS. Additionally, the size distribution and number concentration of the particles were measured. The gas phase was monitored with GC-MS and PTR-MS.

Changing the emission pattern and strength changed the measured GF and the diameter of the dry particles that were activated (D50). However, below 80% RH the GF changes were within the range of the measurement error. The GF(RH = 90%) were between 1.03 and 1.14, and the D50(SS = 0.4%) in a range of 93 - 100nm. The average hygroscopicity parameter κ (calculated according to Petters and Kreidenweis, 2007) was 0.03±0.01 at RH = 90% and 0.08±0.02 at activation. The aerosol mass spectra measured with the HR-Tof-AMS were analyzed with positive matrix factorization (PMF). The contributions of the identified factors were correlated microphysical properties.

The Koehler theory describes the hygroscopic behavior of aerosol particles in both the sub- and supersaturated regime. A parametrization of this equation is necessary since several of the parameters (e.g. the water activity in the droplets) are unknown for atmospheric aerosols.

Applying the κ parametrization of the water activity (Petters and Kreidenweis, 2007) leads to an underestimation of the CCN activity (see black triangles in comparison to colored dots in Figure 1). κ derived from CCN data was up to a factor of 3 higher than κ derived from GF data. There was a RH dependence of κ with a minimum between 90 and 95% RH. To explain the observed discrepancies, an additional parameter (solubility of the organic material or surface tension) is necessary.

In a different approach the Universal Quasi chemical Functional Group Activity Coefficients model (UNIFAC, Fredenslund et al. 1977) was used to predict the water activity in the mixture of water and organic compounds in the droplets. A hypothetical organic molecule was determined whose functionality and corresponding κ(RH) reproduced the observed hygroscopic growth. If realistic values for the molecular mass and density of the solute were assumed (or derived from measurements), very good agreement of the predicted and measured values was achieved (red line in Fig. 1).

Additionally, real molecules, which can be thought of as surrogates for organics in SOA, were calculated with UNIFAC. The exhibited the same general functionality in κ(RH) as the measured data with a distinct minimum between 90 and 95% RH.

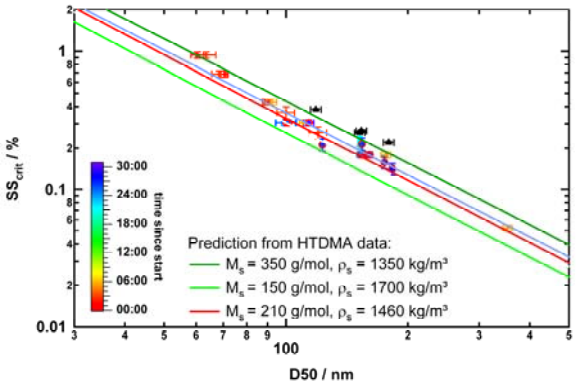

Figure 1. Measured and predicted CCN activation data. The colored dots were measured with the CCN-C (error bars are standard deviation during measurement interval). In black: predicted activation using HTDMA measurements (at 90% RH) and a constant κ. Colored lines: predictions with UNIFAC using different values for molecular mass and density (for details see text above).

Numerous organic compounds are found in the atmosphere and for many of them the thermodynamic properties are poorly known. Dicarboxylic acids are a group of water soluble organic compounds typically found in atmospheric aerosol particles. Studies on their equilibrium vapour pressures for pure substances show discrepancies (Pope *et al*., 2010), and even less is known about their evaporative behaviour in multi-component mixtures. Here, we study the effect of selected activity model on the obtained sub-cooled liquid phase saturation vapour pressure of succinic acid (a dicarboxylic acid) and the effect of inorganic salts on the activity coefficient of this organic compound.

The evaporation rates of solution droplets were measured using a Tandem Differential Mobility Analyzer (TDMA) system coupled with a 3.5 m long laminar flow tube (Koponen *et al*., 2007) providing maximum evaporation time up to 250 s. A monodisperse droplet population is selected with a DMA and let to the flow tube where the droplets evaporate and their size change is measured with a Scanning Mobility Particle Sizer (SMPS). The droplets were atomized from binary succinic acid – water solution or ternary solutions of succinic acid – sodium chloride – water and succinic acid – ammonium sulphate – water. In the latter case the temporal evolution of droplets' composition was also monitored with an Aerosol Mass Spectrometer (AMS).

To study the equilibrium vapour pressures over the mixture droplets, the observed evaporation rates were compared to those predicted by a theoretical evaporation model. In the model, inorganic compound is assumed to be non-volatile and the change of particle size is thus due to evaporation of succinic acid and water. Three activity coefficient models included in the Extended Aerosol Inorganic model, E-AIM, (www.aim.env.uea.ac.uk, see references therein) are used for succinic acid in the ternary cases: fitted activity equation (RK), UNIFAC with Peng *et al*. (2001) corrections (UP) and standard set of UNIFAC parameters (US). In binary cases these were compared also to Dortmund version of UNIFAC (UD) (Gmehling *et al*., 1990).

The saturation vapour pressure of succinic acid ($p_{sat,succ.}$) at 298.15 K extracted from the binary succinic acid – water droplet experiments was $1.29 \cdot 10^{-3}$ Pa, $1.95 \cdot 10^{-3}$ Pa, $1.15 \cdot 10^{-3}$ Pa and $0.90 \cdot 10^{-3}$ Pa when using, respectively, RK, UP, US and UD as the activity model. In general the determined saturation vapour pressures increased slightly as a function of relative humidity when using the first three activity models. This was most pronounced with UP with 25 % variation in determined $p_{sat,succ.}$ value within relative humidity range 60-80 %.

In the ternary case the activity coefficient of succinic acid ($\gamma_{succ.}$) is calculated as for binary solution with the same molality of organic solute, i.e. the effect of inorganic compound on $\gamma_{succ.}$ is ignored. Figure 1 shows that this approach overestimates the evaporation rate when mole fraction of succinic acid is smaller or comparative to that of inorganic compound. The result was similar for both ternary mixtures. Measurements with AMS showed that the uncertainty in the initial fraction of succinic acid in the droplets does not alone explain the discrepancy between the modelled and measured evaporation rates. Neither does the uncertainty in $p_{sat,succ.}$ due to good agreement with large succinic acid fraction. Thus, the result might indicate $\gamma_{succ.}$ being lowered by the inorganic solute. However, the effects of dissociation of succinic acid and uncertainties related to the measurement setup need to be studied in more detail.

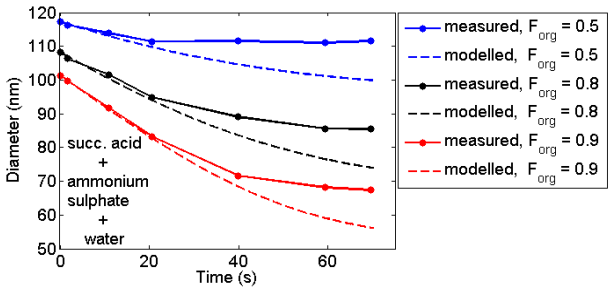

Figure 1. Particle size evolution for three initial fractions of succ. acid (F_{org}) of the total solute at 75% RH.

Presenting author email: lorena.minambres@ehu.es

Atmospheric aerosols generally consist of inorganic species with a wide variety of organic compounds and elemental carbon. On the one hand, sea salt aerosols constitute one of the most abundant types of naturally suspended particulate matter in the troposphere, and are the dominant aerosol species by mass above the oceans. Sodium chloride is the principal component, and also includes less abundant ions such as SO_4^{2-}, Mg^{2+}, Ca^{2+}, K^+ and Br^-. On the other hand, organic matter can amount to 30-50% of fine particulate mass, depending on location (Seinfeld and Pandis, 1998). In addition, sea salt aerosols include appreciable fractions of organic material that can affect properties such as hygroscopicity, phase transition or chemical reactivity. Despite its importance, the physical state of mixed organic/inorganic aerosol particles is not well characterized.

In the present work we study the hygroscopic properties and phase characterization of internally mixed submicrometric particles composed of succinic acid (SA) and NaX (where X=F, Cl, Br or I) by infrared absorption spectroscopy in an aerosol flow cell at ambient temperature for different relative succinic acid/NaX compositions. Infrared spectroscopy is a sensitive technique to characterize aerosol composition, water content and particle phase, and has been used to study other internally mixed organic/inorganic particles (Brooks et al., 2003). The study of the influence of the halogen atom in the NaX/SA system provides physico-chemical insight into the deliquescence process of these aerosols and particle phase.

Aerosols are prepared by atomizing aqueous solutions of desired concentrations to yield submicrometer aerosol particles. The relative humidity (RH) of aerosols is controlled by mixing dry and humid flows of nitrogen. The extinction spectra of particles flowing through an aerosol cell are recorded from 800 to 4000 cm^{-1} with a FTIR spectrometer. Particle phase, composition and water content are measured by monitoring the liquid water extinction spectrum.

The results show that the presence of succinic acid does not appreciably alter the deliquescence process of NaF and NaCl, whereas both NaI and SA/NaI particles exhibit a non-deliquescent behaviour, uptaking water at any RH. SA/NaBr particles, on the contrary, deliquesce at lower relative humidities than pure NaBr particles, the effect being more marked as the SA/NaBr mass ratio approaches unity. Thus the presence of an organic compound with relatively low water solubility, such as succinic acid, internally mixed with sodium bromide aerosol can increase the range of conditions under which the aerosol is a solution, due to specific ion-molecule interactions in the particles that alter their Gibbs free energy. Succinic acid phase in the particles has been spectroscopically monitored at given values of both RH and SA/NaX solute mass ratio. The different hygroscopic properties as the halogen ion is changed can be rationalized in terms of simple thermodynamic arguments and can be attributed to the relative contributions of ion-molecule interactions in the solid particles. The observed behaviour is of interest for tropospheric sea-salt aerosols mixed with organic acids, and, if it can be extended to other organics, can influence the physical and chemical properties of marine aerosols in the atmosphere.

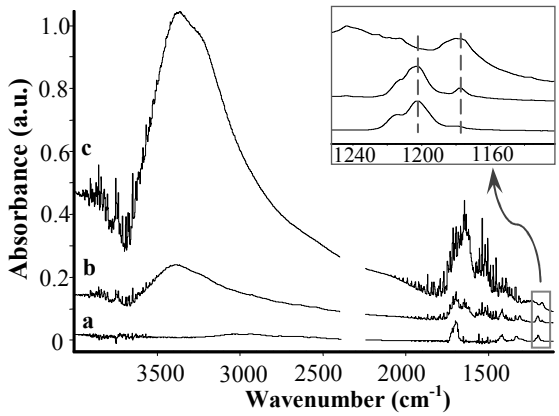

Figure 1. Infrared extinction spectra of internally mixed particles of succinic acid and NaCl at 1:1 SA/NaCl mass ratio and a total concentration of 0.05 kg/L for various RHs. Spectra in (a) and (b) correspond to dry particles exposed to 5% and 75% RH, respectively, whereas spectrum in (c) comes from liquid particles as they exit the atomizer. The inset shows absorption bands of succinic acid that have been used to characterize its phase in the particles: solid (near 1700 cm^{-1}) and aqueous (near 1180 cm^{-1}).

The release of reactive halogen species from sea-salt aerosol contributes a new class of reactants for heterogeneous reactions. These heterogeneous reactions have been overlooked so far, although they may occur with internal and external mixtures of sea-salt aerosol or above a salt-pan and organic aerosol and organic matter in soil. Such reactions can constitute sources of gaseous organohalogen compounds or halogenated organic aerosol in the atmospheric boundary layer.

To study the interaction of organic aerosols with reactive halogen species (RHS), secondary organic aerosol (SOA) was produced from α-pinene, catechol and guaiacol using an aerosol smog-chamber. The model SOAs were characterized in detail using a variety of physico-chemical methods (Ofner et al., 2011). Those aerosols were exposed to molecular halogens in the presence of UV/VIS irradiation and to halogens, released from simulated natural halogen sources like salt-pans, in the presence of UV/VIS irradiation.

The entire organic aerosol and its physico-chemical transformation process were monitored using various spectroscopic methods: Long-path-absorption- and Attenuated-Total-Reflectance (ATR-)-FTIR were used to determine the changes of functional groups and structural elements of the macromolecular aerosols. The optical properties in the UV/VIS range were monitored using diffuse-reflectance-UV/VIS-Spectroscopy. BrO levels were observed by Differential Optical Absorption Spectroscopy (DOAS) in combination with a multi-reflection cell (White-cell). The evolution and change of the aerosol size distribution by the reaction with halogens was observed using an electrostatic classifier coupled to a condensation nuclei counter. Finally, Temperature-Programmed-Pyrolysis Mass-Spectroscopy (TPP-MS) and ultra-high resolution Fourier-Transform-Mass-Spectroscopy (ICR-FT/MS) were used to determine the degrees of halogenation and individual halogenated species.

The heterogeneous reaction of RHS with those model aerosols leads to different gaseous species like CO_2, CO and small reactive molecules like phosgene. Hydrogen containing groups on the aerosol particles are destroyed to form HCl or HBr, and a significant formation of C-Br bonds could be verified in the particle phase. Overall, the optical properties of the processed organic aerosols are significantly changed. Further, the aerosol size distribution of the organic aerosols is strongly influenced (see Fig. 1). The heterogeneous reaction of SOAs with molecular halogens released from the simulated salt-pan at different simulated environmental conditions leads to changes of several physico-chemical features of the aerosol.

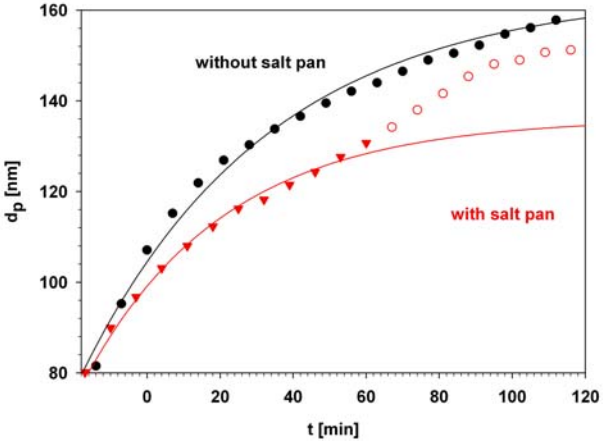

Figure 1. Influence of natural released halogens on the aerosol size distribution of model SOA; the solid lines represent the estimated evolution of the size distribution without the influence of halogens

However, one order of magnitude less BrO was detected in the presence of SOA. This indicates that even the halogen release mechanism could be influenced by the heterogeneous reaction (see Fig. 2).

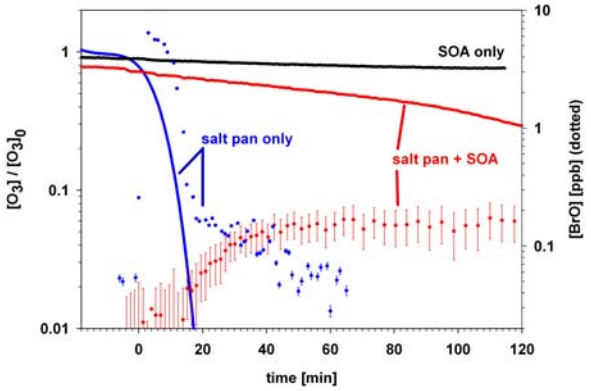

Figure 2. Change of ozone depletion and BrO formation (dotted) under the influence of the model SOA .

Organic compounds are abundant in atmospheric particulate matter, and a large fraction of these compounds are of secondary origin (Jimenez et al., 2009). Besides contributing to the total atmospheric aerosol mass, organic compounds play an important role in growing freshly-formed ultrafine particles to climatically relevant sizes (e.g. Riipinen et al., 2011). To quantify the effect of organic emissions to climate and air quality, atmospheric large-scale models need to realistically simulate the distribution of organic compounds in the atmospheric aerosol size spectrum.

Condensation and evaporation to/from aerosol particles can be reproduced with dynamic models if the thermodynamic and kinetic properties, such as saturation vapour pressures, vaporization enthalpies and accommodation coefficients of the condensing or evaporating vapors are known. In this work we investigate the condensational properties of atmospheric organic compounds, with a special focus on the low-volatile compounds growing the nucleation-mode aerosol (see also Donahue et al., *these proceedings*), and discuss the implications of these results for aerosol growth mechanisms and their representations in atmospheric large-scale models.

By comparing observed growth rates of freshly-nucleated ultrafine aerosol with condensational growth simulated by an aerosol dynamics box model we find that ambient sulphuric acid can account for only a minor fraction of ultrafine aerosol growth, the rest being organics. This observation is consistent with the seasonal pattern of particle growth rates at e.g. the SMEAR II station in Hyytiälä, Finland, for which growth rates show a maximum in the summer along with maximal emissions of biogenic organic compounds (Yli-Juuti et al., *in prep.*). We also find that saturation concentrations of roughly 10^{-3} μg/m^3 or less (corresponding to pure component saturation vapour pressure of the order or 10^{-8} Pa or less) are needed to explain the observed growth (see Fig. 1). Consistent results are found when the evaporation of the nucleation mode aerosol in the heating section of a Volatility-DMPS is modeled with a dynamic evaporation model and compared to measurement data.

These volatilities are significantly lower than those found in fresh chamber-generated or even aged atmospheric secondary organic aerosol (SOA) mass, which typically range from approximately 10^{-2} to 10^{2} μg/m^3 (10^{-7} to 10^{-3} Pa) (see Lee et al., 2010). The observed saturation concentrations are also in the lower end of the corresponding properties of dicarboxylic acids, which are among the least volatile identified SOA molecules with measured vapor pressures ranging from 10^{-8} to 10^{-3} Pa.

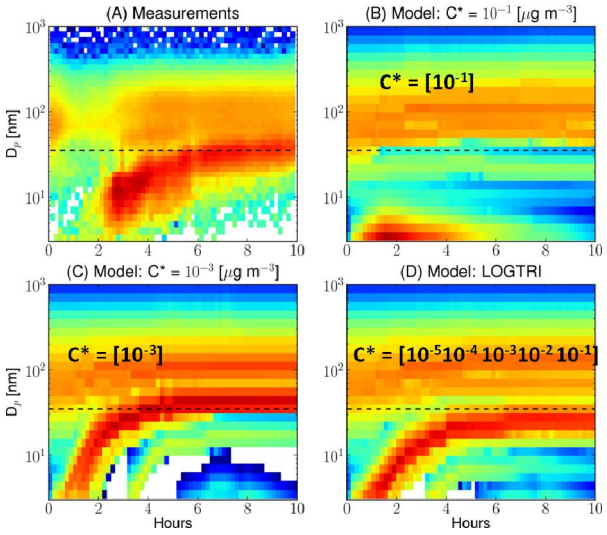

Figure 1. Measured (panel A) and modeled (panels B, C, D) evolution of aerosol size distribution on April 15th 2007 at the SMEAR II station in Hyytiälä, Finland.

Diesel exhaust undergoes rapid cooling and dilution processes when the exhaust is released into the atmosphere. During these processes, gas-to-particle processes like nucleation and condensation can take place modifying the size distribution and physical and chemical characteristics of the exhaust particles.

Particle volatility studies are a practical way to study the gas-to-particle processes of diesel exhaust. In addition to the emission characterizations, volatility studies can produce information about the particle formation processes and about the technical factors affecting them (e.g. exhaust after-treatment, fuel quality).

For example, in several studies the diesel exhaust nucleation mode is shown to include a non-volatile fraction. The initial formation of nonvolatile nucleation mode particles have been showed to take place at high temperature conditions before the exhaust entered into the atmosphere and the formation is affected e.g. by fuel injection pressure and exhaust after-treatment.(eg. Rönkkö et al. (2007), Heikkilä et al. (2009), Lähde et al. (2011)).

On the other hand, the changes of fuel and lubricant oil sulfur content affect mostly to the emissions of totally volatile nucleation mode particles (Karjalainen et al. (2011)).

In the studies above, the particle volatility has been studied using a thermodenuder (TD) where the semi-volatile particle fraction is first evaporated in the heating part and, after that, collected onto the surface of active charcoal in denuder part. The diesel exhaust nucleation mode studies require that, in addition to the effective evaporation of volatile components, the penetration of small non-volatile particles is high enough. Therefore, we built a TD based on the following designing criteria:

1) TD is able to evaporate all semi-volatile species of diesel exhaust particles
2) Evaporated vapors are efficiently collected into the activated charcoal
3) Flow range of TD is 0-10 slpm and the inlet temperature is 300K or higher.
4) Aerosol cools in the denuder part nearly to the inlet temperature of 300K.
5) TD provides a high penetration for non-volatile particles larger than 3 nm.

Designing of the TD was based on simulations by employing CFD packages of Ansys Fluent and Comsol Multiphysics. Losses of non-volatile particles were simulated as a function of particle size by solving the transport equation for different particle sizes in combination with the flow field and heat transfer equations. Evaporation rates of 10 – 100 nanometer sulfuric acid – water particles with concentration of 10^8 particles/cm^3 were simulated (see Figure 1). It can be seen that the particles evaporate in the heating part. In addition, simulations showed that the concentration of the sulfuric acid was reduced by a factor of 300 in the denuder part. The evaporation efficiencies (Karjalainen et al. 2011) and the non-volatile particle losses (Heikkilä et al. 2009) were tested also by generated particles.

In addition to the simulations and laboratory tests, the TD was used in the diesel exhaust particle studies in engine laboratories and on-road. These field measurements showed that the TD is able to remove the volatile nucleation mode particles and condensates from the soot particles (Karjalainen et al. 2011). In engine laboratory measurements the size-distribution measurements of the non-volatile core mode particles agreed well with the results obtained by using the hot dilution setup. Also the studies related to nucleation mode particle charge supported the results(e.g Lähde et al. (2011)).

In summary, simulations, laboratory tests and real engine exhaust measurements confirm that the TD performs well when it is properly operated; the sample flow is not too large, the temperature is not too low and the nucleation mode particles are not too large.

Soot particle aggregates: numerical construction and analysis of influence on laser-induced incandescence and elastic light scattering signals

J. Johnsson[1], A. Karlsson[2], N.-E. Olofsson[1], H. Bladh[1], P.-E. Bengtsson[1]

Presenting author email: jonathan.johnsson@forbrf.lth.se

Soot particles are aerosols that are formed in combustion processes, such as in an IC engine, a gas turbine or a furnace. If the combustion process is not complete, soot particles are often present in the exhaust gases. It is known that these particles have an influence on the climate and that they are detrimental to human health. Carcinogenic polyaromatic hydrocarbons (PAHs) are often present on the particle surfaces, and the smallest particles are especially dangerous, as they easily follow the inhalation air stream down to the lungs, where they can be deposited.

To analyse measurements of soot particle properties, it is important to take into account that the particle structure can be complicated. In general, a soot particle is better described as a soot *aggregate*, which is a cluster of approximately spherical *primary* particles, see Fig. 1a. The configuration in which the primary particles are positioned, and how they are connected to each other, depends on the type of combustion process they were created in. For this reason it becomes relevant to ask what is actually meant by the "size" of an aggregate, and which properties are important to describe the structure. Aggregates produced in the same type of combustion process can be approximately described using a fractal structure (Sorenson, 2001). This means that the radius of gyration of the aggregate, R_g, the primary particle diameter, d_p, and the number of primary particles in the aggregate, N_p are linked, $N_p = k_f(R_g/a)^{D_f}$, where k_f is the fractal prefactor and D_f is the fractal dimension. These two fractal parameters are different for different types of soot; for soot produced in a diffusion flame, $k_f \approx 2.3$ and $D_f \approx 1.8$ (Köylü and Faeth, 1994).

To facilitate the understanding of how to take the shape of soot aggregates into account in size measurements, aggregates with specific properties have been constructed numerically using the method described by Filippov *et al.* (2000). An example is shown in Fig. 1b. The method has also been extended to be able to construct aggregates that include a simple form of necking, so that the particles no longer only have point contact.

Elastic light scattering (ELS) and laser-induced incandescence (LII) and are two techniques that can be used for non-intrusive, time-resolved measurements on soot properties such as volume fraction and size. In ELS, laser light is scattered from the aggregates, and the angle dependence of the scattering intensity can be used to infer size properties of the aggregates. In LII, a nanosecond laser pulse is used to heat the aggregates to a temperature well above

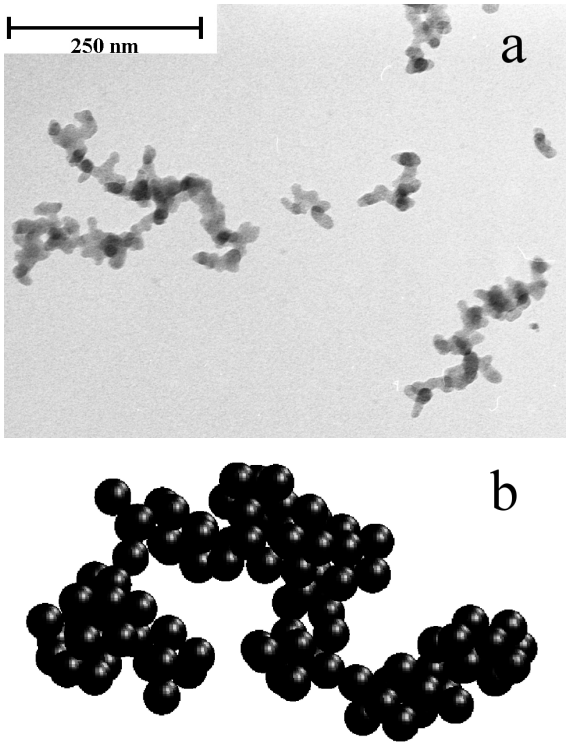

Figure 1: (a) Soot sampled from a flame. (b) Modelled soot particle.

that of the ambient gas. After the pulse, the aggregates cool to the ambient gas temperature with a rate that depends on their size properties.

In this work, ELS from fractal soot aggregates with point-contact between primary particles has been simulated, using modelled soot aggregates. Also, simulation of the heat conduction from soot aggregates has been made, which is relevant for LII measurements. For the these simulations, both aggregates with primary particles in point-contact and various levels of necking are of great interest.

Financial support from Centre of Combustion Science and Technology (CECOST) and the Swedish Research Council is greatly acknowledged.

The morphology of nanoparticle aggregates produced during manufacturing processes of nanomaterials or combustion process is a key parameter to understanding the physical behaviour of these particles. The method of determining the characteristics of fractal clusters (fractal dimension D_f and prefactor k_f) is most often based on sampling of these particles and observation by transmission electron microscopy (TEM), in 2D projection. The obtained micrographs are analysed and 2D morphological information are usually extrapolated to 3D data according to empirical relationships obtained from numerically generated aggregates and proposed by Köylü *et al.* (1995) and Brasil *et al.* (1999).

If soot sampling impact has been studied by Ouf *et al.* (2010), it appears that few experimental validations have been devoted to validate the methodology used for the 2D->3D extrapolation of morphological parameters (Köylü *et al.*, 1995). Indeed, if these digital tools are based on realistic physical principles, the fact remains that these relationships do not include TEM based experimental artefacts (contrast discrepancies caused by monomer's multilayer and overlapping, polydispersity in size of monomers). Moreover, empirical relationships are based on aggregates projections without any preferential orientation. But aggregates may be suspected to adopt a particular orientation during deposition onto TEM grids.

The objective of this study is to carry out an experimental validation of these transposition laws by using electronic tomography.

The nanoparticles aggregates have been observed with a 200 kV LaB_6 TEM JEOL 2100 (IFR 83, UPMC) equipped with a GIF 863 Tridien (GATAN), a SS-CCD 2k x 2k camera and a goniometric sample holder allowing the orientation of the sample from –70° to +70°. Specific software (Digital Micrograph), permits to acquire TEM images with a step of 1° and with automatic focusing/tracking of the investigated object. Using this technique, we have studied nanoparticles aggregates generated using a commercial propane/air burner (CAST, Jing Inc.) and classified in terms of electrical mobility diameter with a differential mobility analyser (DMA 3080L TSI). At the outlet of the DMA, the aggregates are deposited on a TEM grid with the help of a thermophoretic particle sampler (Ouf *et al.*, 2010).

More than 20 aggregates, with a number of primary particles ranging from 10 to 250, have been considered and two separate investigations have been carried out. The first one deals with a potential orientation of aggregates during their deposition on TEM grids. Figure 1 presents the evolution of the number of primary particles measured at several observation angles. The evolution of this parameter has been also numerically computed using DLCA simulation software and considering random or specific orientation of the aggregates during their deposition. According to this comparison, it is not obvious that a specific orientation of the aggregates may be identified during their deposition. This first point validate the use of such sampler for analysing fractal aggregates and most of all that these samples may be used to experimentally validate the transposition relationship.

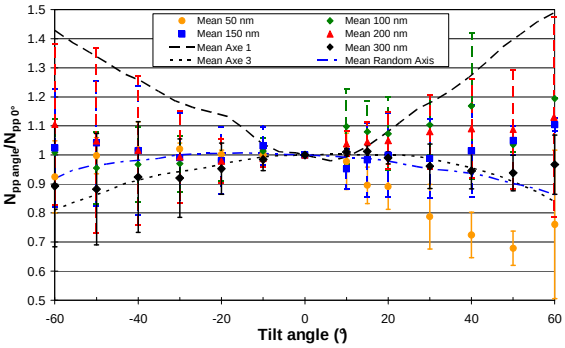

Figure 1. Evolution as a function of the tilt angle, of determined number of primary particles.

The second point, which is still in progress, will aim to establish, using the TomoJ software (Messaaoudi et al., 2007), the 3D morphology of CAST generated aggregates. Finally, these realistic three-dimensional aggregates will be used to define experimental transposition relationships which will be compared to the empirical laws proposed by previous workers.

Effect of Alkali Metal Salt Addition on Hierarchic Assembly of Flame Aerosol Nanoparticles detected by Synchrotron Small-Angle X-ray Scattering

The addition of alkali metal salts (sodium, potassium, cesium salts) and water has been reported in the literature either to increase or decrease soot production in flames(Howard and Kausch, 1980; Fialkov, 1997). On the basis of our previous experimental works by TEM (di Stasio, 2001) and SAXS (di Stasio et al, 2006) we proposed to the combustion community the model of hierarchic aggregation for flame aerosols. The experiments provided the evidence about the fact that the so-called primary particles (30-50 nm), which are the building blocks of soot fractal aggregates (about 100 nm), are in turns constituted by smaller sub-units (~10 nm). We baptised these smaller constituents *sub-primary* particles (di Stasio, 2001).

In this work we studied the effect of addition to the flame of 0.1 mole-wt/liter acqueous solution of alkali metal salts KCl, CsCl, $BaCl_2$, $CaCl_2$ taking into account the previous findings about the formation of hierarchical soot agglomerates. The results show significant effects both on primary and sub-primary particle size and concentration, which are quite new in the literature. In fact previous works were based on laser light scattering techniques which are insensitive below 15 nm because of the background noise by the flame gases. SAXS experiments were performed at the ID02 beamline of European Synchrotron Facility (ESRF) in Grenoble, France. Energy of X-beam was 12.4 keV with $\Delta\lambda/\lambda=0.03$. The beamline was equipped with a scattering tunnel filled by helium with length adjustable between 1 and 10 m at the end of which is positioned the area detector. The shorter scattering distance between flame and detector corresponds to wider scattering angles θ, i.e., to larger scattering momentum $q=(4\pi/\lambda)*\sin(\theta/2)$ and smaller dimension D of detectable particles being $D=\pi/q$. Drops of plain water and alkali metal salts 0.1 mole-wt/liter water solution were aspirated into the air flux before mixing with the ethylene fuel gas. All the results were referred to the addition of pure water. We used the 5 m tunnel configuration and measured a scattering intensity I(q) in the range 0.04 $nm^{-1}<q<0.5$ nm^{-1} (0.004 $Å^{-1}$ to 0.05 $Å^{-1}$) corresponding to a size window for particle detection ~ 6 nm to ~ 78 nm. Analysis of the scattering data was made using the Unified Fitting function approach by Beaucage (1995) implemented by SAS Irena macro by Jan Ilavsky (2009). The results demonstrate that CsCl is effective in reducing either primary or sub-primary particle size but, vice versa, it does increase the concentrations of both. KCl, $CaCl_2$ and $BaCl_2$ have negligible effect on the primary and sub-primary particles but $BaCl_2$ addition leads to the smallest primary and sub-primary particle concentrations observed in these experiments.

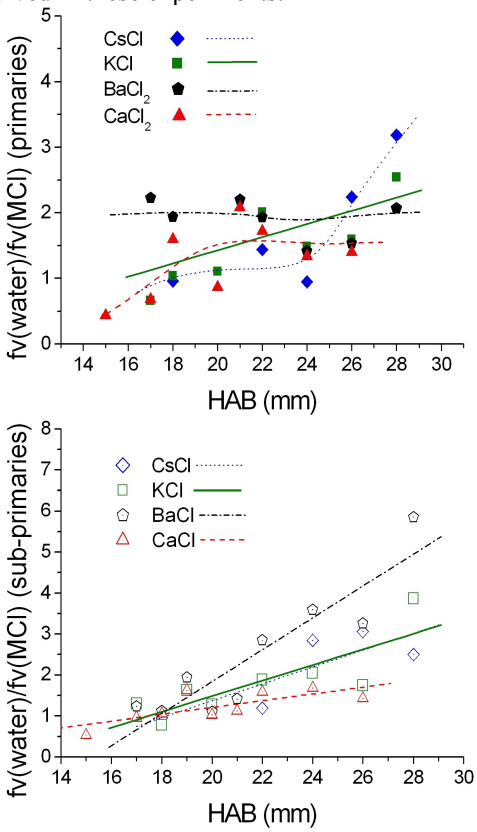

Fig. 1. Top) Effect on volume fraction for plain water vs. Metal Cloride addition in the case of primaries. Bottom) same as Top evaluated for sub-primary particles.

The global effect of soot suppressing is shown in the Fig. 1. $BaCl_2$ and, to a lesser extent, KCl are the additives which yield smaller primary and sub-primary soot volume fraction independently on residence times.

Determination of the refractive index of soot particles in the visble spectrum by extinction spectra

J. Yon, C. Caumon, K. F. Ren, G. Martel and A. Coppalle

CNRS UMR 6614 - CORIA, 76801 BP-12, Saint Etienne du Rouvray, France

Keywords: Aggregates, Index of refraction, Light extinction, Fractals, Soot size distribution

Soot particles, generated by combustion, are fractal-like aggregates. The absorption and scattering of light by these particles can be calculated if their morphology and their complex refractive index are know (Krishnan, 2000; VanHulle, 2002; Yon, 2011). However, up to now, this last parameter is not well known and its determination remains a challenge, as for all carbonaceous amorphous particles. The spectral variation of the complex refractive index of soot matter (m=n-ik) can be predicted using a dispersion model, as the one of Lorentz-Drude (L-D) or Jelisson-Modin (J-M) (1996). However, several parameters of these theories have to be known. This can be done by comparing calculated spectra with measured ones. The extinction spectra of soot particles diluted in a flow are easy to measure in the visible spectrum.

So, in this work the spectral variations of extinction coefficient Kext have been measured for soot particles in the visible spectrum, and the analysis has been performed using the above dispersion models (L-D or J-M) in order to retrieve the values of the complex refractive index m as a function of the wavelength

Soot particles have been generated in an ethylene and two fuel spray flames (di-ester and diesel). The soot has been sampled with a two-stage dilution system (DEKATI FPS 4000) (Ouf, 2010) in order to be introduced in an optical bench at ambient temperature and pressure conditions. The path length is L = 1.5 m and the extinction spectra through the tube are measured by a turbidity system (Ren et al, 2010). Example of such spectra is shown in Fig. 1.

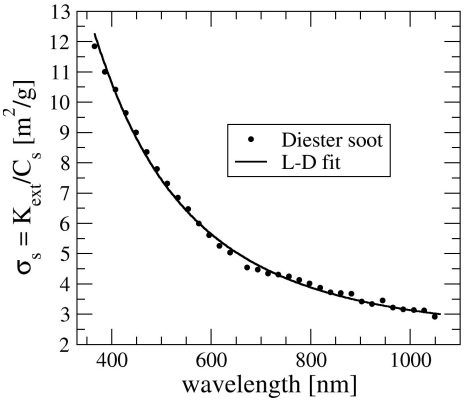

Fig.1: experimental spectrum of the specific extinction coefficient σ_s = kext/Cs of diester soot (σ_s = kext/Cs, with Cs the mass concentration). The continuous line represent the calculated values with the dispersion model of Lorentz-Drude

In the same conditions, other measurements have been performed. The size distribution of the soot N(Dm) was measured by using a SMPS (3010-TSI). These particles were also deposed on a filter and measured by a TEM (Transmission Electron Microscopy). This last experimental set-up permits the determination of soot morphological properties (fractal dimension df, fractal prefactor kf and primary particle size Dp).

From the measured size distribution and from the morphology parameters, the extinction spectra are calculated according to the RDG-FA (Rayleigh-Debye-Gans theory for fractal aggregates) model. The extinction coefficient is given by:

$$K_{ext} = C_a\, E(m) \sum_{D_m} D_m^{d_f} N(D_m) + C_b\, F(m) \sum_{D_m} D_m^{2d_f} g(\lambda, D_m) N(D_m)$$

where the factors Ca and Cb depend on the morphological parameters (df, kf, Dp) of the soot and the wavelength λ. The first and the second terms in the above equation represent respectively the contributions of absorption and scattering processes. E(m) and F(m) are functions of the refractive index m.

Two ways are possible for analyzing the experimental spectra. 1- As it will be shown, the scattering contribution is not important in the extinction process. So by neglecting this contribution, spectral variation of E(m) can be derived directly from Kext measurements. 2- We can also determine the refractive index values of the soot by comparing and fitting calculated values of Kext to measured ones. To this end, a dispersion model has to be used, and the aim of the comparison is to obtain the parameters of the dispersion model, allowing to determine the functions E(m) and F(m). In the present study, the model of Lorentz-Drude and the one proposed by Jelisson and Modine (1996) have been used.

The results obtained with the two procedures will be presented and analysed. As an application, the influences of particle morphology and their temperature on the radiative properties of soot will be also assessed and discussed.

Prediction of soot oxidation reactivity by Raman microspectroscopy

R. Niessner , J. Schmid, B. Grob and N.P. Ivleva

Chair for Analytical Chemistry, Institute for Hydrochemistry, Technische Universität München, Munich, 81377, Germany

Keywords: diesel soot, reactivity, structure, Raman microspectroscopy (RM), temperature-programmed oxidation (TPO)

Presenting author email: Reinhard.Niessner@ch.tum.de

Aerosol soot particles of anthropogenic origin form a class of air pollutants of great concern to air quality. Especially in urban area, soot nanoparticles emitted by diesel engines provide the major fraction of air pollutants and hence must be prevented from leaving the exhaust system. A wide range of particle trapping systems and exhaust aftertreatment technologies are currently under investigation. The necessary regeneration step of such particle traps can be promoted by the formation of highly reactive soot. Therefore the rapid and robust prediction of diesel soot reactivity is desired for investigation and optimization of diesel exhaust aftertreatment systems and hence for reduction of soot emission.

Usually thermo-analytical methods are applied for analysis of soot oxidation reactivity. In particular, temperature-programmed oxidation (TPO), measuring the gasification products by mass spectrometry or infrared spectroscopy and thermo-gravimetric analysis (TGA), measuring the mass decrease are used (Knauer *et al* 2009; Song *et al*, 2007). Moreover Su *et al* (2004) have shown that the soot oxidation reactivity is clearly connected to the microstructure (structural order of soot). High resolution transmission electron microscopy (HRTEM) is usually applied for investigation of soot structure. However, TPO/TGA and HRTEM are too demanding for routine analysis. On the other hand, one can obtain detailed information about the reactivity of soot by measuring the structure with Raman spectroscopy.

Raman spectroscopy is a standard non-destructive tool for the structural characterization of carbonaceous materials based on vibrational fingerprint spectra. By combining Raman spectroscopy with optical microscopy – Raman microspectroscopy (RM) – it is possible to obtain full spectral information with spatial resolution in the micron range. Recent Raman studies have shown a link between reactivity and structure of soot (Knauer *et al* 2009).

We developed multiwavelength Raman micro-spectroscopy (MWRM) analysis prediction of soot oxidation reactivity. This new method is based on the dispersive character of carbon D mode in Raman spectra (i.e. red shift and increase in intensity at higher excitation wavelengths, λ_0). The approach was proven by investigating various diesel soot samples and related carbonaceous materials at different λ_0 (785 nm, 633 nm, 532 nm and 514 nm). In order to compare the behavior of the D mode for various samples and to derive a single parameter characterizing the soot structure, the difference of integrals for pairs of spectra collected at different λ_0 was calculated. MWRM analysis revealed substantial differences in the structural ordering which decreases from graphite, over Printex XE2 and various diesel soot samples, to spark discharge soot. To obtain the relation between structure and reactivity of soot, MWRM analysis was combined with TPO. This allowed us to characterize the oxidation behavior of soot in terms of the maximum emission ($CO + CO_2$) temperature and reactivity index. The latter was calculated by introducing the reactivity limits: spark discharge soot containing a large amount of disorder represents the upper limit, whereas the lower limit is given by graphite powder with high structural order. The comparison of MWRM (viz., the observed Raman difference integrals) and TPO data revealed a linear correlation between soot structure and oxidation reactivity (Figure. 1). Thus we have clearly shown that the MWRM is a rapid analytical tool to predict the oxidation behavior of diesel soot samples and other carbon materials.

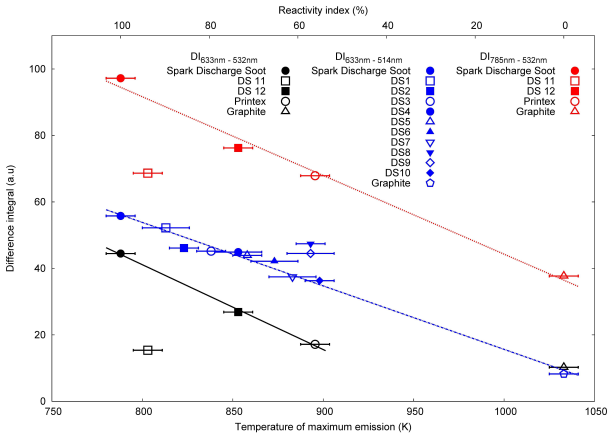

Figure 1. Correlation of oxidation reactivity (temperature of maximum emission, RI_{soot}) and structure (MWRM) of different carbonaceous materials and diesel soot with three different wavelength differences.

Measurement of soot size distribution in flames by inversion of angular light scattering

Caumont-Prim C., Yon J., Coppalle A. and K.-F. Ren

UMR 6614 CORIA, Avenue de l'université, BP 8, 76801 Saint Etienne du Rouvray, France.

Keywords: soot particles, fractals, aggregates, light scattering
Presenting author email: yon@coria.fr

Soot particles are produced by combustion processes. Since a long time, these particles give rise to numerous investigations for their modelling and due to their important implications in human health, flame radiative transfer and climatic impact. Among other information, the determination of soot size distributions at different Height Above the Burner (HAB) in flames is essential. The soot size distribution is determined often by using ex-situ granulometers, after sampling of the particles. But the quenching of aggregation process in the sampling is difficult and raises the question of representativeness of the results (Ouf *et al.* 2010). For this reason, optical measurements are more adapted. By knowing the temperature of the flame, Dynamic Light Scattering technique permits to determine a mobility diameter. But without any more information, soot size distribution can't be derived by this technique. Moreover, soot particles are not spherical and their specific fractal morphology has to be taken into account. Thanks to a simple theory called Rayleigh – Debye – Gans for Fractal Aggregates (RDG-FA theory - Dobbins *et al.*, 1991), measurement of static light scattering can be interpreted in order to determine another size parameter called gyration radius. The inversion by this theory to infer the gyration radius of monodisperse aggregates has been recently validated (Caumont et al. 2010).

Some authors (Dobbins & Megaridis 1991, Köylü 1994) have proposed to determine a representative gyration radius of the polydisperse population with this optical technique. But two distinct radii can be calculated if particles are suspected to scatter only in Guinier or in Power Law regime and that assumption cannot be done without knowing the researched size distribution. Koylu & Faeth (1996) and Iyer *et al.* (2007) proposed an inversion method to calculate the characteristics of the soot size distributions by coupling scattering and extinction measurements. But this method relies on the knowledge of the soot optical index which is unfortunately not accurately known. That's why it is necessary to develop a new approach which doesn't need any primary knowledge.

The present work presents a new inversion method for the determination of the soot size distribution in flames by measuring the scattered light at different angles. It consists in determining for each studied angle, by using the RDG-FA theory, a gyration radius $Rg^*(\theta)$ of a monodispersed population of the same optical behaviour as that of the real polydisperse population.

The $Rg^*(\theta)$ function thus determined informs us polydispersity of the soot. For example, in monodisperse case, $Rg^*(\theta)$ must be constant. In contrary, the variation of this function informs us of the range of polydispersity. So, by supposing the nature of the size distributions (lognormal or self-preserving), it is possible to determine, by this technique, governing parameters of these distributions.

In the present study, that inversion method is proposed to determine the soot size distributions at different HAB in a laminar diffusion ethylene flame.

Session 11D: From PM exposure to health effects 1

Selection of proper markers for a better knowledge of health effects of air pollution. Difficulty in the choice of markers or in the recognition of causative mechanisms?

Keywords: PM, markers of exposure and effect, causative mechanisms, transient and persistent alterations.
Presenting author email: guercio3@unisi.it

The aim of the present study has been to focus on possible markers of effect and susceptibility for a better understanding of the health effects of air-pollution.

Methods: in Milan, Italy, between 2007 and 2010, a comprehensive approach to health effects of air pollution was designed (Prolife Project). In particular, the following studies were performed : 1) PM concentration measurement; 2) comparison between daily concentration of PM or other pollutants and acute hospital admission for respiratory or cardiovascular diseases (n= 53.514); 3) longitudinal studies in frail subpopulations, such as children attending primary school (n=440) and elderly people living in nursing homes (n=198); 4) "*in vitro"* and "*in vivo"* experiments concerning host particle interactions.

Results: Transient or persistent and severe alterations of respiratory or cardiovascular districts were observed, either in children or in old people, in addition to alterations of other system such as sperm-cell function or osteoarticular function. However, in people with similar exposure to pollutants, they depended at a greater extent on individual susceptibility of the host than on intrinsic toxicity of the pollutants. In particular, more severe alterations were observed in subjects with chronic infection, COPD, rheumatoid arthritis or varicocele. It was found that PM determines multiple effects, that cannot be explained by "pure" toxic mechanisms. Therefore, a single marker is insufficient to capture the complexity of host particle interactions. In fact, an ideal marker should reflect at least 2 different mechanisms: 1) the former, that is pollution related (i.e. due to concentration, composition or other intrinsic properties of PM). 2) the latter, that is host susceptibility related. However, pollution-related diseases are a no-threshold phenomenon, i.e. there is no threshold of PM concentration above which the effect is detectable in all individuals, and no level below which there is no effect. Therefore, to capture these complex interactions, other markers should be chosen, partly related, but also partly not related to the presumed intrinsic toxicity of pollutants. These markers should measure individual susceptibility, vulnerability and the overall response of the human being as a whole.

We suggest: 1) a "stepwise approach", based on levels or degrees of evidence in the mechanistic causative role of PM and other airborne pollutants for the occurrence of clinically evident diseases or death in humans; 2) the need for markers of effect, which should be graded, on the basis of the level or degree of possible, transient, persistent or definitive damage. These markers can be classified as phase 1 or molecular markers (molecular alteration, or biological changes such as oxidative stress, ROS production, DNA adduct formation, which should be repaired by usual cellular mechanisms); phase 2, or cellular markers; phase 3, or markers of permanent tissutal damage and phase 4, or markers of clinically evident disease, or permanent function impairment of one organ or apparatus. Finally, a cumulative score is required, which takes into account both these mechanisms (particle related and host related). We must outline, however, that measurement of this final score will also be variable, because it is arbitrary the weight that is given to each end-point and marker: oxidative stress, genetic mutation, inflammation, individual ability to repair damage, risk for autoimmune response. The weight of the various components should also be compared with current knowledge concerning the various diseases of interest and then be greater for the particle related toxic mechanism, when evaluating diseases with low to no evidence for autoimmunity in their pathogenesis. On the contrary, the relative weight could be greater for the host related mechanism, when dealing with clinical outcomes or diseases, for the occurrence of which (rheumatoid arthritis, asthma) autoimmunity is a well known causative factor. As markers of the toxic mechanism we can choose those related with oxidative stress and ROS generation, genetic polymorphisms in drug metabolizing enzymes (GSMT, NADH), which can be responsible for repair capacity, but also we have to select markers expressing host capacity concerning cellular immunity and general markers of good health, in addition to specific markers for each function or district of interest. The final picture of the various markers of interest will be more complicated, and to provide a proper model will be more complex. But, it will be more adherent to what actually occurs in real world and could help in preventing misleading inferences from epidemiological studies.

Effects of elementary school indoor/outdoor PM_{10} on gene expression and blood coagulation

[3]Bavarian Health and Food Safety Authority, Department of Environmental Health, 85764, Oberschleißheim, Germany
[4]Institute of Ecological Chemistry, Helmholtz Zentrum München, 85764, Neuherberg, Germany

Keywords: health effects of aerosols, human lung cell, indoor/outdoor PM_{10}, inflammation, xenobiotica metabolism, blood coagulation.

Outdoor particulate matter (PM_{10}) is associated with a wide range of health effects (Brunekreef *et al.*, 2002) and a European threshold limit of 50µg/m^3 (daily limit, EU Directive 1999/30/EG) was established in 2005. However, most individuals spend at least 85% of their time indoors (Klepeis *et al.*, 2001) where particle concentrations are mostly higher than outdoors (Fromme *et al.*, 2007). Since children represent a vulnerable group, we investigate the health effects of indoor air PM_{10} collected in elementary school classrooms compared to outdoor air PM_{10}.

Methods PM_{10} was collected on Teflon filters (2.3m^3/h; Derenda Inc.) in six elementary schools with two classrooms per school in Munich during teaching hours (5.5h/day). In parallel outdoor air nearby the classrooms was sampled (30m^3/h; high volume sampler; Derenda Inc.). Filter load was determined gravimetrically. Particles were recovered by sonication, lyophilized and resuspended in water. PM_{10} was analyzed for EPA priority PAHs by HPLC and endotoxin by LAL test. For a genome wide gene expression analysis BEAS-2B bronchial epithelial cells were incubated with 10µg/mL classroom and outdoor PM_{10} of one school for 4, 10 and 24 hours. RNA was isolated and analyzed on Affymetrix HG U133A 2.0 expression arrays (14,500 genes). A subgroup of 46 regulated genes was analyzed by real-time-RT-PCR after exposure to PM_{10} samples from all six schools. Effects of PM_{10} on blood coagulation were studied by incubating monocytes isolated from peripheral human blood with different PM_{10} concentrations (1, 5, 10, 50 µg/mL). After 24 h the supernatants were removed, cleared from particles and used in an optimized, highly sensitive blood coagulation assay including multiple temperature controls.

Results Indoor PM_{10} in schools occurred at 117±48µg/m^3. The corresponding outdoor concentrations were 21±15µg/m^3. PAH content was higher in outdoor (47ng/mg vs. 31ng/mg indoor) PM_{10}, endotoxin higher in indoor (130±41EU/mg vs. 13±22EU/mg outdoor) PM_{10}. Genome wide analysis of PM_{10} from outdoor and indoor air showed the induction of the following metabolic pathways: inflammation, metabolism of xenobiotics, tissue remodeling, blood coagulation, and oxidative stress. Inflammation was characterized by overexpression of chemokines (CCL20, CXCL1, IL-8) and cytokines (IL-1, IL-6, LIF). Xenobiotic metabolism was represented by phase-I enzymes (CYP1A1, CYP1B1, ALDH1A3, NQO1). Tissue related genes were MMP1 that degrades extracellular matrix, GREM1 which is induced in pulmonary fibrosis, and IL-24 - a cytokine of wound healing. Blood clotting was represented by the coagulation factor SERPINB2 and oxidative stress by the antioxidative enzyme SOD2. Indoor PM_{10} caused a lower induction of xenobiotic metabolizing genes but an up to 6 fold higher induction of inflammatory cytokines compared to outdoor PM_{10}. These differences correlate with the content of PAH (r^2=0.75 for CYP1A1) and endotoxin (r^2=0.69 for CXCL6) in these samples.

The highest induced gene was SERPINB2 and indeed, our blood coagulation assay with human blood showed a concentration-dependent acceleration of coagulation for indoor particle concentrations at 5 µg/mL and higher and for outdoor particles at 50µg/mL only.

Conclusions PM_{10} concentrations were 5.6 fold higher indoors than outdoors. Although indoor classroom PM_{10} caused less induction of xenobiotic metabolizing genes, it had a stronger endotoxin-related inflammatory effect and a higher potential to facilitate blood coagulation than outdoor PM_{10}. Thus, interventions for the reduction of classroom PM_{10} would be reasonable.

Personal Exposure Assessment of School Children to Airborne Nanoparticles

Rohan Jayaratne, Megat Mokhtar, Lidia Morawska and Mandana Mazaheri

International Laboratory for Air Quality and Health, Institute of Health and Biomedical Innovation
Queensland University of Technology, Brisbane, Australia
Keywords: Childrens Health, Air Quality, Respiratory Health
Presenting author email: r.jayaratne@qut.edu.au

The toxicology and human health effects of airborne nanoparticles are of increasing concern, especially in light of the advent of engineered nanoparticles in recent years. In this study, we used a Philips Aerasense Nanotracer to monitor the daily exposure of school children to airborne nanoparticles. This instrument is a hand-held battery-operated device that measures airborne particle number concentration (PNC) up to 10^6 cm^{-3} and the average diameter of the particles in the size range 10-300 nm. Data are logged every 16 s and subsequently downloaded to a computer for processing and analysis.

Preliminary measurements were carried out with the help of 15 children in three primary schools in Queensland, Australia. Each child was fitted with a device that they wore over a 24-hour school day. Data were stored and downloaded to a lap top computer for later analysis. In addition to the nanotracers, the children also carried with them a small portable GPS device that was used to derive information on their movements. In addition, the parents or guardians of the children were requested to keep a log of their travel and activities. At some time during this period, the child would also undergo a series of clinical tests as part of the study

PNC in the classrooms were monitored with a TSI 3781 condensation particle counter (CPC). This provided the areal exposure for comparison with the personal exposure measured with the nanotracer. The total daily personal exposure of each child to nanoparticles was estimated from the mean PNC recorded by the corresponding nanotracer.

Figure 1 shows the PNC time series recorded by the nanotracer worn by a child and the CPC placed in the classroom over a typical two-hour period of the day. The agreement is reasonably good except for the differences near 12:50h and 13:25h which corresponded to periods when the child was outside the classroom. Figure 2 shows the PNC time series recorded by the nanotracer worn by another child over a 24-hour day. Note the relatively high exposure while commuting to and from school at (a) and (b), respectively. The peaks at (c) and (d) correspond to the lunch break and outdoor play activity, respectively. For this particular child, the mean daily exposure level was 8.8 x 10^3 cm^{-3} which corresponds to a daily exposure of 2.12 x 10^5 particle h cm^{-3} day.

This is part of a study to determine the effect of the exposure to airborne ultrafine particles emitted from motor vehicles on the health of children in schools to be carried out over the next two years at 25 schools in Queensland. From results such as that presented in this paper, the average exposure levels under different circumstances such as while in the classroom, in the home, outdoors and while commuting to school will be determined for over 100 primary school children. These children will also undergo a series of health checks. At the end of this study, we expect our results to assist us to identify the long-term respiratory health indicators that are sensitive to exposure to airborne particles.

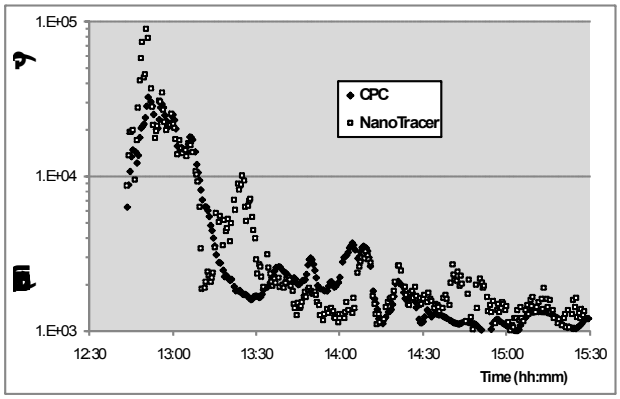

Fig 1: Time series of CPC and Nanotracer measured in a classroom over a two-hour period.

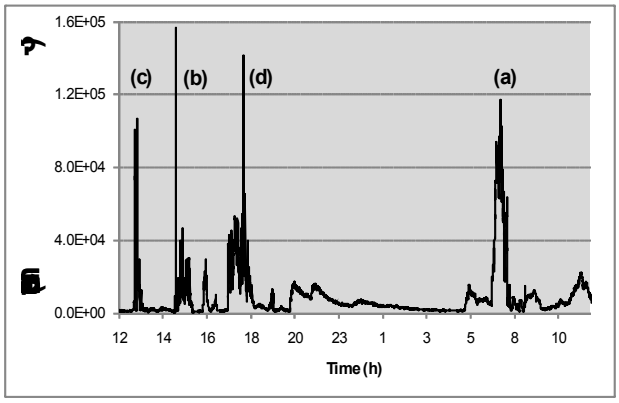

Fig 2: Exposure to PNC as measured by a nanotracer worn by a child over a full 24-hour day.

There is increasing concern regarding the emission of potentially harmful pollutants, such as particulate matter (PM), ozone (O_3), volatile organic compounds (VOCs) and semi-volatile organic compounds (SVOCs), from office equipment (Destaillats et al., 2008). A number of research works report that the operation of printing and copying equipment may contribute significantly to increased indoor air pollutant concentrations, while they have been also associated with health complaints from exposed workers (Lee et al., 2001). The aim of the present work is to study workers exposure levels to particulate matter (PM), carbonyls and ozone in a photocopy / printing centre.

The studied enterprise offers photocopy and digital printing services and is housed in a three storey building. Measurements were carried out during June and July 2010 at rooms of different use, in order to study the effect of the various activities on the observed concentration levels. 24-hr $PM_{2.5}$ gravimetric samples were obtained by the use of LVS Derenta sequential sampler. In addition, real-time measurements of TSP and $PM_{2.5}$ (Thermo MIE Dataram 4000, PDR-1000 and PDR-1200) and O_3 (Ozone Analyzer, Model 49im, Thermo Scientific) were conducted. Carbonyls concentrations during working hours were also measured through active 3-hr sampling in DNPH cartridges, followed by analysis by HPLC with UV detector (Waters 600).

Mean 8-hr TSP and $PM_{2.5}$ concentrations (during working hours) measured at the different floors are presented in Figure 1. Extremely high concentrations were measured at the 3rd floor where the use of different binding techniques (hot glue binding / plasticizer) led to significant particle generation (Figure 2). The increased concentrations observed at the ground and 2nd floor, in comparison to the administrative offices (1st floor), suggest that the intensive use of photocopy machines and printers may also influence indoor PM levels. The measured concentrations were close to the ambient air quality standards for PM_{10} and $PM_{2.5}$ set by E.U.

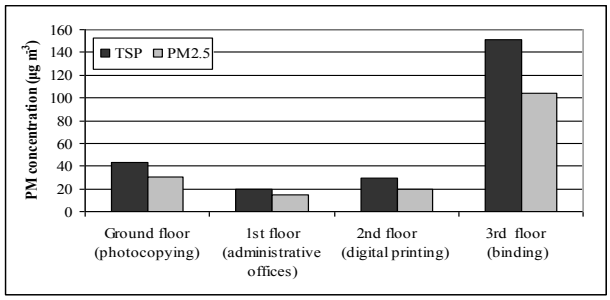

Figure 1. TSP and $PM_{2.5}$ concentration levels during working hours (mean 8-hr values).

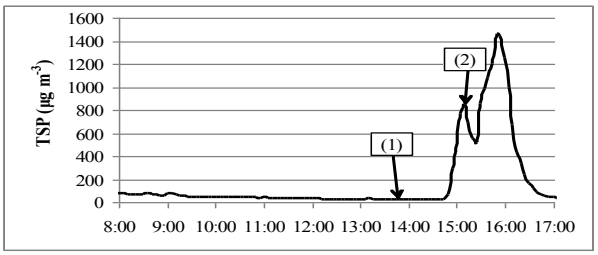

Figure 2. TSP concentration during binding activities. (1) and (2) denote the initiation of hot glue binder and plasticizer, respectively.

The results of gas measurements indicated that photocopy machines and printers may also be important emission sources of ozone and carbonyls (Figure 3 and Table 1).

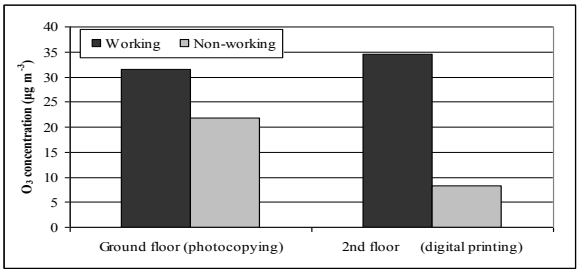

Figure 3. Ozone mean concentration levels during working and non-working hours.

Table 1. Mean 3-hr carbonyls concentrations [μg m^{-3}] during working hours.

	Ground floor (photocopying)	2nd floor (digital printing)
Formaldahyde	9.0 - 11.8	3.0 - 14.1
Acetaldehyde	38 - 102	2.4 - 77.6
Acetone	19.7 - 41.5	6.4 - 35.3
Benzaldehyde	0.54

Presenting author email: aneta.wierzbicka@design.lth.se

The aim of the study was to gain information about fine and ultrafine particles (diameter smaller than 2.5 μm and 100 nm, respectively) in a supermarket in Sweden. Assessed particles' characteristics were: number concentrations and number size distributions. In the studied supermarket, an indoor source of ultrafine particles was observed due to local emissions of terpenes (from storage of washing powders, cleaning products and air fresheners), which in the presence of ozone from outdoors form particles due to gas-to-particle conversions. Additionally conducted chamber study confirmed the observed findings.

Supermarket measurements: were performed continuously for seven consecutive days in the area with washing powders, cleaning products and air fresheners. Particle number concentration (PNC) and size distribution in the range 15 nm to 20 μm were recorded by a scanning mobility particle sizer (SMPS) and an aerodynamic particle sizer (TSI APS 3321). A valve was incorporated into the SMPS sampling system, which enabled alternate measurements of the indoor and supplied ventilation air. Mechanical ventilation supplied heated and filtered air and operated between 4:30 and 22:00. The measured air exchange rate (AER) was ~ 10 h^{-1}, the ozone concentration in ambient air was 30 ppb. In the ventilation system there was no recirculation and no dehumidification, supplied air in 100% was composed of filtered outside air, the filter used was a glass- fibre F7 class filter (EN 779: 2002).

Laboratory experiments: were performed in a 22 m^3 stainless steel chamber, where 200 cleaning products from the same supermarket, were placed. AER was kept at 5 h^{-1}, ozone was supplied until concentrations in the chamber reached 16 ppb and then was switched off to imitate ventilation off conditions in the supermarket. The same set of instruments as in the supermarket were used with additional measurements of ozone and terpenes the latter through collection on carbopack X adsorbent and subsequent GC-MS analysis.

When the ventilation was on the submicrometer PNC inside the supermarket (median 2500, min 1100, max 11000) particles cm^{-3} was higher than in the supplied ventilation air (median 850, min 200, max 4000) particles cm^{-3}, indicating an indoor source of particles. The median GMD inside the supermarket of 42 nm was about 20 nm smaller than in the supplied ventilation air. The presence of nucleation mode particles was assumed to come from local emissions of terpenes (from washing powders, cleaning products and air fresheners), which in the presence of ozone from outdoors (supplied in ventilation air) form particles. The observed concentrations are not high, but considering the high AER (~ 10 h^{-1}) and supply of air with very low particle loads, these contributions are significant.

Interesting patterns were observed when the ventilation was switched off. At this time the removal due to high AER and supply of heated air with low particle loads were eliminated. This might have resulted in local accumulation of terpenes and temperature decrease. A sudden increase in PNC with a number GMD of about 30 nm was observed and can be explained by nucleation via gas-to-particle conversions from terpenes in the presence of ozone. After reaching the peak (within 30 minutes to an hour after ventilation was switched off) a decrease in the PNC was seen, probably due to dilution and spreading within the air in the supermarket and diffusional losses to surfaces. Possibly ozone concentrations were depleted by then due to chemical reactions. At the same time the number GMD increase was observed, this could be due to organic vapour condensation, as the reduced AER results in more time available for gas phase chemistry and particle growth.

Performed chamber experiments confirmed observed patterns. Newly formed particles were of the same size as those observed in the supermarket, and a similar increase in GMD was observed with time. 70% of the determined terpenes, emitted from cleaning products, washing powders and air fresheners, consisted of limonene.

In the supermarket, an indoor source of ultrafine particles was observed due to local emissions of terpenes (from storage of washing powders, cleaning products and air fresheners), which in the presence of ozone from outdoors form particles. More data is needed to determine typical levels of ultrafine particles in supermarkets. The results indicate that even storage of enclosed cleaning products can be a source of ultrafine particles and thus adequate ventilation in places where products containing terpenes are kept are of prime importance in order to minimise exposure to ultrafine particles.

This work was performed within the framework of the Metalund centre of excellence, and financed by the Swedish Councils FORMAS and FAS together with the Development Fund of the Swedish Construction Industry (SBUF).

Particle exposure in public transport – seasonal dependence

K. Hämeri[1], E. Asmi[2] and B. Mølgaard[1]

[1]Department of Physics, University of Helsinki, Helsinki, 00014, Finland
[2]Finnish Meteorological Institute, Helsinki, 00101, Finland
Keywords: Exposure, number concentration, mass concentration, public transport,
Presenting author email: Kaarle.hameri@helsinki.fi

Exposure to traffic related particles have been intensively studied during last years. There is increasing concern on health effects of fine and ultrafine particles and in key focus, there are particles originating from traffic. However, there exist only a few publications considering exposure while in transport. The city buses and trams travel in the middle of the town area and often along the busiest streets where traffic is the major particle source. Thus, the concentrations of tailpipe emissions as well as street dust suspensions are high. Traffic generated particles are transported inside the vehicles and they predispose both the driver and the passengers to high particle concentrations. The topic is especially critical for the drivers, who are exposed to the pollutants for long periods.

Commuters' exposure to traffic-related pollutants has been studied in the Netherlands (Zuurbier et al., 2010). They focused on different modes of transport, routes, and fuel types. We studied earlier the exposure of bus and tram drivers and passengers to fine particulate matter in two types of buses and trams in Helsinki, Finland during summer time (Asmi et al., 2009).

In this study, we investigate the commuters' exposure to fine particles during three seasons in Helsinki, Finland. The measurements of particle number and mass concentration, and black carbon mass were conducted in the cabin and driver's compartment during summer 2005 and winter and spring 2006. The concentrations measured inside the vehicles were compared to simultaneously measured concentrations both right outside of the vehicle and in background monitoring stations. The aim of the study is to compare commuters' exposure during different seasons and thus different weather conditions. The experiments were conducted in buses and trams, both of which were travelling along the same route through the city centre.

Air pollution situation varies greatly between different seasons in Helsinki. During summertime, temperature during daytime is usually around 20 C and the atmospheric mixing is efficient leading to lower average concentrations compared with other seasons. During wintertime, temperature is usually around or a couple of degrees below zero and the mixed layer is rather shallow. The air pollutants accumulate close to the surface leading to worsening of the air quality. During spring, there is a dust episode, which lasts about one month. This is due to sanding of the streets during wintertime. During spring this sand is dry and re-suspended in the air by traffic and the cleaning machines. In summary, springtime is characterised by high mass concentrations, wintertime is characterised by high number concentrations and summertime is the cleanest season. During different seasons, also the air quality inside the buses and trams is expected to be different. This is due to both air pollution outdoors and also the ventilation of the air inside the vehicles. In summer, the vehicles often drive windows open in order to increase the ventilation, while in winter the windows are closed and heating is on. The vehicles have particle filters in the fresh air ventilation system, which lower the indoor concentrations when windows and doors are kept closed.

The results of this study show clear seasonal differences. The pollution levels inside the vehicles are correlated with that outdoors. The correlation is rather similar during all the seasons. Indoor-outdoor ratios of the concentrations were found to be lower during winter compared with spring indicating increased filtration due to closed windows and doors. The indoor-outdoor ratio was lower for trams compared with buses.

In conclusion, when using one-hour averages we found a clear correlation between the concentrations inside and outside of the vehicle, especially for the bus. The correlation when using the background concentration as a reference is not high and in fact, it is negative in one case.

This project was funded by the Finnish Work Environment Fund.

Particles in Indoor Air – results from residential dwellings

Christina Isaxon[1,*], Andreas Dahl[1], Erik Nordin[1], Gunilla Wieslander[2], Dan Norbäck[2], Anders Gudmundsson[1], Aneta Wierzbicka[1] and Mats Bohgard[1]

1 Division of Ergonomics and Aerosol Technology, University of Lund, Lund, Sweden

2 Department of Occupational and Environmental Medicine, Uppsala University, Sweden

Keywords: aerosol exposure, real-time measurements, source identification
Presenting author email: christina.isaxon@design.lth.se

Although we spend a major part of our lives indoors, there is a basic lack of information considering particles of indoor origin and their impact on human health. Airborne particle measurements are frequently conducted in workplace environments, but very few, designed to find associations between human activities, aerosol concentrations and health outcomes, in residential homes.

The aim of this study is to characterize the air quality in residential dwellings (in terms of time resolved particle mass and number concentrations, size distributions, soot, temperature, relative humidity and CO_2 levels), correlate this data to various indoor activities and study associations between exposure to airborne particles and health effects/symptoms of the inhabitants.

For seven consecutive days time resolved stationary air measurements are conducted in randomly selected homes (N=42) in the area of Lund in southern Sweden. Aerosol instruments used are MiniDISC (University of Applied Sciences, Windisch, CH), Nanotracer (Philips Research) Indoor Air Quality monitor (IAQ3016, Lighthouse), DustTrak (TSI) and a soot monitor (microAeth AE51, Magee Scientific). The instruments are placed at a central location in each home, close to, but not in, the kitchen. All measurements are made during off-pollen season (October-April). CO_2 data is collected and used to calculate the air exchange rate. Petri dishes are used for collection of potential allergens. The habitants are asked to fill in detailed activity log books.

A thorough examination of each home – e g construction year, floor and wall materials, and ventilation system - is conducted according to a structured protocol. In addition, the participants fill in a 9 page translated and modified version of the IUATLD (International Union Against Tuberculosis and Lung Disease) questionnaire covering topics such as current and previous health status, professional history and everyday habits.

After the measurement period a non-invasive medical examination is conducted, including rhinometry, study of tear film break-up time and measurement of NO in exhaled air. During the measurement period ambient air variations were monitored constantly from a station in northern Lund.

. A data classification is carried out by sorting the data into two categories: occupancy time (at least one person present in the dwelling/residence) and non-occupancy time. An example is shown in Figure 1.

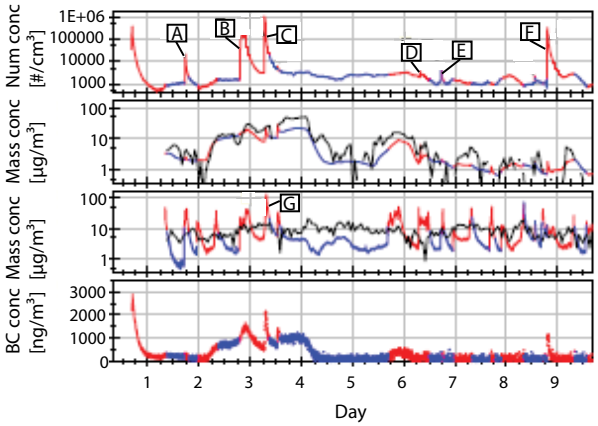

Figure 1. From top to bottom: Number concentrations (MiniDISC), PM_1 (IAQ3016), PM_{10-1} (IAQ3016) and black carbon concentrations (AE51). ug/m^3 denotes reading quantities from the optical instrument, using a density of 2,5 g/cm^3. Red lines denote that somebody was present and blue lines that the dwelling was empty. Black lines are background $PM_{2.5}$ and $PM_{10-2.5}$ respectively. Marked peaks are explained in Table 1 below.

Table 1. Peaks in Fig 1 and their heights above baseline concentration.

Peak	Num conc [#/cm^3]	PM_1 [µg/m^3]	PM_{10-1} [µg/m^3]	Activity
A	20000	0.5	35	Cooking
B	150000	6.8	0	Burning candle
C	1000000	0	0	Burning candle
D	1900	5	5	Cooking
E	2800	0.4	0	Cooking
F	320000	1.1	6.5	Cooking
G	-	15	110	Extinguishing candle

In a major part of the studied homes the concentration of particles, in particular in the sub micron size range, were higher when someone was present. Mean number concentration levels elevated by several hundred percent (indicated by the miniDISC, which is most sensitive for particles 20-120 nm), when someone was present in a dwelling, were not uncommon. The time resolved data in combination with the activity log books made it possible to trace peaks in concentration to a specific activity or usage of a specific appliance. It was also possible to see the relative strength of the indoor aerosol sources.

This work was performed within the framework of the Metalund centre of excellence, and financed by the Swedish Councils FORMAS and FAS together with the Development Fund of the Swedish Construction Industry (SBUF).

Session 11E: Comparison of Different Measurement Methods

Correlating the opacity-based dustiness behaviour to material specific properties

S. Bach, E. Schmidt

Department of Safety Engineering / Environmental Protection, University of Wuppertal, Germany
Keywords: Dust, Air quality, Optical instrumentation, Respirable aerosols.
Presenting author email: sbach@uni-wuppertal.de

The background of this research project is to examine the possibilities of a single-drop apparatus for the measurement of the dustiness behaviour of powders called DustView (Palas® GmbH, Karlsruhe). Objective is to find an algorithm for the coherence between the opacity values of the DustView respectively their time-related development and the concentration of specific aerosol fractions inside its so-called dust chamber.

Figure 1 shows the laboratory set-up, where an aerosol spectrometer (OPC) is directly connected to the dust chamber of the single-drop apparatus. It allows the simultaneous measurement of the extinction of two laser beams in different heights (3 resp. 13 cm above ground plate) and the particle size distribution and number concentration of the aerosol dispersed in the chamber in the same heights respectively.

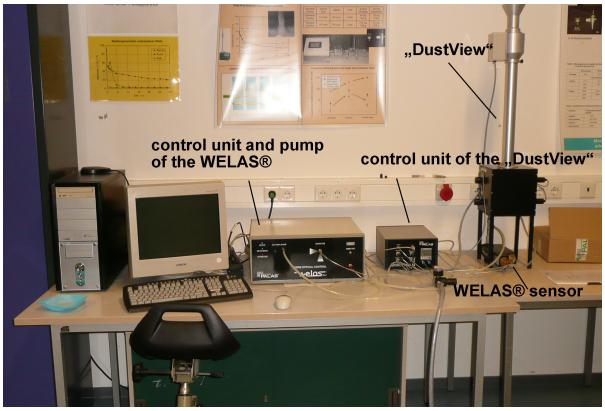

Figure 1. Modified version of the Palas DustView®, including single-drop apparatus and OPC “WELAS®”

Additionally, other material-specific properties have been measured, to ensure the best possible knowledge of the examined powders. Figure 2 shows all assimilated material features.

In Germany, there are limit values for the mass concentration of the respirable and inhalable dust fraction in workplace atmospheres. These are defined in the TRGS 900 (2010) and are 3 resp. 10 mg/m^3 at present.

The size fractions refer to the aerodynamic diameter of a particle, whereas the aerosol spectrometry gives the light scattering diameter. Van Buijtenen *et al.* (1974) define two possible ways of converting one into the other. Either, the aerodynamic shape factor of the material is known or the aerosol spectrometer has to be calibrated for each material. Here, only the particle density has been used as in Schmidt (2001), for the aerodynamic shape factor of the materials was mostly unknown and the calibration would have been too time-consuming for an uncertain outcome.

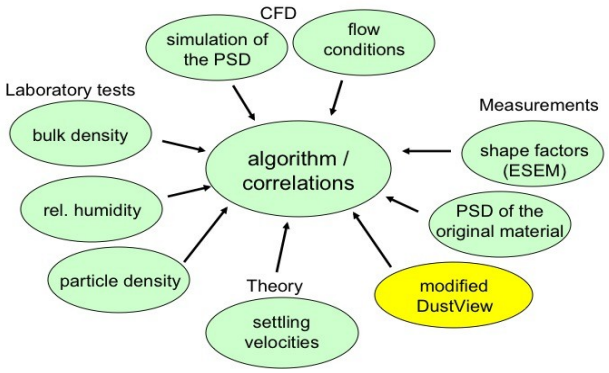

Figure 2. Measured and calculated material specific properties

The large amount of data collected for each material makes it difficult to locate correlations between two or more properties. What kind of dustiness-based data is suitable for the data mining process is yet to be determined. Additionally to the so-called dustiness number, calculated from the maximum opacity value and the 30-second-value of each measurement, it may also be the integral under the opacity curve or the offset between the peaks of the opacity curves of the two lasers. Also conceivable would be a value at a specific time, where the sedimentation process has already removed particles of a defined size. This would have to take the particle-specific settling velocity into account. All above named data could possibly correlate with the mass concentration of a specific aerosol fraction.

The correlation analysis is being carried out with the software “The Unscrambler X”, developed by CAMO®, Norway. Considering the two laser units, the correlation between OPC results and opacity seem to be better in the height of the lower laser.

Soot particles represent the main absorbing matter in the atmosphere. It has also been shown that black carbon (BC) can gain coating through aging processes (Jacobscon, 2001). The impact of this BC ageing on the climate ranges from BC optical properties modification to the removal of absorbing matter by wet deposition and cloud properties modification. This highlights the importance of measuring BC concentration and mixing state in understanding and modelling global warming.

Unfortunately, the exact measurement of BC remains difficult. The Single Particle Soot Photometer (SP2) can assist in that sense by directly measuring the mass of refractory black carbon (rBC) in each individual particle independently of the amount of coating. In addition, a semi-quantitative coating thickness and volume fraction of rBC can be retrieved within a limited size range using a scattering measurement and a MIE scattering model for coated rBC particles.

Despite great potentials this measurement technique remains an emerging method and work is still needed to characterise the repeatability of the measurement and understand possible discrepancies between instruments.

We present here selected results from the SOOT11 project which aimed at comparing 6 SP2s from 6 different institutes with themselves and other techniques. Different types of soot particles were introduced in the AIDA chamber, Karlsruhe, where they undergone various processes (such as coagulation, stepwise coating or cloud activation) and then measured.

Before any measurements took place, the instruments have been optimized and calibrated using the same protocol. However, the KIT instrument could not reach optimal laser power and it is therefore excluded from parts of this comparison.

Figure 1 shows the integrated mass size distribution over the entire 18th of November of rBC from a CAST (Combustion Aerosol STandard) burner obtained from 5 SP2s. Firstly, we can state that the mass size distributions agree fairly well despite a slight shift in diameter of around 20nm. This discrepancy in diameter is most likely due to calibration uncertainties. The times series of integrated rBC mass concentration (D_{MEV}>80nm) measured by 5 SP2s reveals agreement within 25% (Figure 2). Furthermore, the coating steps do not affect the measurement of rBC, in agreement with previous studies (e.g. Moteki, 2007). Slightly different trends observed by the 5 SP2s are caused by size dependent differences of instrument response in combination with increasing particle size due to coagulation.

A comparison of the above mentioned other parameters and with other techniques will also be presented.

Evaluation of an improved unipolar diffusion charger for size distribution measurements

Keywords: nanoparticle, unipolar diffusion charging, charge distribution, size distribution

Nanoparticles have been reported to be of possible health concern. Exposure to nanoparticles hence needs to be monitored, e.g. in view of worker protection. The best estimate of a worker's exposure can be derived from mobile, ideally personal measurements, taking aerosol samples in the breathing zone of the worker. Requirements for such mobile nanoparticle exposure monitors are small size, low weight and the delivery of health relevant information. The discussion on the health relevance of different aerosol metrics is still under discussion and hence a sophisticated exposure monitor should provide versatile information on the aerosol, i.e. the particle size distribution which under several assumptions can also be converted into size integrated number, surface area or volume/mass concentrations. Besides the abovementioned requirements, a portable or personal workplace monitor must not use any harmful substances. Bipolar aerosol chargers using radioactive materials, as commonly used in mobility particle sizers should hence not be used. Unipolar diffusion chargers, based on electrical corona discharge are therefore a preferred option. They provide higher charge levels which at the same time can be advantageous and disadvantageous. If the concentration is determined by electrical means, i.e. with an electrometer, the higher charge level provides a better signal and therefore allows for the measurement of lower concentrations. On the other hand the charge and hence mobility distribution for each particle size is broader, making multiple charge correction (MCC) in the data deconvolution algorithm more complex. To perform the MCC procedure correctly, the charge distribution has to be well known and mathematically described in a way that can be implemented in a software algorithm.

We evaluated an improved unipolar charger, which is based on the existing and proven 'opposing flow principle' (Medved et al., 2000). It is intended to be used in a portable aerosol sizer, which is currently under development within the EU-FP7 project Nanodevice. Improvements of the charger mainly concerned practicability such as ease of cleaning and prolonged maintenance intervals. This improved charger was subject to a detailed investigation of the charging efficiency as a function of particle size in a size range from 20 to 400 nm, which is the intended size range of the aerosol sizer. The determined average charge levels are comparable to those reported for an earlier version of the charger (Jung & Kittelson, 2005). The charge distributions were determined by measuring the electrical mobility distribution of monodisperse particles downstream of the charger. Figure shows exemplarily the charging efficiency for the uncharged as well as the singly to five-fold charged fractions. It can be seen, that 20 nm particles are charged with approximately 50% efficiency. The investigations further revealed that for 400 nm particles, up to 25 elementary charges need to be considered in the data deconvolution scheme. All charge levels followed a lognormal distribution which were fitted and described by mathematical functions to be included in an algorithm.

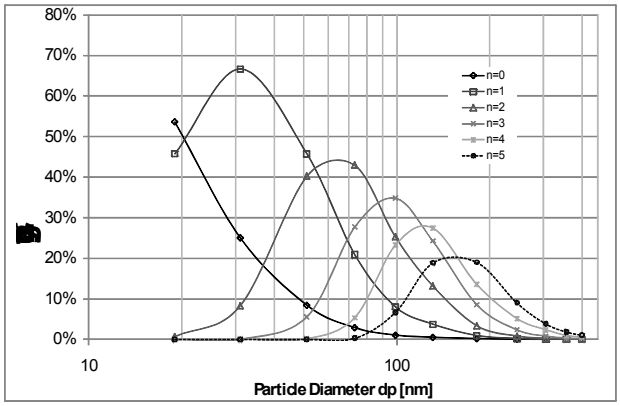

Figure : **Charging efficiency as function of particle size for charge fraction from 0 to 5**

The design of the charger and the experimental set up will be presented along with the measured results and their mathematical descriptions. The outcome of the investigations will be discussed in view of possibilities for use in miniaturized electrical mobility analyzers.

Evaluation of the performances of SidePak AM510 nephelometer compared to the Tapered Element Oscillating Microbalance (TEOM) method for $PM_{2.5}$ mass measurement

Federico Karagulian, Claudio A. Belis, Fritz Lagler, Maurizio Barbiere, and Michel Gerboles

In order to evaluate the personal exposure to ambient $PM_{2.5}$ it is necessary to perform measurements using portable instruments. However, there are no such instruments complying with the reference method for ambient $PM_{2.5}$ measurements (EN 14907). The comparability of these instruments could be assessed with measurements by equivalent analyzers like the Tapered Element Oscillating Microbalance (TEOM). In this work the characteristics of the portable nephelometer SidePak™ AM510 Personal Aerosol Monitor manufactured by TSI Inc. were evaluated against a TEOM equipped with a Filter Dynamics Measurements System (FDMS). Conventionally, light flux measured by the SidePak AM510 is calibrated with respect to Arizona road dust and then multiplied by an environmental k-factor to yield mass concentration. However, this calibration shows a low comparability between the SidePak AM510 and the TEOM-FDMS.

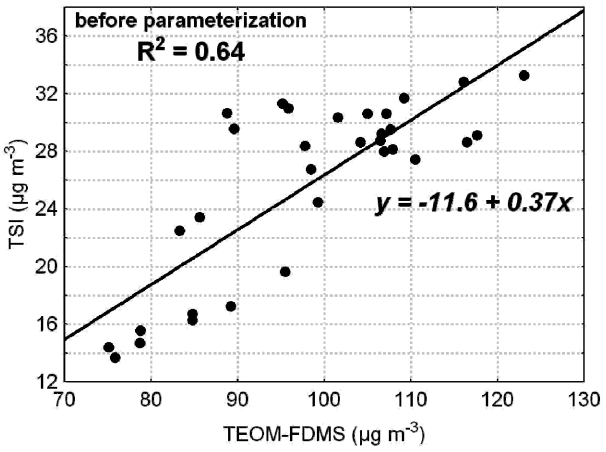

Figure 1. Raw semi-hourly average for the portable nephelometer SidePak AM510 *vs* TEOM-FDMS data.

$PM_{2.5}$ sampling with 20 instruments was carried out in background and kerbside sites in the Po valley (Italy). Results showed that the response of the SidePak AM510 samplers is highly sensitive to the chemical composition of particles. As a consequence, the growth of aerosol particles due to water uptake has an impact on the light scattering coefficient and therefore, in the estimation of PM number concentration.

The relationship between particle number and particle mass was developed through the parameterization of the TEOM-FDMS mass concentration (Baron and Willeke, 2001). It has been showed that the refraction index of the sampled particles depends both on a growing factor and the hydrophilic and hydrophobic mass fraction (Zieger et al, 2010). In addition, this parameterization accounts for different chemical composition for particles sampled at different micro-environments including rural and urban sites.

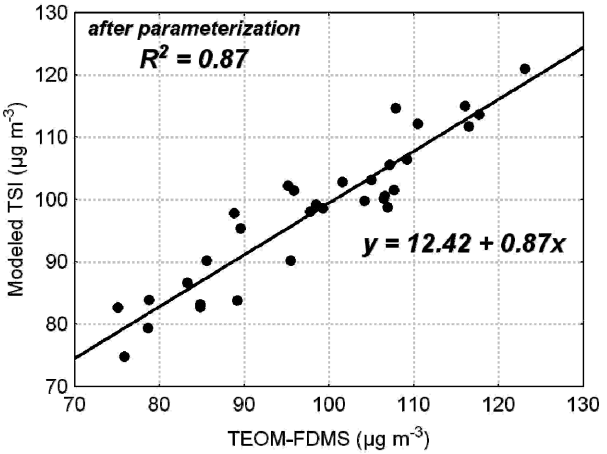

Figure 2. Modeled semi-hourly average for the nephelometer SidePak AM510 *vs* TEOM-FDMS data.

Modeled SidePak AM510 data were plotted *vs* reference TEOM-FDMS data showing a slope closer to 1 and a reduced uncertainty. Consequently, it was observed an increase in the coefficient of determination R^2 up to 25% and 60% in rural and urban sites, respectively. Therefore, we propose the parameterization developed in this work as a new method to correct sampled data collected with nephelometers in environments with high relative humidity.

Evaluation of the High Resolution Centrifugal Particle Mass Analyser

J.P.R. Symonds[1], M.G. Rushton[1], K.St.J. Reavell[1], C. Lowndes[1], A.E. Ellison[1] & J.S. Olfert[2]

Presenting author email: jps@cambustion.com

The Centrifugal Particle Mass Analyser (CPMA) selects aerosol particles by their mass:charge (*m/q*) ratio to produce a monodisperse aerosol (Olfert and Collings, 2005). As mass is a well defined quantity and not subject to morphological bias, and the CPMA's mass setpoint does not depend upon any gas properties (e.g. viscosity, mean free path) the CPMA offers advantages over a DMA for monodisperse classification.

Pre-charged aerosol is passed between two concentric metal cylinders which have a potential difference applied between them. The cylinders are rotated about their common axis, thus creating opposing electric and centrifugal forces. Particles with a larger *m/q* ratio are deflected outwards, and collect on the outer cylinder. Particles with a smaller *m/q* ratio are deflected inwards and collect on the inner cylinder. Only particles with the selected *m/q* ratio will pass through the classifier.

If we chose to rotate the cylinders at the same angular velocity, then the system of forces will only balance exactly along a central trajectory. So only particles amongst those with the correct *m/q* ratio which enter along this trajectory will emerge; others will be lost. It would also be possible for particles away from the centre line, *not* of the desired *m/q* ratio, to emerge from the classifier, thus broadening the transfer function.

Crucially and uniquely, the CPMA is designed such that the cylinders can be rotated at *different speeds*. The inner cylinder is rotated slightly faster than the outer cylinder, and the resultant radial velocity profile creates a stable system of forces under which a theoretical transfer function of 1.0 at the desired setpoint is possible, thus allowing a high transmission efficiency.

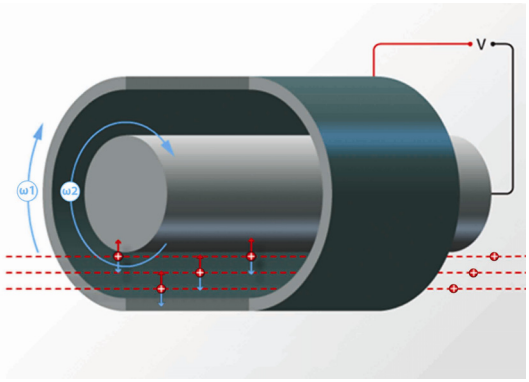

Figure 1: CPMA Principle: $\omega_2 > \omega_1$

This enables the resolution of the classifier to be increased by increasing its length, without a corresponding particle loss penalty; approaching a typical DMA's resolution. The CPMA can be used in a similar way to a DMA if a particle charger such as a radioactive neutraliser is used upstream, and step scanning of the particle mass spectrum is possible if a CPC is used downstream. If used in tandem with a DMA, determination of size to mass relationships and hence the mass-mobility exponent is possible, from which particle morphology can be inferred (Olfert, Symonds and Collings, 2007; Symonds *et al*., 2008).

A prototype CPMA has been used in several recent studies, for example as a mass standard in instrument comparisons (e.g. Cross *et al*., 2010). We present here results achieved using improved pre-production classifiers which have a higher resolution than the early prototype. These include validation of the mass accuracy of the systems with PSL spheres, and the determination of size to mass relationships and particle morphologies by the tandem DMA-CPMA method described above. Aerosol morphologies examined include spherical particles (e.g. PSL), cubic particles (NaCl), and fractal particles (e.g. soots).

In the field, aerosol in-situ measurements are often performed under dry conditions (relative humidity RH<30-40%). Since ambient aerosol particles experience hygroscopic growth at enhanced RH, their micro-physical and optical properties - especially the aerosol light scattering - are strongly dependent on RH. The knowledge of this RH effect is of eminent importance for climate forcing calculations or for the comparison of remote sensing with in-situ measurements.

Here, we will present results from a four-month campaign which took place in summer 2009 in Cabauw (Netherlands) and was part of the Cabauw Intercomparison Campaign of Nitrogen Dioxide measuring Instruments (CINDI). During this campaign different remote sensing and in-situ instruments were used to derive atmospheric gas species and aerosol properties. The aerosol scattering coefficient $\sigma_{sp}(\lambda)$ was measured dry and at various, predefined RH conditions between 20 and 95% with a recently developed humidified nephelometer (WetNeph). The scattering enhancement factor $f(RH,\lambda)$ is the key parameter to describe the effect of RH on $\sigma_{sp}(\lambda)$ and is defined as $\sigma_{sp}(\lambda,RH)$ measured at a certain RH divided by the dry $\sigma_{sp}(\lambda,RH=dry)$. The measurement of $f(RH)$ together with the dry absorption measurement allows the determination of the actual extinction coefficient $\sigma_{ep}(\lambda)$ at ambient RH. In addition, a wide range of further aerosol properties were measured in parallel. The measurements were used to characterize the effects of RH on the aerosol optical properties. A closure study showed the consistency of the aerosol in-situ measurements. Due to the large variability of airmass origin and aerosol composition a simple categorization could not be established. If $f(RH)$ needs to be predicted, the chemical composition needs to be known.

Four MAX-DOAS (multi-axis differential optical absorption spectroscopy) instruments retrieved vertical profiles of $\sigma_{ep}(\lambda)$. The aerosol extinction corresponding to the lowest profile layer can be directly compared to the in-situ values, which were re-calculated to ambient RH. The comparison showed a good correlation of R^2=0.62-0.78, but a factor of 1.5-3.4 higher extinction coefficients compared to the in-situ measured values. Best agreement is achieved for a few cases characterized by low aerosol optical depths and low planetary boundary layer heights. Differences showed to be dependent on the applied MAX-DOAS retrieval algorithm. The comparison of the in-situ data to a Raman lidar (light detection and ranging) showed much better agreement if the Raman retrieved profile was used to extrapolate the directly measured extinction coefficient to ground.

Session 11F: Atmospheric Applications of Aerosol Modelling

A 19th Century model for secondary organic aerosol

D. Topping[1,2], G. McFiggans[2]

[1]National Centre for Atmospheric Science (NCAS), University of Manchester, M13 9PL
[2]Centre for Atmospheric Science, University of Manchester, M13 9PL
Keywords: Aerosol modelling, SOA (Second. Organic Aerosols), Modelling (microscale), Absorption.

Introduction

Atmospheric aerosol particles are an important yet uncertain component of climate change and air quality. Comprised of inorganic and organic material, the inorganic fraction is restricted to a few well-understood compounds. However, organic material can comprise many thousands of, largely unidentified compounds with a wide range of properties. Mechanistic understanding and knowledge of individual compounds involved in the chemical evolution of aerosol particles is far from complete.

Whilst focus is often given to uncertainties in pure component properties, such as vapour pressure, attention is rarely given to how processes occurring within and on aerosol particles are formulated and combined. For example, the recently postulated phenomena of bulk to surface partitioning within aqueous droplets is now accounted for by altering the way concentrations are treated within a Gibbsian framework. An alternative way of understanding this is having to distinguish between a bulk and surface phase within equilibrium calculations. Another largely neglected property of aerosol particles is the size. This is unfortunate as the size of an aerosol influences the equilibrium composition and phase state for a given set of ambient conditions and chemical composition. Incorporating the influence of curvature in theoretical constructs can be complex. The equilibrium vapour pressure of any condensate increases above a curved surface, influencing the range of material expected to condense to an aerosol of a particular size. However, basic equilibrium absorptive partitioning models, which are either fit to chamber yields or used in conjunction with detailed chemical schemes, neglect the influence of curvature. This will therefore lead to errors in prescribed composition and volatility for conditions in which size is likely to play an important role: unseeded/nucleation chamber experiments. The same conceptual problems will influence predictions of CCN activation potential. Whilst the influence of curvature is explicit within the Kohler equation, this only accounts for the equilibration of water between and gaseous and particle phase. Direct use of the Kohler equation therefore does not implicitly account for the co-condensation/evaporation of semi-volatile components as the relative humidity changes.

Abstract review

In this work we present development and application of a partitioning model based on a novel simple iterative algorithm. Like most equilibrium models, the novelty in the algorithm arises from an ability to combine theoretical constructs important for aerosol properties, in a numerically stable manner. In essence, the model is a collection of frameworks centred on the work of Gibbs and Thomson in the late 19th century. The model has already been applied to simulations involving 10000 compounds with consideration of non-ideality (McFiggans et al 2010). By extending the model to include the influence of curvature we discuss the impact on the volatility distribution and composition of sub 100nm aerosol particles generated from a range of gas phase oxidation products. Model predictions are then extended to cloud activation potential.

Again, it is largely forgotten that Kohler theory, or the Kohler equation, was derived by minimising the Gibbs energy for a system comprised of involatile solutes and water. Previous studies have already noted the potentially large impact of co-condensation on the point at which an aerosol activates into a cloud droplet. However, such models are limited to the number of compounds which can be modelled. Whilst complex thermodynamic models such as ADDEM (Topping et al 2005) include the influence of curvature on deliquescence and CCN activation, no consideration of the above phenomena has yet been built into it. Here we present the potential pitfalls of neglecting the possibility of co-condensation/evaporation on predictions of CCN activation using the same model already described earlier.

Impact of aerosol activation on modelled regional particulate matter

W. Gong, C. Stroud, S. Gong, P.A. Makar, M.D. Moran, J. Zhang, N. Shantz and W.R. Leaitch

Science and Technology Branch, Environment Canada, Toronto, Ontario, M3H 5T4, Canada
Keywords: aerosol cloud interaction, activation, aerosol modelling, atmospheric pollution
Presenting author email: Wanmin.gong@ec.gc.ca

Aerosol-cloud interactions play an important role in the atmospheric hydrological cycle and in the fate of atmospheric pollutants. One of the key processes is the activation of atmospheric aerosol particles to form cloud droplets. Aerosol particles, particularly those that are water-soluble or that contain water-soluble components, can serve as cloud condensation nuclei (CCN). Under suitable supersaturation conditions, condensation of water vapour on these CCN can proceed rapidly and lead to the formation of cloud droplets, i.e., aerosol activation process. Aerosol activation is controlled by the size and composition of the particles, and by the rate of cooling of the aerosol.

The representation of aerosol activation in 3-D large scale (global and regional) models varies from primarily empirically based parameterizations, e.g., linking droplet number concentration to either aerosol mass or number concentration (Boucher and Lohmann, 1995; Gong et al., 2003), to more physically based parameterizations, mostly relying on a parcel model concept (e.g., Abdul-Razzak and Ghan, 2000; Nenes and Seinfeld, 2003). Studies have shown that there can be significant variability in modelled droplet number concentrations from these different activation parameterizations under certain conditions. In the climate modelling community there is a tendency to be moving away from the more empirically based parameterizations to more physically based mechanistic approaches for representing the aerosol activation processes, although these mechanistic approaches have not reduced the uncertainty range of the indirect aerosol effect due to new uncertaintes in representing the detailed processes. Within the air quality community, the attention has mainly been focused on aerosol mass rather than size distribution so far, although aerosol activation (or nucleation scavenging) can also have an impact on aerosol mass: it directly affects the wet removal of aerosols in the case of precipitation and indirectly the dry removal of aerosols through the impact on the size distribution of cloud-processed aerosols.

In this study, we use a regional air quality model, AURAMS, developed at Environment Canada to assess the impact of the variability in aerosol activation on the modelled regional particulate matter (PM) concentrations. AURAMS is an off-line, multi-pollutant, regional air-quality modelling system with size segregated (sectional) and chemically speciated representation of aerosols (Gong et al., 2006). AURAMS has been using a simple activation scheme based on an empirical relationship between cloud droplet number density and aerosol number density (Jones et al., 1994). Recently, a more physically based activation scheme based on Abdul-Razzak and Ghan (2002) has been implemented in AURAMS. For sectional representation of aerosol size spectrum, Abdul-Razzak and Ghan (2002) established a relationship between the maximum supersaturation reached by an air parcel (under known updraft) and an effective critical supersaturation which can be evaluated from the critical supersaturation of individual sections. For this implementation, the standard deviation of updraft is parameterized as a function of liquid water content (Hoose et al., 2010), and the aerosol wet size at critical supersaturation is used as a first guess for evaluating droplet size dependent parameters.

Model simulations are carried out for the 2004 ICARTT field campaign period over eastern North America. Figure 1 shows that in-cloud oxidation is simulated to have contributed to over 40% of ambient fine sulphate over eastern seaboard region for this period. In this paper, we will discuss the variability of aerosol activation resulting from the different schemes and the subsequent impact on regional PM (both mass and size distribution). The impact on aerosol radiative properties will also be discussed.

Presenting author email: nriemer@illinois.edu

The composition of carbonaceous aerosol particles changes continuously after emission during their transport in the atmosphere. Coagulation, condensation, and photochemistry are contributing processes, collectively known as aging. This changes the particles' physico-chemical properties, in particular their hygroscopicity, from initially hydrophobic to more hydrophilic, and hence their ability to become cloud condensation nuclei. Parameterizations of black carbon aging are widely used in large-scale aerosol models. The aging process is typically modeled as a first-order system with the single parameter of aging rate or its inverse, the aging time-scale. While conceptually simple, the actual value of the aging time-scale is not well constrained.

In this study we present a method for explicitly calculating aging time-scales of black carbon aerosol using the particle-resolved model PartMC-MOSAIC. The stochastic particle-resolved model PartMC explicitly resolves the composition of individual particles in a given population of different types of aerosol particles, and accurately tracks their evolution due to emission, dilution, and coagulation (Riemer *et al.*, 2009). PartMC was coupled with the new state-of-the-art aerosol chemistry model MOSAIC (Zaveri *et al.*, 2008), which simulates the gas- and particle-phase chemistries, particle-phase thermodynamics and dynamic gas-particle mass transfer in a deterministic manner. The coupled model system PartMC-MOSAIC predicts number, mass and full composition distribution, and is therefore suited for applications where any or all of these quantities are required.

PartMC-MOSAIC was applied to a suite of scenarios to simulate the evolution of aerosol emissions of different types (diesel soot, gasoline soot, meat-cooking aerosol, mineral dust) in different environments. For these scenarios we developed number-based and mass-based aging time-scales using the activation of the particles at a given supersaturation as a criterion for aging. We also quantified the extent to which aging is due to condensation versus coagulation processes.

Figure 1 shows an example of day-time aging time-scales as a function of supersaturation threshold for a heavily polluted scenario. Here, the aging time-scales are less than 1 hour for supersaturations larger than 0.3%.

Overall our study shows that the aging time-scale is heavily dependent on the supersaturation threshold and on environmental parameters such as temperature and relative humidity. It can vary significantly between day and night regimes.

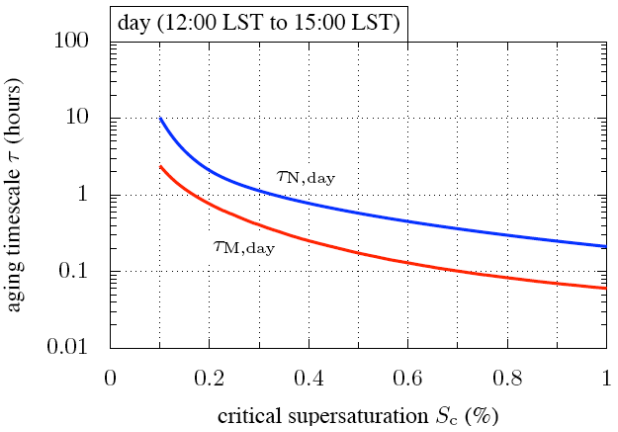

Figure 1. Day time averages of the aging time-scale (number-based aging time-scale in blue, mass-based aging time-scale in red).

Time evolution of the concentration of PM10, PM2.5, and NO_2 in Central Europe until 2015: will we meet the limit values set by the European Commission in time?

S. Wurzler[1] , H. Hebbinghaus[1], M. Memmesheimer[2], G. Piekorz[2], E. Friese[2], H. J. Jakobs[2], C. Kessler[2], A. Ebel[2], and P. Bruckmann[1]

[2] Rhenish Institute for Environmental Research (RIU), EURAD-Project, University of Cologne, Aachener Strasse 201-209, D-50931 Cologne, Germany

Keywords: Aerosol Modelling, Atmospheric aerosols, NO_2, PM, EU notification procedure

High levels of particle (PM10, PM2.5) and NO_2 concentrations are known to cause adverse health effects. Therefore, the EC air quality directives set limit and target values for various pollutants, such as PM10 and NO_2. Where these limit values are exceeded, plans and programmes have to be set up to meet the limit values in future. Deadlines to accomplish this task are 2005 for PM10 and 2010 for NO_2. Failure to comply can result in a proceeding at the European Court of Justice with the sentence to pay a quite considerable fee.

Meanwhile we have reached the year 2011. There still remain plenty of exceedance situations all over Europe, with e. g., already 85 exceedance situations for NO_2 and 8 exceedance situations for PM10 in North Rhine-Westphalia (NRW) alone. Especially problematic are heavily trafficked street canyons.

The only way out is to enter the notification procedure as described in EC directive 2008/50/EG. In short, if a European member state does not manage to comply to the limit value in time, it can fill in a stack of tremendous forms detailing why it is a special case, where the limit value could not be reached by all means taken in time, and how the member state intends to comply to the limit value in the near future. These completed forms are checked in detail by the commission and in case your plans appear to be plausible, you may get a time extension to comply to the limit value until the year 2015.

One of the details to be given in the forms is the time evolution of the background concentrations of air pollutants until the year to 2015. Therefore, model simulations have been performed to assess the time evolution of the background concentrations of air pollutants.

The background concentration of PM10, PM2.5, and NO_2 was simulated with the European Air Pollution Dispersion Model (EURAD, Memmesheimer et al., 2004). The EURAD model simulates the concentration due to emissions, transport, and chemical transformation. The meteorological data stem from the MM5, transport is modelled by solving the 3-D advection and diffusion equation. The chemical model CTM2 treats chemical processes and the Modal Aerosol Dynamics Model (MADE) is used to account for secondary aerosol (Schell et al., 2001). The model is run in a one-way nesting with two grids, the largest domain spanning Europe in a horizontal resolution of 125 x 125 km². Nested in this is the area of Central Europe with 25 x 25 km² horizontal resolution. This nesting allows the consideration of long-distance transport.

Model simulations have been performed for the years 2009 and 2015, using in both cases the meteorological conditions of the year 2009. The emission data was taken from EMEP.

One of the main results is that the background concentrations decrease from the year 2009 to the year 2015. In Germany for example an average decrease of the NO_2 and of the PM10 burden in the range of 1 – 2 µg/m³ was found. The number of PM10 exceedance days (daily average concentration > 50 µg/m³) was reduced by 3 – 6. Taking NRW as example, this reduction of the regional background concentrations would help to avoid two of the exceedance situations for NO_2 and PM10 each. Thus, just to wait and hope the best is not a very good solution, as for NRW 98 % of the exceedance cases for NO_2 and 75 % of the exceedance cases for PM10 will still remain in the year 2015 if no further measures are taken.

Scope of this paper is to present the time evolution of the regional background concentrations for air pollutants such as NO_2 and PM10 from the year 2009 until the year 2015. Apart from the large scale evolution some examples for heavily trafficked street canyons with additional measures for emission reduction will be shown. Special focus will be set on the difficulties met while trying to oblige to the European Air Quality directives. A further question is whether reality follows the model, as up to now the NO_2 background concentrations in NRW persistently refuse to show a decline.

Keywords: activation, cloud, aerosol modelling, regional scale, volcanic ash.
heike.vogel@kit.edu

After resting for 187 years the vulcano Eyjafjallajökull, Island wake up again at March 20th, 2010. Starting at April 14th massive emissions of volcanic ash occurred and finally lead to a shut down of civil aviation over entire Europe.

The emissions went on with variable strength until May 23rd, 2010. The volcanic eruption offers a unique field experiment for investigating atmospheric processes as transport, radiation and cloud formation on a large variety of scales applying both observations and numerical models. In addition to the academic interest the huge economic costs of the shutdown of the civil aviation raised the need of accurate forecasts of the temporal and spatial distribution of the ash plume.

To simulate the dispersion of the ash plume we used the comprehensive online coupled model system COSMO-ART (Vogel *et al*., 2009) in an operational forecast mode at Deutscher Wetterdienst (German Weather Service, DWD). COSMO-ART is the extension of the operational weather forecast model of DWD. In the operational mode three day forecasts were launched every six hours with the same model setup as for the weather forecast. Actual meteorological observations that are made during the six hour time interval are assimilated into the model. Six individual size distributions of the ash particles were simulated starting from 1 µm up to 30 µm. Deposition, sedimentation, and below cloud scavenging were taken into account. For the source heights we used data that were published by the volcanic ash advisory centre London (VAAC), UK which is responsible for making the official forecast of ash coming from volcanoes in Island according to international agreements.

Beside the simulation in the operational mode we did several model runs using the analysis of the COSMO results as input data. These sensitivity studies show the influence of different processes on the distribution of the ash particles. Using the measurements that were performed by DLR (Schumann et al., 2011) we calibrated our model results and compared them with measured size distributions at Hohenpeissenberg (Flentje et al., 2010).

Ash particles emitted by the volcano act as cloud and ice nuclei and, therefore, they should modify cloud formation within the plume. To simulate the impact of the various aerosol particles on the cloud microphysics and therefore on cloud properties COSMO-ART was coupled with the two-moment cloud microphysics scheme of Seifert and Beheng (2006) by using comprehensive parameterisations for aerosol activation (Barahona et al., 2010) and ice nucleation (Barahona and Nenes, 2009) The activation of the ash particles is based on FHH adsorption activation theory (Kumar et al., 2009) and measurements of the activation behaviour of ash samples of the Eyjafjallajökull. Results of these simulations will be presented.

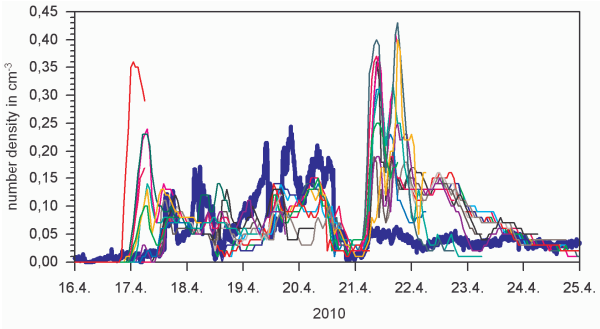

Figure 1. Observed number densities at 3.25 µm at Hohenpeissenberg and model results for the individual forecast runs.

The influence of ion-induced nucleation on atmospheric aerosols based on data from the CERN CLOUD experiment

E.M. Dunne[1], K.S. Carslaw[1], C.L. Reddington[1], J. Almeida[2] and the CLOUD collaboration[2]

[1]School of Earth and Environment, University of Leeds, Leeds, LS2 9JT, UK

Keywords: aerosol modelling, ion-induced nucleation.
Presenting author email: E.Dunne@leeds.ac.uk

Here we quantify the contribution of ion-induced nucleation to global aerosol based on new results from the CLOUD experiment at CERN. We also quantify the response of aerosols to a change in the nucleation rate in an attempt to explain apparent correlations between aerosol and Forbush decreases. Away from the surface, ion concentrations are controlled by cosmic-ray induced ionization. A range of observations support a connection between cosmic ray intensity and the Earth's climate, on time-scales from days (Pudovkin and Veretenenko, 1995) to centuries (Eichler *et al*, 2010) to millennia (Bond *et al*, 2001).

Because ions stabilise sub-critical nuclei, ion-induced nucleation is a strong candidate for the atmospheric nucleation mechanism, especially in remote regions with low concentrations of precursor vapours. When determining the impact of the phenomena on the climate, a global aerosol microphysics model (such as GLOMAP) is a vital tool due to its inclusion of the various processes which affect particle growth and deposition.

We will present the results of the implementation within a global model of the first parametrization of ion-induced nucleation based on experimental observations rather than theoretical predictions. This parametrization is the result of work in the ternary H_2SO_4-NH_3-H_2O system by the CLOUD collaboration at CERN. We show that nucleation in this "inorganic" system is unable to explain most boundary layer nucleation and observed particle concentrations.

We also quantify the response of aerosol to changes in the nucleation rate that might accompany Forbush decreases. During a period of intense magnetic activity which causes the sun to emit charged matter, the stream of cosmic rays reaching the Earth can be partially blocked. The result is a reduction in atmospheric ion concentrations that lasts for several days. There have been studies showing a strong (Svensmark et al., 2009) and a weak (Laken et al. (2009); Calogovic et al., (2010)) correlation between Forbush decreases and cloud and aerosol properties. The suggested cause of these correlations was a change in the ion-induced nucleation rate.

To test the maximum effect of a Forbush decrease on aerosol, we performed a series of monthly simulations with daily resolution. We reduced the nucleation rate by 15% for a period of ten days in the middle of each month, and analysed the effect on condensation nuclei (CN), cloud condensation nuclei (CCN), aerosol optical depth and the Ångstrom exponent. This allows us to estimate the bounds of a transient change in the nucleation rate on aerosol and cloud properties. In figure 1, we show the mean

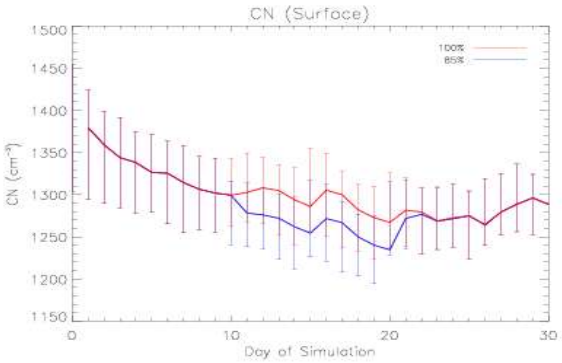

Figure 1: A time-series of globally-averaged perturbed and unperturbed condensation nuclei with radius > 3 nm.

perturbed and unperturbed condensation nuclei over six monthly simulations. We find a negligible change in cloud condensation nuclei concentrations and aerosol optical depth in the atmosphere.

We would like to thank CERN for supporting CLOUD with important technical resources, and for providing a particle beam from the CERN Proton Synchrotron. Session 12A: Marine Aerosols / Mineral Dust

Primary and secondary marine organic aerosols over the North Atlantic ocean during the MAP experiment

Particulate matter in the marine boundary layer represents one of the most important aerosol system at the global scale. The relative importance of primary sources (seaspray) and secondary processes for the formation of organic and inorganic particles in the marine atmosphere is still controversial.

A multi-technique analytical approach was exploited to characterize submicron organic aerosol collected over the North-East Atlantic Ocean, outside continental pollution plumes, in the frame of the EU project MAP (Marine Aerosol Production). Samples were collected at Mace Head (Ireland), for the whole 2006, and onboard the research vessel Celtic Explorer (CE), between June and July 2006. Elemental analysis, ion chromatography, proton nuclear magnetic resonance spectroscopy (^{1}HNMR) and liquid chromatography-mass spectrometry provided a comprehensive characterization of the complex mixture of water-soluble (WSOC) and water insoluble (WIOC) organic carbon in submicron aerosol.

On average, WSOC accounted for 63% of total carbon in ambient aerosol samples, well above its contribution to the organic carbon contained in native seaspray particles (ca. 10 %) formed by bubble bursting experiments onboard the CE (Facchini et al., 2008a). The enrichment of WSOC in ambient aerosol can be due to secondary organic compounds condensing on sea spray, or to the prolonged atmospheric oxidation of primary organic compounds.

The results of the chemical characterization demonstrated that WIOC is structurally similar to lipids and that the less hydrophilic fraction of WSOC consists of a distribution of alkanoic acids and diacids, having an average carbon number between 8 and 9, and which comprise the early generation products of fatty acids degradation. More oxidized products, like sulphate esters of C6 – C11 hydroxycarboxylic acids, are found in the most polar fraction of WSOC, together with MSA and low-molecular weight amines, which are all of biogenic origin (Facchini et al., 2008b).

The nature of the dominant WSOC fraction unaccounted for by molecular characterization was investigated by means of factor analysis techniques applied to NMR spectral datasets. The decomposition of the NMR spectra provided a clear split between five factors, the first two being dominated by MSA (with HMSA and low-molecular weight oxoacids and diacids) and amines (plus organic compounds carrying terminal methyls), respectively. These two factors are consistent with a SOA components formed by gas-to-particle conversion processes. The profile of Factor 3 shows a limited content of aromatic moieties and of hydroxyl groups, with a greater proportions of alkyl moieties, containing methylenic chains, terminal methyls and carboxylic groups. The similarity between Factor 3 and the spectra of the less hydrophilic WSOC fraction relates this factor to the oxidation products of primary biogenic organics. The fourth factor traces anthropogenic sources and its spectral profile fits that of a “typical” oxidized organic aerosol of continental polluted areas.. Finally, the profile of Factor 5 is characteristic of purely aliphatic compounds, carrying cheto/carboxyl substituents and enriched in hydroxyl groups. Such oxidized organic aerosol cannot be explained by continental sources and may represent an additional class of marine SOA, not apparently linked to the routes of fatty acid degradation.

These results highlight the complexity of the organic chemical composition of submicron particles in the marine atmosphere, and provide evidence for the contributions from primary biogenic materials, their atmospheric oxidation products and from compounds deriving from the gas-to-particle conversion of volatile organics emitted by the marine biota.

Predicted change in emissions of sea salt aerosol for the years 1870-2100

H. Struthers[1], A. M. L. Ekman[2], P. Glantz[1], E.M. Mårtensson[1,3], and E. D. Nilsson[1]

[1]Department of Applied Environmental Science, Stockholm University, Stockholm, SE-11418, Sweden
[2]Department of Meteorology, Stockholm University, Stockholm, SE-10691, Sweden
[3]Department of Earth Sciences, Uppsala University, SE-752 36, Uppsala, Sweden
Keywords: Marine aerosols, sea salt, climate effects
Presenting author email: hamish.struthers@itm.su.se

Sea salt aerosol contributes significantly to the global aerosol burden and radiative budget, and may be the dominant contributor to light scattering and the dominant source of cloud condensation nuclei (CCN) in remote marine areas. The main physical driver of sea salt emissions is the surface wind speed (U_{10}) with emissions being regulated by the sea ice cover in the polar regions (Nilsson *et al*. 2001). An increasing number of studies support the conclusion that sea salt aerosol emissions are dependent on the sea surface temperature (SST) (e.g. Hultin *et al*. 2010). New measurements also indicate that there may be a dramatic enhancement of total number emission at temperatures near the freezing point of water. In addition, SST appears to influence the shape of the size distribution of the aerosol emissions (see Figure 1). This is important from a climate perspective because the scattering of solar radiation and the formation of cloud droplets are highly dependent on the particle size of the aerosol.

The aim of this study is to examine the long-term trends in the emission of sea salt aerosol by employing a commonly used sea salt aerosol source parameterization (Mårtensson *et al*. 2003) and output from the World Climate Research Programme's (WCRP's) Coupled Model Intercomparison Project Phase 3 (CMIP3) multi-model dataset. This analysis allows us to estimate the relative roles of different drivers of sea salt emissions on global and regional scales.

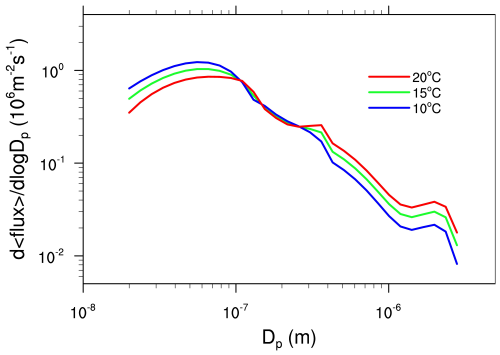

Figure 1. The Mårtensson et al. (2003) sea salt aerosol source parameterization (for U_{10} = 9 ms^{-1}).

The sea salt source parameterization used in this work is visualised in Figure 1 for a range of SSTs. The main features of this source parameterization are: (a) in agreement with other studies, sub-300 nm particles dominate the number emissions (b) the flux in the smallest size range (20nm - 145nm) decreases with increasing SST whereas for the largest size range (419nm - 2.8um) the opposite trend holds, and (c) the particle flux for the intermediate sizes (145nm - 419nm) is relatively insensitive to SST. Combining this parameterization with U_{10}, SST and sea ice fraction taken from the CMIP3 multi-model archive allows us to construct a global sea salt emission model covering the period 1870-2100.

Results

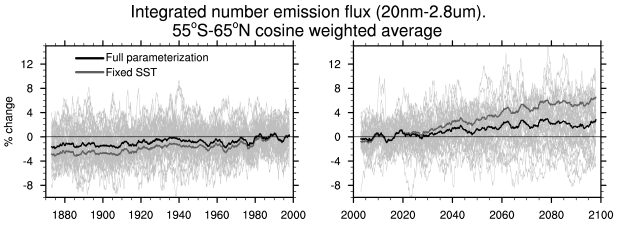

Figure 2. Time-series of sea salt aerosol emissions. Thin lines indicate individual model results (full parameterization) with the thick lines being the ensemble model average.

Figure 2 shows an example of the estimated sea salt emissions. The black lines show the near global, ensemble model average emissions using the full Mårtensson parameterization (Figure 1). The heavy grey lines show the same time-series but with the SSTs held fixed in the source parameterization. Results in the left hand panel are derived from the 20th century CMIP3 output and the right hand panel from the so called SRES A1b (medium) scenario. The difference between the black and the heavy grey lines then indicates how SST influences the emissions. These results suggest that if future SST changes are ignored, the increase in integrated particle emissions over the 21st century is overestimated by more than a factor of 2.

The results obtained in the present study also indicate that different drivers control the sea salt aerosol emissions in different regions of the globe. In the Arctic, sea ice extent is the most important parameter determining the change in sea salt emissions. On the other hand, in temperate latitudes (55°S-60°N) both U_{10} and SST substantially influence the emissions whereas in the southern ocean, U_{10} is the dominant parameter.

Keywords: Marine aerosols, CCN, bubble bursting, particle size distribution.
Presenting author email: andrew@kemi.ku.dk

Sea spray aerosols are of major interest to global climate models due to their large uncertainty in indirect and direct radiative forcing and poorly understood emission characteristics. A new experimental sea spray aerosol bubble tank is characterized and preliminary results are presented for bubble generation, bubble size distribution, and particle emissions.

In this study, the major processes of bubble formation are examined with respect to particle emissions. It has been suggested that a plunging jet, formed by a continuously flowing nozzle placed vertically above a water surface, closely resembles breaking wave bubble entrainment processes and subsequent bubble size distributions (Fuentes et al. 2010). The physical characteristics of our bubble tank are shown in Table 1. The tank consists of a stainless steel cylinder closed at both ends with fittings for recirculating flow for the jet and aerosol sampling.

Table 1 Sea spray tank characterization

Tank Dimensions	
H = 46.2 cm	V_{tot} = 16.3 L
D = 21.2 cm	V_{sample} = 9 L
A = 353 cm^2	$H_{headspace}$ = 20.7cm
Nozzle Parameters	
D_{nozzle} = 4 mm	$v_{jet,\ o}$ = 4.3 m s^{-1}
H_{nozzle} ~ 20 cm	$v_{jet,\ surf}$ = 4.7 m s^{-1}

The sub-surface bubble plume characteristics can be calculated using parameters specified by Claret & Lasheras (1997) and are given in Table 2. When the Weber number (We) is less than unity, surface tension forces are greater than inertial forces and bubbles will remain intact until reaching the surface.

Table 2 Bubble plume characteristics (1mm bubble)

Angle of Plume Cone = 12.5°
$v_{1mm,\ T}$ = 0.22 cm s^{-1}
$H_{1mm,\ T}$ = 21.6 cm
$W_{1mm,\ T}$ = 7.8 cm
We_{1mm} = 6.7 × 10^{-5}

In addition to calculated values, bubble spectra were analyzed for a frit placed in the bottom of the tank at range of air flow rates (

Figure **1**). Particle size distributions for both the frit placed in the tank and the plunging jet are shown in Figure 2.

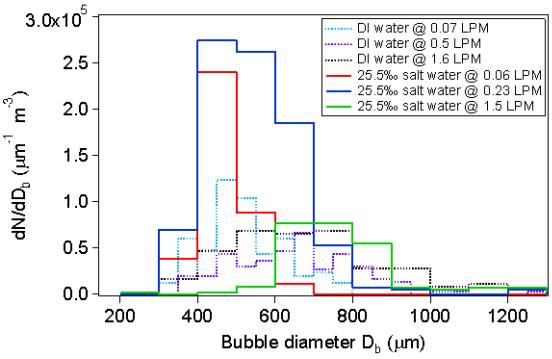

Figure 1 Preliminary photograph-analyzed bubble size distributions for the frit placed in the bottom of the tank.

The difference between the particle size distributions could be caused by high particle loss due to scavenging and entrainment processes of the plunging jet (Bin 1993). The difference in concentration could also be attributed to the shear forces exerted on bubbles that rise to the surface causing incomplete bursting which could also partly explains the disparity in particle size distributions.

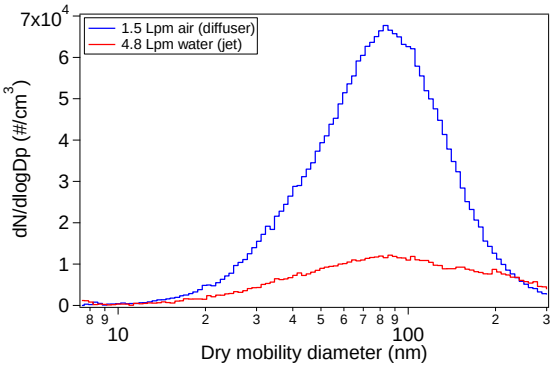

Figure 2 Particle size distributions for the frit and the plunging jet for artificial sea water of salinity 35‰.

Radiative properties of mixed biomass-mineral dust aerosol in the thermal infrared during SAMUM-2

C. H. Koehler[1], T. Trautmann[1] and E. Lindermeir[1]
[1]Remote Sensing Technology Institute, German Aerospace Center, Oberpfaffenhofen, 82234, Germany
Keywords: Radiative properties, Mineral dust, Biomass burning, Field measurements
Presenting author email: claas.koehler@dlr.de

The Saharan Mineral Dust Experiment (SAMUM) is a 7-year national German project dedicated to the radiative and micro-physical properties of mixed biomass and mineral dust aerosol. It comprised two field experiments in Morocco (May-June, 2006) and Cape Verde (January-February, 2008). We intend to present results of ground-based radiance measurements in the thermal infrared (TIR) obtained during the 2008 field experiment at Praia with a D&P Model 102 FTIR . These measurements are complemented by space borne measurements with the IASI FTIR on board METOP-A.

Furthermore we conducted radiative transfer simulations based on the data measured by other SAMUM-2 groups including LIDAR derived aerosol layer heights, airborne measurements of aerosol size distribution and off-line chemical analysis of aerosol samples collected by the DLR Falcon research aircraft. A comparison of simulated and measured radiances at top and bottom of the atmosphere (TOA, BOA) reveals insight into the validity of several approximations commonly made in TIR radiative transfer, such as the assumption of spherical model particles or the representation of the complex mineral mixture in terms of a single (wavelength-dependant) effective refractive index. Figure 1 is an example of a comparison of measured and simulated data obtained during a dust event on January 25th, 2008. The dust radiative effect is clearly visible when comparing the measurement to the clear-sky simulation. Apparently the OPAC (Hess *et al*, 1998) and Volz (1973) models agree relatively well with the Maxwell-Garnett effective medium theory, which uses the refractive indices of pure mineral constituents identified in the chemical analysis, while the model of Shettle and Fenn (1979) seems to underestimate the aerosol emission. An interesting effect occurs around 1100 cm^{-1}, where a considerably different behaviour between measurement and simulation is observable. Based on similar observations by Thomas and Gautier (2009) we suspect this to be attributable to the non-spherical shape of the aerosols, which is not accounted for in the simulations. We plan to conduct further investigations adressing this issue using spheroidal model particles and intend to discuss the results in our presentation.

This work contributes to the development of a generally accepted benchmark model of aerosol TIR radiative properties, which is essential for validation of fast radiation models commonly found in climate simulations, weather prediction or satellite retrieval algorithms.

Presenting author email: bernard.grobety@unifr.ch

Volcanic eruptions contribute significantly to the sulfur content of the troposphere and the stratosphere (Oppenheimer, 2003). Satellite and ground-based remote sensing allow to measure the main gaseous species in an eruption plume e.g. SO_2 and H_2S. Gaseous sulfur species have a strong influence on the radiative properties of the atmosphere. Electron microscopy of aerosols sampled at different volcanoes with mild eruptive and/or fumarolic activity (Stromboli, Vulcano, El Chichon, Oldonyo Lengai) have shown, that even close to the eruption vent, there is a considerable amount of sulfur in the plume, that is not present as gaseous compounds, but bound to either liquid sulfuric acid droplets or in solid sulfate minerals. The environmental effect of the condensed sulfate phases is different from the original gaseous compounds. It is, therefore, important to understand the underlying transformation processes.

The quantity of sulfur released in or transformed to non-gaseous compounds, which are not taken into account by the remote sensing measurements, is poorly constrained. Aerosol formation in an eruption or a fumarole plume is very complex and occurs over a large temperature range (Symonds and Reed, 1993). Solid and liquid particles may be formed through magma disintegration, eruption conduit wall erosion, and through condensation or resublimation from the gas phase. In liquid aerosol particles, cooling and or evaporation can lead to precipitation of solid sulfate phases. We used geochemical modelling to explore possible particle forming reaction in a model system Na-K-Ca-Mg-(Fe)-S-C-O-H and temperatures for the primary gaseous/liquid phase ranging from ambient to 800°C. Gas phase reactions were modelled with the software HSC (OUTOTEC), whereas aqueous geochemistry (precipitation) was explored using the Geochemist's Workbench code (RockWare). The thermodynamic database had to be completed with data for some of the sulfate minerals.

The modelling results were compared with aerosol samples collected along the crater rim and at the base of Stromboli (Italy) and El Chichon (Mexico) volcano. Up to 1000 particles were analyzed by automated single particle scanning electron microscopy imaging and chemical analysis by energy dispersive spectroscopy (EDS) as well as transmission electron microscopy (TEM, Fig.1). The sampled aerosols contained condensed sulfuric acid particles as well as a number of sulfate minerals, mainly aphthitalite, $(K,Na)_3Na(SO_4)_2$, thernadite Na_2SO_4, and arcanite K_2SO_4 resp. their hydrated cousins.

At the base of Stromboli, magnesium sulfates made their appearance. Compared with the thermodynamic modelling results, this sequence is much in favor of an initial condensation of sulfate rich alkaline brine droplets and subsequent precipitation of the sulfate phases when the droplets evaporate. The expected order of precipitation is arcanite -> aphthitalite -> thenardite (mirabilite) -> magnesium rich sulfates. For El Chichon a similar evolution was found. A preliminary estimation of the solid sulfate flux from the fumarolic vents of El Chichon gave around 0.1 kgs^{-1}.

Source profile of the local wind-blown soil contribution to respirable airborne particulate matter in the southern area of Rome (Italy)

A. Pietrodangelo[1], R. Salzano[1], S. Pareti[1], E. Rantica[1] and C. Perrino[1]

Presenting author email: pietrodangelo@iia.cnr.it

Source profiles play a key role in the source apportionment (SA) of airborne aerosol. The more unambiguous is the marker-vs-source relationship, the more consistent and accurate is the apportionment of model-estimated aerosol mass contributions. Nevertheless, some source categories still remain poorly characterised, like the crustal materials from non-industrial fugitive dust.. It is uknowledged that either mineral dust from natural rocks or anthropogenic originated dust (i.e. from building sites) can be re-suspended by both human activities and natural events, sharing an exchangeable fate for residence time and size segregation paths in the planetary boundary layer (Korcz et al., 2009).

Large uncertainties or lacks in emission inventories exist (EMEP, 2010), which concern different fugitive dust contributions. The wind-blown surface soil holds particular interest, especially if it is profiled at local (regional or intra–regional) level. Indeed, intra-regional variability in the chemical and mineral composition of surface soils is generally more evident than what is concerned for road dust and building materials, the latter usually showing minor site-oriented differences in the source fingerprint.

Finer fractions of particulate matter from surface soils are easily re-suspended by local winds and may contribute to the respirable fraction of PM (Rodriguez et al., 2009). It is also reasonable to expect that this contribution affects the total PM mass more frequently than dust outbreaks from the Saharan region. In Rome (Italy), between 2003 and 2008 only 8 to 30% of exceedances to PM10 limit value could be ascribed to desert dust outbreaks.

To our knowledge, so far no source profiles have been published of the respirable PM fraction re-suspended from wind-blown local soils neither of Italy nor of other European countries.

In this work, we present the chemical and mineralogical profile of the respirable fraction of re-suspended surface soil in the Southern area of Rome. Overall 12 bulk samples of surface rock were collected at locations were the geological lithosomes of this area emerge from soil (Giordano et al., 2006). After sieving up to 50µm size, the dust was re-suspended in a proper box under controlled conditions and the PM_{10} fraction was collected on Teflon filter membranes by low-volume sampling. Bulk elemental analysis of the 50µm size dust and of the PM_{10} samples was performed by EDS-XRF. XRD analysis was performed on the 50µm size dust to obtain the mineralogical composition of samples, after assessment that the 50µm size and the PM_{10} fractions are comparable in terms of elemental composition (fig. 1).

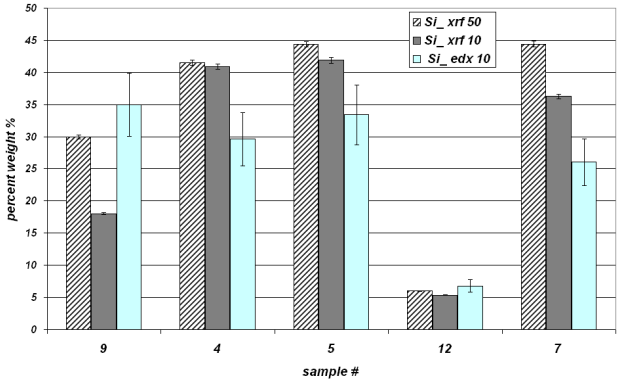

Figure 1. Inter-technique (SEM/EDX vs XRF) assessment of comparability between the 50µm size and the PM10 fraction of surface rock samples. Here results for Si are reported for some of the collected samples.

Moreover, about 500 single particles per-sample were analysed for morphology and chemical composition by SEM/EDX microanalysis. Results of single particle analysis were finally matched with the database of the RRUFF Project (Downs, 2006) and/or the database of the GEOROC Project (Sarbas et al.). Statistical matching of particle spectra with the elemental composition of minerals obtained from 'reference' databases was performed by sequential PCA (Espinosa et al., 2004) and SLR. Finally, particles identified with known minerals were characterised for size segregation in the PM_{10} fraction after estimation of their aerodynamic diameter.

There is much uncertainty in the magnitude and sign of the radiative effect of mineral dust. A large part of this uncertainty stems from uncertainties in the refractive index of dust, which controls the proportioning of scattering and absorption of light. Aircraft and satellite measurements are presented here in order to refine the uncertainty in the refractive index.

A synthesis of aircraft measurements will be presented: firstly from the DODO (Dust Outflow and Deposition to the Ocean) experiments (McConnell *et al*., 2008) which took place over Western Africa during February and August 2006, and secondly new measurements which will be taken during the upcoming Fennec campaign over the central western Sahara during April and June 2011, providing data from locations within the Sahara that have previously been unsampled by scientific aircraft.

Results from DODO focus on calculations of the refractive index mineral dust. Here, a synthesis of optical, chemical and physical in-situ aircraft measurements are used to calculate the refractive index mineral dust encountered over West Africa. Radiative transfer studies are able to validate refractive indices obtained from chemical and optical approaches (McConnell *et al.*, 2010), and also allow comparisons and validations of satellite retrievals (Ryder *et al.*, manuscript in preparation).

Radiative transfer modeling and measurements of broadband shortwave irradiance at a range of altitudes are used to test and validate these calculations for a specific dust event on 23 August 2006 over Mauritania. Two techniques are used to determine the refractive index: firstly a method combining measurements of scattering, absorption, size distributions and Mie code simulations, and secondly a method using composition measured on filter samples to apportion the content of externally mixed quartz, calcite and iron oxide-clay aggregates, where the iron oxide is represented by either hematite or goethite and clay by either illite or kaolinite.

The imaginary part of the refractive index at 550nm (n_i^{550}) is found to range between 0.0001i to 0.0046i, and where filter samples are available, agreement between methods is found depending on mineral combination assumed. The refractive indices are also found to agree well with AERONET data where comparisons are possible. n_i^{550} is found to vary with dust source, which is investigated with the NAME model for each case. The relationship between both size distribution and n_i^{550} on the accumulation mode single scattering albedo at 550nm (ω_0^{550}) are examined and size distribution is found to have no correlation to ω_0^{550}, while n_i^{550} shows a strong linear relationship with ω_0^{550}.

Radiative transfer modeling indicates that Mie-derived values of n_i^{550} and the goethite-kaolinite combination resulted in the best agreement with irradiance measurements, for the particular dust event examined. The radiative effect of the dust is found to be very sensitive to the mineral combination (and hence refractive index) assumed.

For a dust event on 22 August 2006, satellite (Seviri and GERB) retrievals of aerosol optical depth, fluxes and radiances are compared to aircraft radiation measurements and modelled radiances and fluxes using measured optical properties in three different radiation models. Satellite retrievals and models show mostly good agreement, though discrepancies at certain wavelengths point towards errors due to a lack of coarse mode in Seviri retrievals.

Finally an overview of the optical and physical properties of dust measured during the Fennec campaign in April and June 2011 will be presented. Results will provide new information on the optical properties of dust in regions of the Sahara that were previously unsampled, and information on size distribution of dust in the centre of the Saharan heat low.

Optics of semi-externally mixed polluted mineral dust

S. N. Tripathi[1], S.K. Mishra[2], S. G. Aggarwal[2], and A. Arola[3]

[1]Department of Civil Engineering, Indian Institute of Technology, Kanpur, 208016, India

Keywords: semi-external, carbonaceous, mineral dust, hematite, shape.
Presenting author email: snt@iitk.ac.in

The radiative forcing estimation of the polluted mineral dust is limited due to lack of knowledge on morphology, mixing state with the carbonaceous components and the hematite content in the pure dust (Forster et al., 2007). The accumulation mode mineral dust has been found to mix with anthropogenically produced black carbon, organic carbon and brown carbon during long range transport.

The above features of the polluted dust are not well accounted for in the optical models and lead the uncertainty in the numerical estimation of their radiative impact. The Semi-external mixing being a prominent mixing of dust and carbonaceous components has not been studied in detail.

In present study, we consider the pure mineral dust composed of non-metallic components (such as Quartz, Feldspar, Mica and Calcite) and metalic component such as hematite, Fe_2O_3 (Mishra and Tripathi, 2008). The hematite percentage in the pure mineral dust governs its absorbance. Based on this hematite variation, the hematite fraction in pure mineral dust has been constrained between 0–8%. The morphological and mineralogical characterization of the polluted dust (Alexander et al., 2008) led to consider the three sphere, two sphere and two spheroid model shapes for polluted dust particle system (Figure1). The pollution gives rise to various light absorbing aerosol components such as black carbon (BC), brown carbon (BrC) and organic carbon (comprising of HUmic-Like Substances, HULIS, OC) in the atmosphere. These model shapes have been considered for the mineral dust getting polluted with (1) organic carbon (especially HULIS component) (2) Brown carbon and (3) black carbon by making a semi-external mixture with pure mineral dust.

The optical properties (e.g. Single Scattering Albedo, SSA; Asymmetry parameter, *g* and Extinction efficiency, Qext) of above model shapes for the polluted dust have been computed using Discrete Dipole Approximation, DDA code. The SSA was found to vary depending on hematite content (0–8%) and model shape composition. For the two sphere BC-mineral dust cluster, hematite was found to be dominating absorber compared to that of black carbon as the ratio of black carbon radius to dust radius, R_{BC}/R_{dust}, decreases. The two spheroid system composed of organic carbon and dust with 0% hematite (OCD'-0) showed the maximum deviation of SSA (i.e. ~5%) compared to the two sphere system of same composition and hematite content (OCD-0). SSA was found to be more sensitive to hematite content than that of particle shape. Compared to SSA, *g* was found to be more sensitive towards particle shape. For three-sphere model shapes with 0% hematite composed of black carbon-dust-dust (BCDD-0), brown carbon-dust-dust (BrCDD-0) and organic carbon-dust-dust (OCDD-0), the deviation of SSA and *g* relative to conjugate BC, BrC and OC spheres are ~68% and ~31%, ~83% and ~31% and ~70% and ~33%, respectively. The modeled polluted dust optics will provide a better basis for radiative forcing estimation and many sensitivity studies.

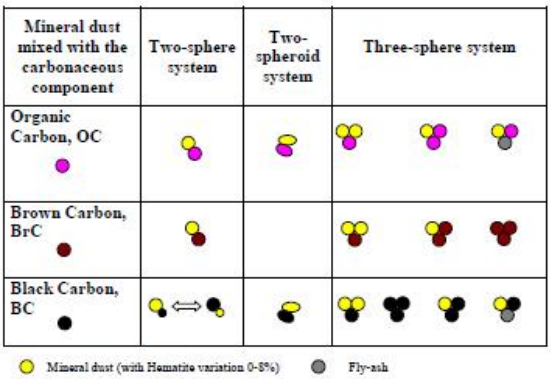

Figure 1. The pure mineral dust (yellow sphere) mixed with the carbonaceous components namely, OC, BrC, and BC are shown as pink, dark tan, and black spheres, respectively (First column, top to bottom). Semi-externally mixed polluted mineral dust two-sphere and two spheroid model shapes comprising of mineral dust with OC, BrC and BC, respectively are shown in second and third column, top to bottom. BrC-mineral dust two spheroid model shape has not been modeled as BrC occurs in spherical form. The three sphere model shape of mineral dust with OC, BrC and BC, respectively are shown in fourth column, top to bottom. Some of the three sphere systems were modeled with fly-ash (shown with grey sphere) based on the experimental observations.

Reconstruction of aerosol extinction from visibility and aerosol mass concentration in Budapest, Hungary

A. Molnár[1], D. Párkányi[2], K. Imre[2] and V. Gácser[2]

[1]Air Chemistry Group of Hungarian Academy of Sciences, University of Pannonia, Veszprém, P.O. Box 158, H-8201, Hungary
[2]Department of Earth and Environmental Sciences, University of Pannonia, Veszprém, P.O. Box 158, H-8201, Hungary
Keywords: aerosol composition, extinction coefficient, PM10, urban aerosol.
Presenting author email: amolnar@almos.uni-pannon.hu

The aim of this work is to present the results obtained in a closure experiment, in which the aerosol extinction coefficient is estimated and reconstructed. On one hand, the extinction coefficient is estimated from visibility data by using the Koschmieder theory. On the other hand, applying similar approach to the method of IMPROVE network (e.g. DeBell et al., 2006) the aerosol extinction is reconstructed on the basis of aerosol chemical composition.

Visibility and aerosol data summarized in this work were collected in two sampling campaigns between 2nd February, 2009 and 2nd March, 2009; and between 20th July 2009 and 20th August 2009. In these campaigns beside visibility measurements parallel aerosol samples were collected at Marczell György Observatory of the Hungarian Meteorological Service in Budapest, Hungary.

Visibility (visual observation) and PM10 mass concentration (β-gauge measurements) were available on hourly basis. Parallel daily aerosol sampling was also carried out in order to measure the chemical composition of PM10. From these samples inorganic ions (chloride, sulfate, nitrate, ammonium and sodium), total carbon and the light absorbing carbon contents were determined by means of ion chromatography, total carbon measurements (Astro Model 2100 TOC) and PSAP, respectively.

Form visibility data the extinction coefficient is derived by the Koschmieder formula. The extinction coefficient referring to dry air was estimated by applying the γ-approach. A significant, linear correlation is found between PM_{10} mass concentration and the dry extinction coefficient (Fig.1).

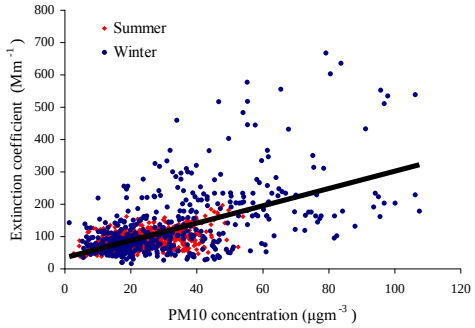

Figure 1. Dry extinction coefficient derived from visibility as the function of PM10.

On the other hand, considering the aerosol chemical composition the mass concentration of PM_{10} aerosol is reconstructed. The reconstructed and the directly measured PM_{10} mass concentrations agreed well in both sampling campaigns.

By means of multiple linear regression, the relationship between the aerosol chemical composition and the measured extinction coefficient is also studied. Our results show that the extinction coefficient (the scattering coefficient) can be effectively estimated from the chemical composition of the PM10 (Fig 2).

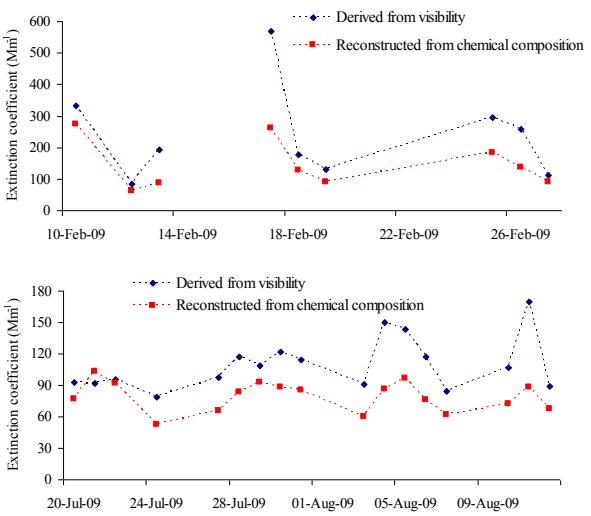

Figure 2a and 2b. Variation of the extinction coefficient derived from visibility and reconstructed from aerosol chemical composition in winter (a) and summer (b) campaigns.

Wavelength dependent Angström exponent based source apportionment and its correlation with aerosol size distribution

T. Ajtai[1], M. Schnaiter[2], C. Linke[2], Á. Filep[1], N. Utry[1], Z. Bozóki[3], G. Szabó[1]

ajtai@titan.physx.u-szeged.hu

Due to its strong influence on the climate and its adverse health effects, in-situ characterisation of light absorbing carbonaceous matter (LAC) is in the middle of scientific interest today. LAC is a mixture of graphite-like particles and light-absorbing organic matter having various sources. Due to the fact that the absorption spectra of LAC are characteristic for its constituents, its measurement can be a valuable tool for in-situ source apportionment (Andreae and Gelencsér, 2005). Despite of their importance, the absorption features of the LAC are very poorly characterised, especially in case of the recently discovered organic fraction, the so called brown carbon (BrC). This uncertainty stems from both the lack of reliable instrumentation and also from the chemical complexity of BrC, which causes high variations in its optical properties (Andreae and Gelencsér, 2005). The LAC has rather featureless optical absorption, which however has a sharp and characteristic increase toward the shorter wavelengths. Therefore the light absorption by LAC become more characteristic in the UV wavelength region and the efficiency of the source apportionment could be increased by multi-wavelength measurements including wavelengths in UV (Hoffer et al, 2005, Andreae and Gelencsér, 2006). The only method that can be used to measure light absorption by aerosols in-situ is photoacoustic spectroscopy (Meinrat O. Andreae, 2001), but most of the available photoacoustic instruments operate only at one wavelength.

In this work we focus on in-situ source apportionment based on the optical absorption of LAC measured by our novel multi-wavelength photoacoustic instrument (4λ-PAS). The 4λ-PAS operating at four wavelengths (1064nm, 532nm, 355nm and 266nm) and apply wavelength independent non-site specific calibration, therefore it provides a unique and novel possibility of source apportionment based on the absorption measurement. Several physical and chemical properties of the ambient were also measured during the presented experiments, in order to further support the interpretation of the results and to reveal the correlation between the measured quantities. The reported experiments were made under different field conditions at different sites.

We will demonstrate that the reliability of the source apportionment by optical absorption measurement can be increased by using UV wavelengths too and that the wavelength variation of the fitted Angström exponent is also characteristic for the components of LAC. By comparing absorption and size distribution based source apportionments, a correlation between these approaches were found (Fig.1.) Correlations between the observed variations in the optical absorption spectra and the variations in NO_x and CO concentrations also confirm that the residential heating and the traffic are the main sources of the seasonal and diurnal variation in the Angström exponent.

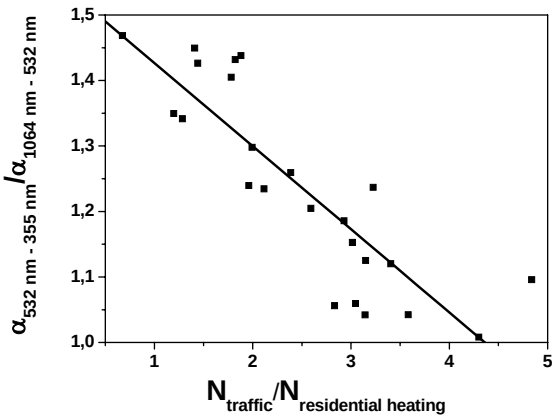

Figure 1. The ratio of the Angström exponents (α) in the short (532nm-355nm) to the long (1064nm-532nm) wavelength range as the function of the ratio of aerosol number concentrations (N) in the CMD = 20 nm ("traffic aerosols") to the CMD = 120 nm ("residential heating") mode.

Retrieving aerosol size distribution using wavelength dependence of aerosol optical depths

Sumita Kedia* and S. Ramachandran
Physical Research Laboratory, Ahmedabad, India
Keywords: Aerosol measurement, Aerosol optical depth, size distirbution, Ångström exponent
Presenting author email: sumita@prl.res.in

Atmospheric aerosols exhibit large variability in their size distribution depending on their source regions, production mechanism and mixing processes in the atmosphere. Aerosol size distribution is an important parameter, which strongly influences the radiative properties of aerosols such as phase function and spectral scattering. The spectral variation in aerosol optical depth (AOD) can be represented by Ångström exponent (α), obtained from Ångström power law given by

$$\tau = \beta \lambda^{-\alpha} \quad (1)$$

where τ is the AOD at wavelength λ, and β is the turbidity coefficient. α is the slope of ln τ versus ln λ data and it depends on the ratio of concentration of fine and coarse mode aerosols in the atmosphere. Higher α value signifies an increase in the concentration of fine mode particles whereas a lower a indicates an abundance of coarse mode aerosols. The fine mode aerosols are mainly attributed to the particles produced by fossil fuel/biomass burning and/or gas-to-particle conversion mechanism (anthropogenic sources), while coarse mode aerosols correspond to mechanically generated aerosols such as sea salt and mineral dust (natural sources).

Ångström power law is well suited for the short spectral bands, but when the spectral range is extended and the aerosol size distribution becomes multimodal, departure from the linear behavior of power law is observed. The departure from linearity of ln τ versus ln λ data is a function of aerosol size distribution. In such conditions, a curvature is observed in the aerosol optical depth spectra which contain useful information about the aerosol size distribution.

In the present study we have examined the spectral dependence of AODs, their spatial and temporal variability over two contrasting environments in western India, namely Ahmedabad and Gurushikhar (Figure 1) using ground based measurements. Ahmedabad is a semiarid, industrialized, urban location with several small and large scale industries. The city has a population of $\sim$5.8 million and is located in the southeast direction of the Thar desert. Gurushikhar is a relatively pristine site at an altitude of about 1.7 km with a population of $\sim$50000 and is $\sim$300 km northeast of the Thar desert. The site is situated at the highest peak of Aravalli range of mountains in western India with a cleaner and stable atmosphere [Kedia and Ramachandran, 2011].

Measurements of AODs at five different wavelength bands centered around (0.4, 0.5, 0.65, 0.75, and 0.875 μm) were conducted using a hand held sunphotometer over both the study location during October 2006 - December 2008. AODs over Ahmedabad are more than two times higher than Gurushikhar at all the wavelengths indicating higher aerosol loading over Ahmedabad throughout the study period.

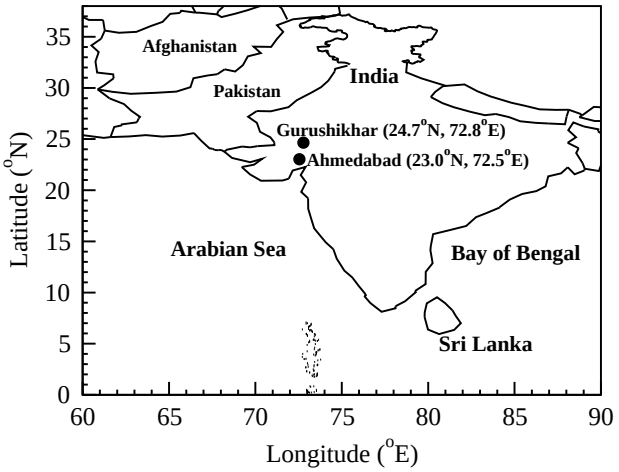

Figure 1: The study locations Ahmedabad and Gurushikhar are marked on India map.

α is higher over Ahmedabad than Gurushikhar suggesting higher fine mode aerosol concentration over Ahmedabad. A polynomial fit to the ln τ versus ln λ showed the presence of changing dominant aerosol types as a function of season over both the locations. The coefficients of polynomial fit are used to get confirmation on the dominant aerosol mode over the study locations as a function of seasons. About 87% and 78% of AOD spectra are found to be dominated by wide range of fine mode fractions or mixture of modes during winter over Ahmedabad and Gurushikhar respectively. During premonsoon >80% of AOD spectra are found to be dominated by coarse mode aerosols over both the locations. During monsoon $\sim$70% of AOD spectra are coarse mode dominant over Ahmedabad. In postmonsoon <40% of AOD spectra are dominated by coarse mode aerosols over both the locations. This characterization of aerosols is important in assessing the response of different aerosol types on radiative forcing and regional climate.

Details on the methodology adopted and results obtained on the curvatures in AOD spectral distribution will be presented and discussed.

Keywords: Light scattering, Relative humidity, Hygroscopic growth, Field measurements, Nephelometer
Presenting author email: paul.zieger@psi.ch

Atmospheric aerosol particles change in size due to water uptake which is determined by their chemical composition and the ambient relative humidity (RH). As a result also their optical properties - especially the aerosol light scattering - strongly depend on RH. Therefore, long-term measurements of aerosol physical and optical properties are generally recommended at dry conditions in order to keep measurements comparable (e.g. RH < 30 - 40% as recommended by (WMO 2003)). However, for the comparison of such ground-based measurements with other optical aerosol measurements (e.g. lidar, MAX-DOAS or satellite retrieval), for the purpose of aerosol correction of satellite retrievals, or for the use in climate models, accurate knowledge of the RH effect is very important.

The key parameter to describe the influence of RH on the aerosol light scattering is the scattering enhancement factor $f(\lambda,RH)$, which defined as the scattering coefficient $\sigma_{sca}(\lambda,RH)$ at a certain RH divided by the dry scattering coefficient $\sigma_{sca}(\lambda,RH=dry)$:

$$f(\lambda, RH) = \frac{\sigma_{sca}(\lambda, RH)}{\sigma_{sca}(\lambda, RH = dry)},$$

where λ denotes the wavelength.

Here, we will present measurement and modeling results of the aerosol scattering enhancement, which are based on our field experiments using a new developed humidified nephelometer (Fierz-Schmidhauser et al. 2010c). Results will be shown for aerosol found at the high alpine site Jungfraujoch (Fierz-Schmidhauser et al. 2010a), for Arctic aerosol measured at Ny-Ålesund, Spitsbergen (Zieger et al. 2010a), for maritime aerosol measured at Mace Head, Ireland (Fierz-Schmidhauser et al. 2010b), and for aerosol typically found at Cabauw, the Netherlands (Zieger et al. 2010b). The latter one was performed from June to October 2009 and was part of the GEOmon initiated Cabauw Intercomparison Campaign of Nitrogen Dioxide measuring Instruments (CINDI). Here, our measurements allowed the determination of the extinction coefficient at ambient RH, which was com-pared to several MAX-DOAS and LIDAR measurements also performed at Cabauw in that period.

Figure 1 shows back trajectories color coded with the scattering enhancement measured at the time of the air parcel arriving at the station (here for the three field campaigns carried out at Jungfraujoch, Ny-Ålesund, and Cabauw during 2008 and 2009). Depending on the aerosol type (origin) the *f*(RH) (here shown at 85% RH and for λ=550nm as an example) varied between approx. 1.3 and 6.6.

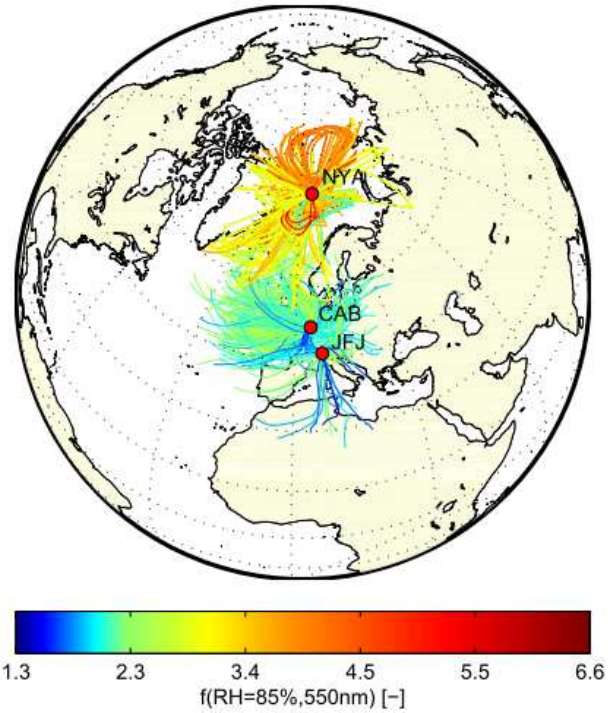

Figure 1: Back trajectories (48 h backward calculations) for the investigated sites: Jungfraujoch (JFJ), Ny-Ålesund (NYA), and Cabauw (CAB). The trajectories are color coded with the mean scattering enhancement *f*(RH=85%,550nm) measured at the site.

Reducing the uncertainty in estimates of the impact of aerosol on climate remains at the center of interest in the climate changes discussion. The Amazon Basin is one of the most crucial regions in the world where these effects may be studied from many points of view. In particular, it is important to identify and to quantify the processes and sources that control the regional aerosol concentrations, in order to obtain a reliable quantification of their global impacts. We expect that a better understanding - and modelling - of these processes and sources may provide a better understanding of the feedbacks between climate and aerosol concentrations.

As a part of the LBA/BARCA experiment, an airborne campaign was conducted, using the two engine INPE aircraft (National Institute for Space Research), from 16 November to 2 December, 2008, corresponding to the transition period from dry to wet season in Amazon Basin. The flight legs are shown in the Figure 1, where the main cities are indicated. The aircraft was instrumented for collecting data on aerosol spatial distribution/concentration and size distribution and, in addition, measurements of trace-gases including O_3, CH_4, CO, CO_2 and N_2O were also performed. Sixty-eight profiles were obtained up to 4 km, covering an important part of the Amazon Basin. Total aerosol number concentration was measured at 1 Hz time resolution using a TSI 3010 Condensation Particle Counter model. A Thermo Multi Angle Absorption Photometer model 5012, operating at 637 nm, was used for measurements on aerosol light absorption, and for optical scattering by atmospheric particles, the aircraft was equipped with a three wavelength (450, 550, and 700 nm) TSI 3665 nephelometer. Aerosol number size distributions were measured with a TSI SMPS 3080 for particles ranging 10–354 nm.

This work presents the spatial distribution of the aerosol optical properties in Amazonia during the transition between dry and wet season, when the aerosol population is strongly influenced by biomass burning emissions (Figure 2). The Amazon Basin is a region of intense convective activity, and the spatial and temporal description of the optical properties of these particles supports the assessment of the impact of changes in the regional land use, not only on the regional climate, but also at the global scale.

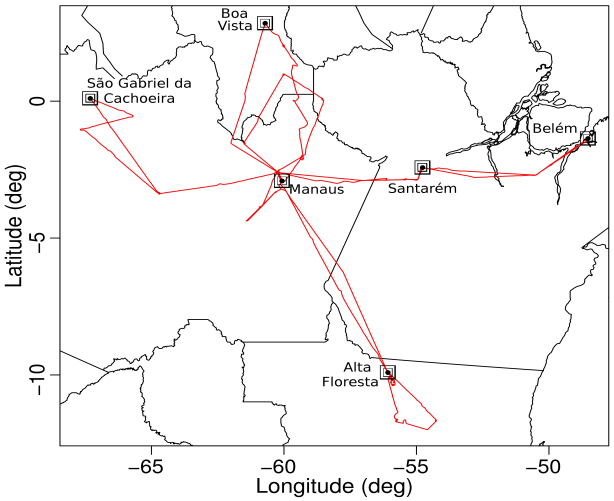

Figure 1: Mapping of the flight tracks during the BARCA-A airborne campaign, covering an important part of the Amazon basin during the dry season.

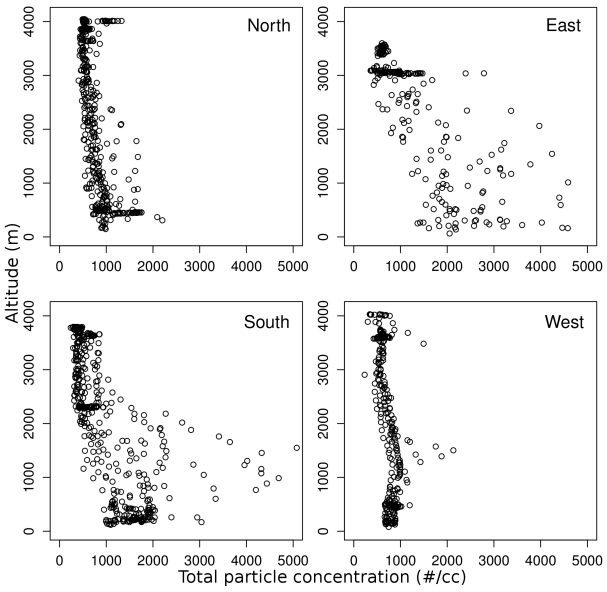

Figure 2: Total aerosol concentration vertical profiles for the northern, eastern, southern and western sectors of Amazonia during the transition from dry to wet season, November 2008. The aerosol population is strongly influenced by biomass emissions.

Keywords: Combustion aerosols, ship emissions, particle number, semi-volatiles.
Presenting author email: kfu@force.dk

Introduction

Particle emissions from diesel engines are traditionally regulated according to the emitted particle mass. EU emission standards will from 2015 also include standards for the emitted number of particles from land-based diesel vehicles. An increasing focus is turned towards emissions from marine diesel engines. Compliance measurement systems for particle number emissions have been recommended for on-road diesel vehicles (Anderson *et al.*, 2010). The recommended systems include a sampling system involving thermo-evaporation in order to remove volatile material before measuring the total particle number. In this study, the effect of thermo-evaporation on the measured particle number, size and on the morphology of the particles emitted from a ship engine was investigated. The engine studied was a 7 MW MAN two-stroke marine engine, and the fuel used was gasoil containing 0.002% sulfur.

Methodology

The particle number concentration in the engine exhaust at 50% engine load was measured by an ELPI (Electrical Low Pressure Impactor). The sampling system included dual ejector diluters. The temperature of the first diluter was increased in steps from 150 °C to 450 °C. Size distributions were studied by SMPS (Scanning Mobility Particle Sizer). Impactor samples collected at 150 °C and 350 °C were examined by AFM (Atomic Force Microscopy) and SEM (Scanning Electron Microscopy).

Results and conclusions

The results for particle numbers measured during increasing sample temperature are shown in figure 1.

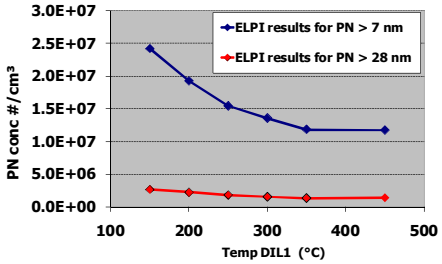

Figure 1. Number of particles from a marine diesel engine, measured by ELPI during increasing sample temperature.

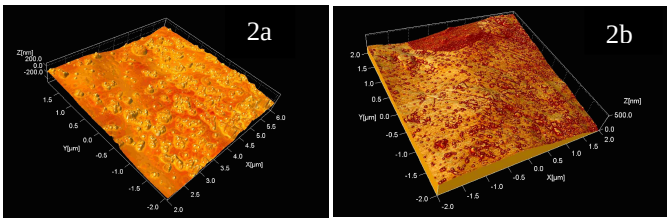

Figure 2. AFM image of particles sampled at 150 °C (2a) and at 350 °C (2b).

Figure 2a and 2b shows the results of the AFM analysis for particles collected during periods with sample heating to 150 °C and 350 °C, respectively. In figure 2, the color shading superimposed on the topography shows the local phase signal measured by the AFM. A change in color contrast, representing a change in the phase, is typically caused by variations in the material properties such as viscoelasticity, friction or hardness. In figure 2a, contrast variations can be observed within each particle, indicating that the particles consist of materials with different properties. In figure 2b, the contrasts are less distinct. The phase signal is more uniform within the individual particles, indicating that the majority of particles sampled at 350 °C have less varying material properties. The more homogenous particle material at 350 °C can be explained by the effect of thermo-evaporation, i.e. residuals of un-combusted hydrocarbons (e.g. fuel and lubrication oil) have evaporated from the particles. Likewise, small, condensed oil droplets will evaporate rapidly at 350 °C, and this explains the reduced particle numbers at increasing temperatures in figure 1. The results show that it is important to control the sampling temperature when sampling particles from marine diesel engines. As for land-based diesel engine test protocols, the results presented here indicate that test procedures for marine diesel engines become more robust when the sampling system includes a thermo-evaporation at 350 °C.

This work was supported by the The Danish Agency for Science, Technology and Innovation and MAN Diesel & Turbo.

In the framework of the global warming policy, the impact of nanoparticles emitted by aircraft engines on the environment meets an increasing interest. Indeed, these soot aggregates are directly injected in the troposphere and the low stratosphere and may lead to the formation of condensation trails, which affect the global radiative budget (Lee, 2010). They can also have a non negligible impact in airport areas and their vicinity (Puente Lelièvre, 2006).

This study focuses on the properties of soot aggregates emitted by three different civil CFM56 aircraft engines tested at Snecma and designed for short, medium and long haul flight. Soot samples are collected at the ground level by impaction on Transmission Electron Microscopy grids (Figure 1) that are located 27 m behind the engine exit (Delhaye, 2007). The sampling is performed during engine cycles that cover LTO and non LTO settings and represent what happens in the airport areas. We present the evolution of two characteristic mean sizes of soot aggregates that differ significantly from an engine to another. Indeed, our measurements lead to a soot aggregates geometric mean gyration diameter (d_g) that ranges from (52 ± 3) nm to (89 ± 4) nm between the three tested engines, whereas the geometric mean diameter of the primary particles composing the aggregates (d_p) ranges from (4.22 ± 0.06) nm to (9.9 ± 0.1) nm (Table 1). An analysis is proposed to understand in which way the evolution of these two soot characteristic sizes is correlated to some potentially relevant engine parameters. The d_g and d_p mean values determined in this work are really smaller than those of soot originating from Diesel and wood combustion (Chandler, 2007; Gwaze, 2006) and may represent an opportunity to identify aircraft soot among carbonaceous aerosols in the atmosphere.

The size and shape of soot aggregates weigh on their light diffusion properties. Any variation of these characteristics can lead to non negligible consequences on the global radiative budget. The submicrometric size of soot particles and aggregates is also of importance regarding air quality and human health since they can reach and interact with lung cells. It is then important to study their microphysical properties according to various engine settings if one want to model and understand their role in physical and chemical processes in the atmosphere as well as their impact on human health.

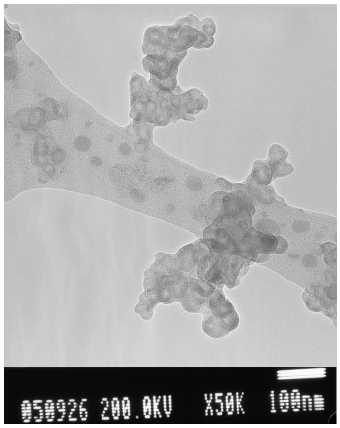

Figure 1. TEM picture of a soot aggregate sampled 27 m behind a CFM56 engine.

Characteristic sizes	d_p (nm)	d_g (nm)
CFM56-B	8.0 ± 0.2	54 ± 2
CFM56-5C	9.9 ± 0.1	89 ± 4
CFM56-7B	4.22 ± 0.06	52 ± 3
Wood (Gwaze, 2006)	25.5 ± 3.5	-
Diesel (Chandler, 2007)	20 ± 5 – 29 ± 8	156-270

The potential of biofuels in shipping for mitigating the climate impact – Results from the integrated BIOCLEAN study

Presenting author email: andreas.petzold@dlr.de

The use of biofuels for stationary power generation or propulsion in shipping gains increasing importance in the framework of CO_2 reductions and the use of energy from renewable sources. The knowledge on emission characteristics of various biofuels and resulting climate impacts however is very limited.

BIOCLEAN investigated the emission of CO_2, NO_x, hydrocarbon compounds, SO_2, H_2SO_4 and particulate matter in terms of particle number, particle size, and chemical composition from medium-speed four-stroke large diesel engines for different fuel types. The tests included heavy fuel oil (HFO) with a fuel sulphur content of 2.17 weight-% (wt-%) as the fossil high-sulphur reference fuel, marine gas oil (MGO) with a fuel sulphur content of < 0.1 wt-% as a fossil low-sulphur fuel, and palm oil, soy bean oil, sunflower oil and waste edible fat as biofuels.

The simultaneous consideration of climate-active trace species like NOx, particulates and sulphur-containing particle precursors on one hand and of the most important climate-active exhaust constituent CO_2 on the other hand allowed for the investigation of trade-off effects of CO_2 emissions reduction and potentially increasing emissions of other climate-active trace constituents. Model studies using a coupled climate chemistry model for the treatment of direct and indirect aerosol effects on climate investigated the climate response in case of replacing heavy fuel oil by biofuels. The greenhouse gas emissions associated with the production and use of the biofuels were included by means of a fuel lifecycle analysis which also considered land use chances associated with the growth of energy plants for the production of biofuels.

The investigated set of biofuels demonstrated good combustion properties in the single-cylinder four-stroke test engine. No significant increase in engine degradation and corrosion was observed for biofuel use. Biofuels emission properties at 75% engine load relative to HFO are listed in Table 1.

Table 1. Emissions from biofuels relative to HFO

Property	Emission rel. to HFO
NO_x	≅ HFO
Particulate matter (mass)	10 - 15% of HFO
Particle number	2 – 3 × HFO
Particle number non-volatile	30 – 60% of HFO
Black carbon	15 - 30% of HFO
Organic matter	≥ HFO

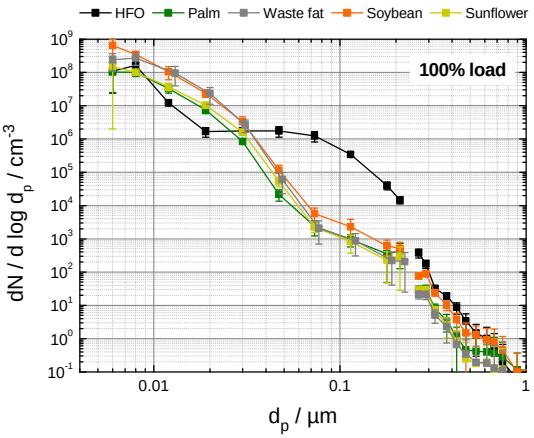

Figure 1. Number size distribution of particles emitted from a marine Diesel engine operating on different biofuels and on heavy fuel oil (HFO) as a reference case.

When using low sulphur fuels (MGO, biofuels) the emissions of particulate matter (PM) and especially sulphate and black carbon are significantly reduced compared to HFO, see Fig. 1. This effect is of similar magnitude for the low sulphur fossil fuel MGO and for biofuels. Emissions of NO_x and CO are of similar magnitude as for HFO while the emissions of gas-phase hydrocarbons are also reduced for low-sulphur fuels.

Climate effects were investigated for the hypothetical case that in 2006 all HFO is replaced by biofuels (mainly palm oil or soy bean oil), while MGO is still used in the international shipping fleet. Associated CO_2 emissions include the additional greenhouse gas emissions during the lifecycle of the biofuels. The resulting CO_2 emissions were evaluated as reduction or increase compared to the reference case of using HFO.

Direct and indirect effects of emitted particulate matter are almost exclusively associated to the sulphate content of emitted PM. Therefore, the modification of aerosol climate effects is of similar magnitude for the low sulphur fossil fuel MGO as for the investigated biofuels. For all low sulphur fuels, the direct effect is reduced by a factor of 4 to -3 mW m^{-2}. The indirect effects are reduced by a factor of 3 to -100 mW m^{-2}.

Presenting author email: z.ristovski@qut.edu.au

Particulate emissions from compression ignition engines are a major health concern. Clearly strategies are required to address the diesel particulate matter problem, with alternative fuels, such as biodiesel, having been recently considered to ameliorate the problem. This study considers a physico-chemical characterisation of particulate emissions from a compression ignition engine to determine the effect of using 3 biodiesel feedstocks at 4 different blend percentages.

Particulate emissions testing was performed on a naturally aspirated 4 cylinder engine with a Euro II (off-road) emissions certification. The engine was coupled to a water brake dynamometer to provide a load to the engine. In addition to ultra-low sulphur diesel (< 10 ppm sulphur), three biodiesel feedstocks; namely, soy, tallow and canola were tested at four blend percentages (20%, 40%, 60% and 80%). The opportunity also arose to test neat soy biodiesel (ie 100% soy), yielding fourteen different fuel types, all of which were tested at the intermediate speed (1400 rpm) full load (300 Nm) setting for this engine - a test mode known as rated torque.

A two-stage unheated system was used to dilute the exhaust before particulate measurement; consisting of a dilution tunnel followed thereafter by a Dekati ejector diluter. Particle number size distributions were measured with a scanning mobility particle sizer. A TSI 3550 Nanoparticle Surface Area Monitor (NSAM) was used to measure the lung deposited surface area (tracheo-bronchial) emitted by the engine. Size distributions were also measured after passing the sample through a TSI 3065 thermodenuder (set to 300 ^{o}C). Heating the particles enabled the impact of thermal treatment to be explored. A thermodenuder loss correction was performed using dried NaCl particles.

Of line chemical measurements were performed directly from the dilution tunnel. Filter sampling was performed for particle phase PAHs and XAD-2 resin was used to sample vapor phase PAHs. Reactive Oxygen Species (ROS) measurements were performed by bubbling the exhaust through impingers containing a solution of a profluorescent nitroxide probe (BPEANit) in DMSO. More details on the ROS sampling and quantification methodology can be found in Miljevic et al. (2010).

Figure 1 shows particle number size distributions for the 3 biodiesel feedstocks and 4 blend percentages. The shift to a smaller median particle diameter can also be readily observed as the blend percentage is increased, and does so in a monotonic fashion. Size distributions are also shown where the poly-disperse size distribution was passed through a thermodenuder set to 300 ^{o}C for the canola feedstock. The canola feedstock was chosen to illustrate the "volatility" of particles, as they had the highest volatile organic content, subsequently exhibiting significant evaporation in a thermodenuder.

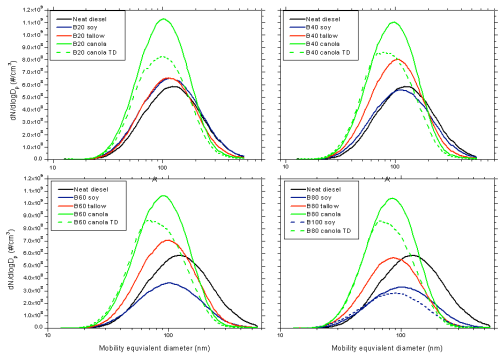

Figure 1. Particle number size distributions for various biodiesel feedstocks and blend percentages.

ROS are generally classed as "semi-volatile" organic compounds that evaporate when exposed to thermal treatment with a thermodenuder (Miljevic et al 2010). It therefore seems intuitive to seek a correlation between ROS concentrations and the volume percentage of the particle that is composed of organic material. Assuming that the organic material is volatile from the volatility measurements, we have calculated the organic (ie volatile) volume percentage of particles. In general higher ROS emissions were associated with particles that have a greater organic volume percentage. Despite one potential outlying data- point, the Pearson correlation co-efficient for this relationship is quite strong (~ 0.83).

Overall the results show that whilst significant particle mass reductions are achieved with all 3 biodiesel feedstocks, unregulated particulate emissions, such as particle number concentration and ROS concentrations are increased by some and all feedstocks, respectively.

Keywords: Diesel emissions, Nucleation mode
Presenting author email: tero.e.lahde@iki.fi

The diesel exhaust regulation focuses nowadays to accumulation mode particles. The accumulation mode dominates the regulated total particle mass and the upcoming number based non-volatile diesel exhaust particle limit is directed to accumulation mode.

The diesel exhaust particle size distribution, however, contains often two distinctive modes, the nucleation mode and the accumulation mode. The accumulation mode consists of the carbonaceous charged soot agglomerates and species accumulated on the surface of the agglomerate. Traditionally, the nucleation mode was thought to be formed in cooling dilution through vapour nucleation. Recently, however, also nucleation mode is shown to possess an electric charge and non-volatile fraction with certain engine assemblies. The formation mechanisms of the non-volatile nucleation mode are still mostly unknown; (see Lähde T. *et al*, 2011 and references therein).

The non-volatile diesel exhaust particle size distribution characteristics are studied here as a function of fuel injection pressure (FIP). FIP adjustment is an often used combustion optimization method in in-cylinder particle emission control diesel engines. FIP increase decreases the soot mode mass effectively, but the changes in the non-volatile nucleation mode (core) are still unknown.

Here the effect of fuel injection pressure change is studied for non-volatile particle size distribution.

Particle distributions were measured with two SMPS, equipped with DMA 3085 and CPC 3025 and with DMA 3081 and CPC 3776 (Tsi Inc.). Measured size range was between 3 nm and 400 nm.

Sample was diluted first with porous tube type diluter and second with ejector diluter also heated double ejector was used in the study. The particle population was "dried" with a thermodenuder designed for particles with diameter below 30 nm.

In addition to particle measurements also aerosol ion charge distribution was measured briefly. The ion distributions were measured with a DMPS without neutralizer. The DMPS was also equipped with DMA 3085 and CPC 3025 (Tsi Inc.).

The studied research engine was a 6 cylinder, 7.4 L, common-rail injection engine. The effect of fuel injection pressure on the particle population was studied with three load conditions (18%, 48% and 98%) @ 1500 min^{-1} engine speed and multiple injection pressures ranging from 60 MPa to 160 MPa. No exhaust aftertreatment was used in the measurements. The fuel sulphur content was 12.5 mg/kg.

A bimodal non-volatile size distributions were measured with medium (48 %) and high (98 %) loads, but at a low load (18 %) the distribution was unimodal, example distributions in fig. 1. At high load, also the ion distribution was bimodal resembling the particle size distribution and practically similar non-volatile size distributions were measured with two different dilution systems.

At the medium and high load the number concentration of the core mode increased with increasing FIP and simultaneously a decrease in soot mode size and concentration was detected. At medium load, also the core size changed with FIP. The core mode GSD was generally higher at medium load than at high load. The core was absent at the low load at all FIPs, although the soot mode size and concentration decreased with increasing FIP similarly to high and medium load.

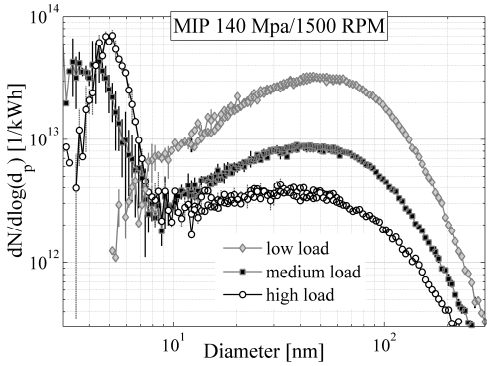

Figure 1. Non-volatile particle distributions measured with low, medium and high load. FIP=140 MPa, speed 1500 RPM

Diesel exhaust particle size distributions typically consist of two distinctive modes, often called soot and nucleation modes (Kittelson, 1998). Soot mode particles are solid carbonaceous agglomerates formed in fuel combustion process. Nucleation mode particles can be formed by gas-to-liquid processes during exhaust dilution and cooling processes or, as shown in recent studies (e.g. Rönkkö et al. 2007; Lähde et al. 2009), by the formation of non-volatile core particles at near cylinder conditions followed by particle growth during the exhaust dilution and cooling processes. Typical semi-volatile condensates and adsorbents on the particles are hydrocarbons and sulfur compounds that originate from the fuel or lubricant. The mean diameters of the soot mode and the nucleation mode typically lie around at 40–100 nm and 3–40 nm, respectively, while the size of non-volatile nucleation mode core particles is typically below 10 nm.

Conventional diesel oxidation catalysts (DOC) efficiently oxidize carbon monoxide and unburned hydrocarbons. Furthermore, they produce NO_2 which can be used in diesel particulate filter regeneration at low temperatures. In addition, in oxidizing aftertreatment devices some of the SO_2 from the engine is oxidized to SO_3 which can react with water vapour and form gaseous sulfuric acid. Sulfuric acid has been proposed to be a precursor in sulfur-driven nucleation mode formation.

We studied the effect of fuel sulfur content on diesel exhaust particle emissions in a light duty Euro 4 diesel application and the existence of the sulfur-driven nucleation mode under aerosol laboratory conditions. In the engine laboratory tests, three fuels with different sulfur contents were used: 10 ppm, 50 ppm and 350 ppm (mass contents). The fuels chosen conform to different legislation limits worldwide; S10 in EU, S50 e.g. in Hong Kong and Singapore, and S350 in India. The test engine was equipped with a partial diesel particulate filter. The aerosol laboratory tests were performed after the engine laboratory tests to find answers for some of the key observations.

The driving operation in the engine laboratory consisted of two consecutive modes: a low load point and a medium load point. The first driving mode was performed at low engine load so that the exhaust gas temperature was less than 250 °C and exhaust aftertreatment regeneration did not occur. At this load, the exhaust particle size distribution consisted of the non-volatile soot mode only. During the second driving mode, performed at medium load, volatile nucleation mode particles were observed with S50 and S350 fuels.

In the aerosol laboratory the formation of sulfur-driven nucleation by SO_2 oxidation in an oxidative aftertreatment was extensively studied. The generated nucleation mode had similar physical characteristics as in the engine laboratory study and in other studies of volatile nucleation mode particles (e.g. Lähde et al. (2009). In addition, in situations where high gas temperature followed a low temperature phase, similar trends in particle formation was observed both in the engine laboratory and in the aerosol laboratory studies. It was observed that, sulfur compounds stored at low temperature conditions in the aftertreatment device were later released at an elevated temperature and thereby affected the nucleation mode. This observation is in agreement with the studies of Giechaskiel et al (2007).

Reactive oxygen species (ROS) emissions from diesel engines running on various biofuels

S.D. Stevanovic[1, 3], B. Miljevic[1], N.C .Surawski[1, 2], S.E. Bottle[3], R. J. Brown[2] and Z.D. Ristovski[1]

Due to rising worldwide demand for energy and the prospect of climate change as a result of greenhouse gas emissions, there is a need to develop alternative energy sources. Therefore it is important to verify the potential of biofuels, as a renewable energy source, and to estimate the health and environmental impacts of their implementation (Gomes and Muylaert de Araújo 2009)

The mechanisms of particulate matter related adverse health effects are still incompletely understood, but a hypothesis under investigation is that many of these effects may derive from oxidative stress, initiated by the formation of reactive oxygen species (ROS) at the surface of and within target cells. Cumulative epidemiological and experimental data support the association of adverse health effects with cellular oxidative stress, including the ability of PM to induce pro-inflammatory effects in the nose, lung and cardiovascular system .High levels of ROS cause a change in the redox status of the cell and its surrounding environment, thereby triggering a cascade of events associated with inflammation and, at higher concentration, apoptosis.

The main aim of this study was to examine the relationship between different alternative fuel substitutions and the oxidative potential of particles emitted from an ethanol fumigated common rail diesel engine that was also equipped to run with biodiesel. To estimate the oxidative potential of ethanol and biodiesel at two different load settings, a pro-fluorescent probe BPEA nitroxide was used. This probe is poorly fluorescent; however the presence of ROS triggers a fluorescence response which makes it a powerful optical sensor for radicals and redox compounds. Samples were collected by bubbling aerosol for 20-30 minutes through an impinger containing 20 ml of 4 μM BPEA nitroxide solution after which fluorescence was measured. The amount of ROS was calculated based on the difference in fluorescence intensity for the test and the filtered control sample and was further normalised to the PM mass. Tests were designed to present emission differences due to changes in fuel and load settings.

The collection of other data was performed to support ROS measurements which involved volatility measurement using a Volatility- Tandem Differential Mobility Analyser (V-TDMA) system and particle composition using a Time of Flight Aerosol Mass Spectrometer (ToF-AMS).
The results depicting volatility properties as well as size-resolved aerosol chemical composition will be discussed.

Figure 1 shows ROS concentrations for diesel (E0), 3 ethanol substitutions of 10, 20 and 30 % (E10, E20, E30 respectively) and neat soy biodiesel (B100). It can be noticed that with an increased ethanol substitution (and also for biodiesel) an increased amount of ROS can be observed, with respect to E0.

It is proposed that ethanol combustion involves more available OH radicals that oxidise the particle surface. This might be a reason for the observed increase in the ROS on the surface of the soot particles (Surawski, Miljevic et al. 2009).
Furthermore at full load setting, concentration of ROS is significantly lower for all fuels, except for biodiesel. In addition, emissions with 100% biodiesel contained the highest concentration of ROS per mg of PM.

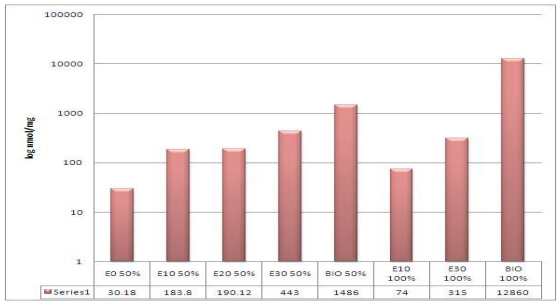

Figure 1: Average ROS concentrations for different fuel and load settings. Note that concentrations of ROS per mg of particulate matter are presented on a logarithmic scale.

Session 12D: From PM exposure to health effects 2

Exposure Analysis for the Inhalation of Ultra-fine Particles Emitted from Household Devices

T. Schripp[1], I. Kirsch[1], S. Willenborg[1] and T. Salthammer[1]

[1]Material Analysis and Indoor Chemistry, Fraunhofer WKI, Braunschweig, 38108, Germany
Keywords: exposure, lung deposition, FMPS, indoor aerosols.
Presenting author email: tobias.schripp@wki.fraunhofer.de

The release of ultra-fine particles from heated surfaces of household appliances has been intensively studied in the past years (Wallace, 2006; Mullen, 2008) due to the increased public interest in the exposure against anthropogenic particles. In most cases the highest emission rate was observed for particle diameters between 20 nm and 100 nm. These particles are known to penetrate the human lung down to the alveolar region. The present study aims at the quantification of particles that are deposited in the different regions of the human lung in the presence of active household appliances.

The emission strength of different household devices, like, e.g., toasters and grills, was determined in a 1 m³ emission test chamber at an air exchange of 3 h^{-1}. The devices were operated without the presence of consumables (e.g. food) for ≤ 10 min (device-specific) three times within three hours. For the simulation of real indoor conditions one household device, a flat iron, was additionally operated (10 min) in a 48 m³ emission test chamber at an air exchange rate of 0.12 h^{-1}. The particle concentration in the chambers was monitored by a Fast Mobility Particle Sizer (FMPS) that measures particles at diameters between 5.6 and 560 nm in 32 channels.

Table 1: Deposition estimates for male adults (sitting) on the basis of FMPS measurements in the 48 m³ emission test chamber and outdoor air. The total deposition is given in combination with the contribution of the modelled four lung compartments to the total deposition. The particle density is assumed to be 1 g/cm³; values for a density of 2 g/cm³ are given in brackets.

Uptake rate	Chamber blank	Lab background	Flat iron
Number [10^9 /h]	0.43(0.50)	6.93(16.03)	0.39(2.37)
Surface [cm²/h]	0.01(0.01)	1.55(2.31)	0.13(0.19)
Mass [µg/h]	0.01(0.02)	3.08(9.05)	0.19(0.55)
ET [%]	17(25)	13(15)	13(15)
BB [%]	4(6)	3(3)	3(3)
bb [%]	23(28)	20(21)	20(22)
AI [%]	56(41)	64(61)	64(60)

The results of the measuring instrument were coupled with an algorithm which estimates the retaining efficiency of four compartments of the human lung and providing the number, surface, and mass of the deposited particles. The algorithm bases on the particle deposition model by the International Commission on Radiological Protection (ICRP, 1994). Two different particle densities (1 and 2 g/cm³) were applied in the ICRP model. The results are given in Table 1 and can be extended for different activities, sex, and ages. The lung compartments of the extrathoracic airways (ET), the bronchi (BB), the bronchioles (bb), and the alveoli (AI) were considered. The lab background was sampled over 5 hours in the emission test chamber lab (mean particle concentration: 55447 #/cm³).

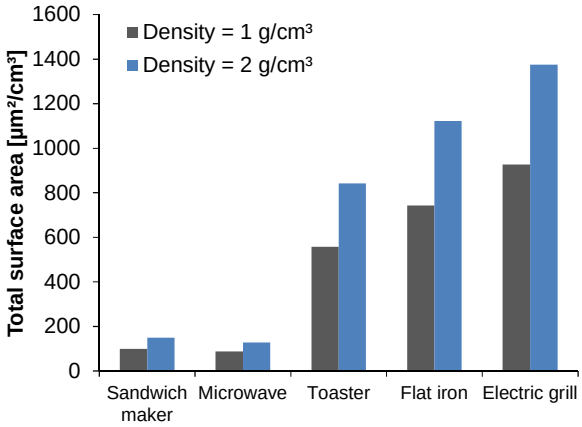

Figure 1: Estimated lung-deposited surface area on the basis of 1 m³ emission test chamber measurements.

The results in Figure 1 demonstrate that the combination of a high time resolved particle measuring instrument and a feasible lung deposition model can be used to determine a ranking of different household appliances in regard of their particle emission behavior. Furthermore, the applied model supports the assumption that the main amount of particles from the device-specific emissions are retained in the deep lung regions. Due to the dependence of the deposition on the particle density the chemical composition of these particles is vitally needed to assess the toxicological effects of the deposited matter. Especially for devices of daily use like toasters and microwaves the risk assessment is of high importance for the further classification of other source of ultra-fine particles in the office environment like hardcopy devices.

Presenting author email: a.schmidt@see.leeds.ac.uk

We quantify the potential negative health hazard that would arise if a Laki-style eruption were to happen under present-day conditions using an advanced global aerosol microphysics model (GLOMAP, Mann et al., 2010) together with concentration-response functions from the literature (Pope et al., 2002; Ostro, 2004). The 1783—1784 AD Laki eruption lasted 8 months and represents one of the largest flood lava eruptions in recent history (Thordarson & Self, 2003). The emission of ~122 Tg of volcanic SO_2 over the course of 8 months (Thordarson et al., 1996; Thordarson & Self, 2003) is of the same order of magnitude as the current total of global anthropogenic SO_2 emissions per year (e.g. Smith et al., 2010).

According to our simulations a total of around 139,000 additional cardiopulmonary fatalities would arise in Europe in the year following a Laki-style eruption. Thus, our results show that such a volcanic air pollution event would be a severe health hazard, increasing excess mortality in Europe on a scale that is at least comparable with excess mortality due to seasonal flu. Our simulations reveal highest excess cardiopulmonary mortality rates in the Netherlands, Belgium, UK, Germany, and northern France, which is a result of population density combined with highest pollutant concentrations (in our case particulate matter with diameters smaller than 2.5 microns).

We compare our findings to historical records of the aftermath of the 1783—1784 AD Laki eruption which suggest an increase in mortality in summer 1783 (e.g., Grattan et al., 2003; Witham & Oppenheimer, 2005), and find that the simulated scale and the spatial pattern of mortality are very similar.

We will also discuss the magnitude of SO_2 and sulphate aerosol concentrations at commercial flight altitude. Moreover, we will discuss seasonal variabilities in the risk to impact human health and aviation.

Given historic records of the Laki eruption and the probability of a recurrence of such an event we deem it crucial to assess the scale on which a future Laki-style eruption could impact society.

Keywords: lung deposition, health, aggregated particles, dose
jenny.rissler@design.lth.se

The particle mass and surface area is believed to be crucial parameters for the health effects of inhaling non-soluble air-borne particles. Often the deposited dose and particulate surface area are estimated from particle number concentrations measured by DMA techniques. For spherical particles such estimations are good. For non-spherical particles, however, the estimations can deviate from the real deposited surface area or mass by an order of magnitude. Aggregated or agglomerated particles require additional information about both particle shape and particle effective densities.

The aim of this work is to describe and apply a methodology for assessing surface area and mass of aggregated/agglomerated particles based on number size distributions measured by DMA-techniques. The method is applied in three studies: estimating the deposition in the human respiratory tract of diesel soot, deposition of gold aggregates in protein solutions and direct unto cell cultures (Savi et al., 2008).

The principle of the method used to estimate the surface area size distribution is shown in Figure 1. As input (*i*) the mass of the individual aggregates of a certain mobility diameter $m_{agg}(d_{me})$, (*ii*) the primary particle size (d_p), and (*iii*) number size distribution ($dN_{agg}/d\log d_{me}$) are needed. For mass determination of individual aggregates the novel DMA-Aerosol Particle Mass Analyzer (DMA-APM McMurry et al., 2002) is used. The mass size distribution of the aerosol is estimated by combining the results of the DMA-APM system and the number size distribution. For estimation of surface area the size of the primary particles is also needed, here estimated from TEM images.

From $m_{agg}(d_{me})$ and d_p the number of primary particles of the individual aggregates of a certain size ($N_p(d_{me})$) is calculated (assuming a density of the primary particles of ρ_p=1.8 g/cm^3 for soot and 19.3 for gold) according to $N_p(d_{me}) = m_{agg}(d_{me})/(\rho_p \cdot \pi \cdot d_p/6)$.

By combining $N_p(d_{me})$ and the particle number size distribution, the distribution of the total number of primary particles of all aggregates of a certain d_{me} is estimated, and thereafter the total surface area of all aggregates of a certain d_{me} ($SA(d_{me})$). Knowing the size resolved fraction of particles deposited (measured or modeled) in the lung, into the protein solution or onto the cell cultures, the total deposited dose and surface area is determined.

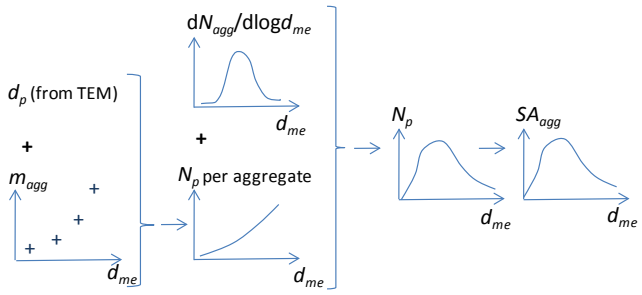

Figure 1. Principle of the methodology.

The method was applied in the three studies. All showed that when estimating mass from size distributions measured by an SMPS assuming spherical particles, gave 4-6 times higher doses than if the measured particle mass was used. Surface area was not as sensitive for aggregation state and the aggregates had a larger surface area than if assuming spherical particles, by typically 2-3 times. The contact area between primary particles in the aggregate is assumed to be infinitesimal. According to TEM images the true contact area is larger and the real surface area will probably lie between the two extremes; spherical particles and agglomerates.

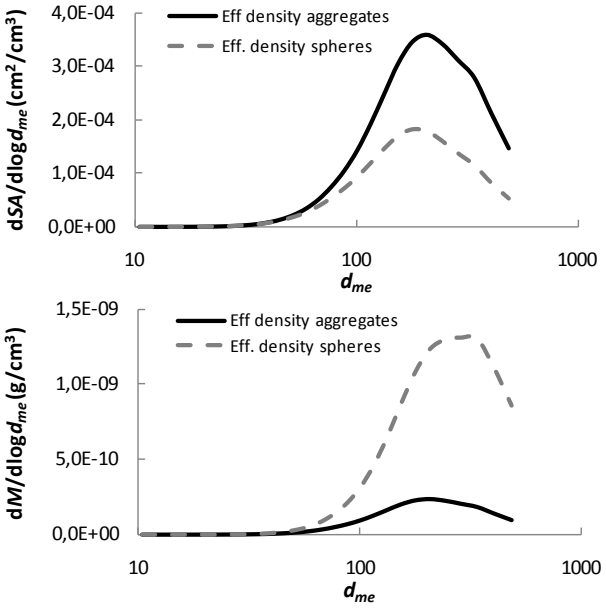

Figure 2. Distributions of surface area (*SA*) and mass (*m*) assuming either spherical or aggregated particles.

Optical scattering observations in two occupied residences with wood-burning stoves

I.D. Longley, J. Gadd

National Institute of Water & Atmospheric Research Ltd, Auckland 1010, New Zealand
Keywords: Indoor particles, Indoor sources, Wood combustion, PM10.
Presenting author email: i.longley@niwa.co.nz

Introduction

Domestic wood-burning stoves used for home heating are the largest source of ambient PM_{10} emissions in many cities and rural towns in New Zealand. Air quality management policy in such locations is currently focussed on replacement of wood-burners with newer low-emission burners, or alternative energy sources. Such policy is being driven by, and judged against, the ambient Air Quality National Environmental Standard for PM_{10} - with an assumption that this is a proxy for exposure and health effects. However, New Zealanders spend 70% of their time indoors at home and on winter evenings when wood-burners are operated most of the populace is likely to be indoors.

Previous studies on indoor levels and sources of PM in homes burning wood for heating have been very limited and generally focussed on filter samples. However, the low temporal resolution of such techniques prevent an examination of the processes involved and key sources, especially considering the multiple pathways by which wood-smoke can potentially enter the home.

Our aim was to conduct a limited exploratory observational study to determine whether the wood-burner was a significant indoor source in two typical New Zealand homes, and to explore whether particle concentrations in these homes was correlated with ambient PM_{10} observed at nearby regulatory monitoring sites.

Methods

A TSI Sidepak integrating nephthelometer was installed consecutively in two occupied homes in Christchurch for two weeks each in winter 2009. The instrument nominally reported "PM_{10}" (derived from light scattering measurements) at 1 minute resolution. Several other parameters were recorded, including flue and room temperature. Participants used their own supply of firewood and used their wood-burner in the usual way. They also kept a diary of fire-lighting and wood additions.

A number of limited follow-up experiments were conducted in a 'control' home focussing on the woodburner 'start-up' procedure, relying on PM_{10} measurements and video of the firebox.

Results

In the occupied homes indoor concentrations were characterised by rapid elevations (lasting 1 – 5 minutes and occurring once or twice a day) followed by smooth exponential decays. 1-minute peaks varied greatly ranging from 110 to 2800 $\mu g\ m^{-3}$ (mean = 690 $\mu g\ m^{-3}$) and were strongly predictive of 24-hour mean concentrations, which varied from 22 to 140 $\mu g\ m^{-3}$. By comparing these data with concurrent data from local ambient sites we estimate that 24-hour indoor concentrations were 3 to 10 times higher than concurrent ambient concentrations.

1-minute peaks often coincided with the start of wood-burning, as indicated by the increase in flue temperature. The 20 largest peaks (all above 200 $\mu g\ m^{-3}$) were all related to fire-starting or fuel addition, with paper addition leading to larger concentrations than wood addition.

The follow-up test confirmed that the rapid rise in indoor PM_{10} coincided with the initial match-lighting and the early stage of burning the first kindling, and ended when the firebox door was fully closed and burning had become self-sustaining. The highest concentrations were recorded when paper, but no wood, was lit.

Discussion

There was effectively no linear relationship between ambient PM_{10} and the indoor light scattering measurements on the basis of either 24-hour or 1-hour averages when all data was considered. When peaks caused by wood-burning were removed from the data set, the temporal pattern in baseline indoor PM more generally reflected ambient PM_{10}.

The follow-up study confirmed the co-incidence of rapid peaks and the fire-starting procedure. It also showed that, using these materials, the peaks could be largely avoided by user technique.

Our results show that true exposure may be substantially higher in wood-burning homes compared to both non-wood-burning homes and in the ambient air – and that presence of an operating wood-burner is a substantial modifier of the relationship between ambient air quality and exposure.

This study was conducted within the Healthy Urban Atmospheres programme funded by the Foundation for Research Science and Technology (New Zealand). Ambient PM_{10} data was provided courtesy of Environment Canterbury.

Outdoor/indoor particle infiltration factor in Rome and its relation with urban air quality

Despite the fact that, in industrialized nations, people spend a large amount of time indoors, the information on air pollution inside buildings is very poor as compared to ambient air quality. So, necessarily, most epidemiological studies estimate personal exposure on the basis of outdoor levels. Nevertheless, actual human exposure to atmospheric pollutants is regulated by pollutant penetration efficiency and time variability in air exchange rate in indoor environments.

Methods

A four-season indoor and outdoor Particle Number Concentration (PNC) monitoring in two residential homes in Rome was carried out (particles between 0.02 and 1 µm in aerodynamic diameter, 1-minute resolution). A third particle sampling point in downtown Rome, located in the Italian National Health Institute monitoring station, was considered as the reference site. Particulate matter and primary gaseous pollutants concentration data, monitored in ten stations of Rome air quality network, were evaluated to investigate the relation between urban ambient pollution and internal air quality. Finally, with the aim of studying the influence of atmospheric stability on air pollution levels, natural radioactivity data, provided by the near city CNR-Institute of Atmospheric Pollution stability monitor, were taken into account (Perrino, 2001).

We observed that indoor source events (i.e. cooking or cleaning) can cause indoor/outdoor ratios to exceed one, particularly for less ventilated periods (winter). So, through the study of different seasonal patterns (Hänninen, 2010), indoor PNC in the absence of internal sources were reconstructed to better estimate the home infiltration factor (see Figure 1).

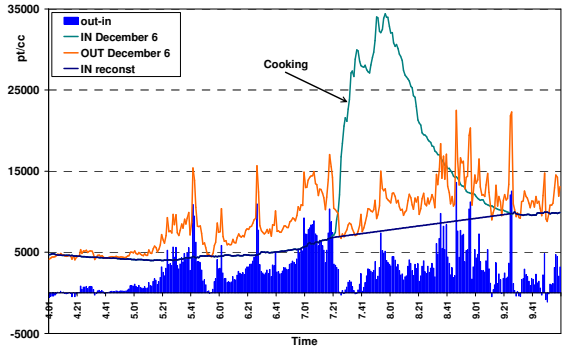

Figure 1. Indoor/outdoor PNC with and without an internal particle source.

Results

Different seasonal patterns; a good correlation between average indoor/outdoor daily values; huge differences in temporal patterns considering a shorter time scale between summer and winter (when the air exchange rate is slower because of different home dynamics; i.e. windows left open/closed) were observed.

It is remarkable that a good correlation between PNC registered indoor in the sampling sites and the main primary gaseous pollutants measured in the urban network stations (see Figure 2) was registered.

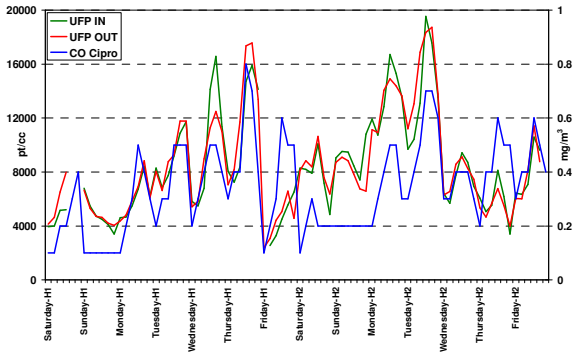

Figure 2. Summer days comparison between indoor/outdoor PNC (in red and green) and CO measured in a urban background station (in blue).

Finally, an innovative interpretation of natural radioactivity data allowed us to distinguish between the two main components of urban air quality: atmospheric stability and pollutant emissions so to better understand the real influence of urban pollution on indoor air quality.

Simulated airway particle deposition in an urban environment impacted by biomass smoke

A.C. Targino[1], P. Krecl[2], C. Johansson[3]

[1] Universidade Tecnológica Federal do Paraná, Londrina, Brazil

Populations living in large urban conglomerates are usually exposed to enhanced particle concentrations due to anthropogenic emissions. To make matters worse, urban areas may also be subject to pollution outbreaks caused by long-range transport (LRT) (Saarikoski et al., 2007)

In 2006, the European continent faced an abnormally warm spring period. As a result, agricultural fires broke out in Eastern Europe and became uncontrolled causing serious transboundary pollution episodes in areas as remote as the Arctic (Stohl et al., 2007). This study investigates the effect of this pollution outbreak on the health of Stockholm's population. To assess and quantify the aerosol load impact on the human health, we contrast three aerosol load scenarios: (1) a period dominated by the LRT event, (2) a period dominated by local emission sources, and (3) a period with combined LRT and local sources. To do so, we employ the Multiple Path Particle Dosimetry (MPPD) model that calculates the fraction of particles deposited in specific parts of the respiratory system (Anjilvel and Asgharian, 1995). Model aerosol input parameters were based on in situ measurements at a street canyon site in Stockholm (Figure 1), whereas airway morphology and breathing conditions were chosen from the literature for activities with different exertion level (rest, quiet and moderate cycling).

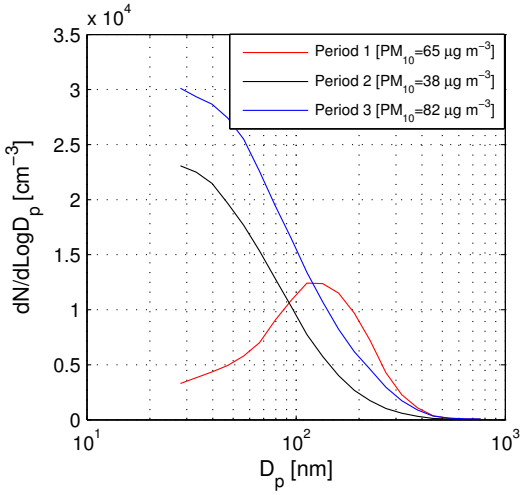

Figure 1. Mean particle number size distributions and PM_{10} mass concentrations measured in Stockholm for the three selected periods.

The results show that the maximum deposition fraction of the inhaled aerosol mass for an adult is observed during period 2 for all breathing conditions (Figure 2). For all cases, the deposition fraction increases from nasal to the alveolar region (not shown). Even though the maximum PM_{10} mass concentration was observed during the LRT event, the maximum potential risk to pulmonary disease is observed in the period dominated by local traffic emissions.

These preliminary results suggest that the definition of clean and polluted conditions, for health studies, should be linked to ultrafine particle concentrations rather than to PM_{10} (or $PM_{2.5}$) mass concentrations.

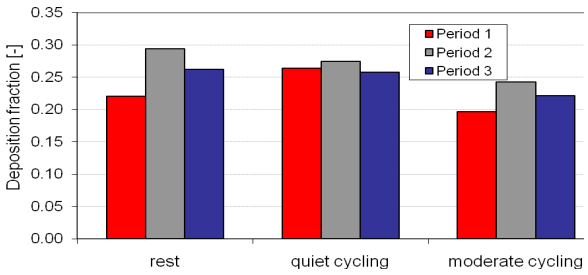

Figure 2. Aerosol deposition fraction in an adult per period and under rest, quiet cycling and moderate cycling conditions.

Keywords: Aircraft plumes, combustion aerosols, lung deposition, hygroscopicity.
Presenting author email: hagen@mst.edu

A major portion of atmospheric particles found in both urban and rural areas consists of carbonaceous material derived from both biogenic and anthropogenic sources. Particulate matter (PM) from on-road vehicular traffic has been correlated to increases in mortality and morbidity. PM from jet engine exhaust (JEE) falls into a similar size range, but its inhalation health impacts have been less well studied. JEE PM has unique properties with respect to deposition, retention kinetics, and clearance pathways in the human respiratory system, and is composed of sizes that readily travel gas streamlines that penetrate the deepest regions of the lung; this is a concern as deposited JEE PM in these regions could potentially cross the blood-membrane barrier and migrate into the bloodstream.

In two field campaigns PM size distribution and hydration data was acquired by the Missouri University of Science & Technology Center of Excellence for Aerospace Particulate Emissions Reduction Research (Missouri S&T COE), at Hartsfield-Jackson Atlanta International (ATL) and Oakland International (OAK) airports (Herndon et al 2008; Whitefield et al 2007). JEE PM was sampled downwind of active taxi- and runways during normal airport operations. The sample locations were selected adjacent to airport runways at distances of 100 m or greater from take-off sites, and chosen so JEE plumes would be transported by prevailing winds to a sampling probe feeding the diagnostic instrumentation. For both campaigns aircraft tail numbers were recorded for identification of airframes and engine types. Weather conditions were also monitored and recorded continuously throughout testing periods.

Using the JEE PM data collected during plume studies performed down-wind of active runways at ATL and OAK, lung deposition probabilities of JEE PM (as a function of particle size) can be determined using the International Committee of Radiological Protection (ICRP) lung deposition model. Surface area is the characteristic PM parameter most strongly correlated with health impacts (Stoeger et al 2006). Using the deposition probabilities and size resolved number distributions, a Surface Area Deposition Index (SADI) was developed. This new parameter, SADI, characterizes JEE PM lung deposition as the surface area of deposited PM per kilogram fuel burned. SADI allows for equitable comparison among various jet engine types while also proving a surface area metric for meaningful health impact correlations. An example of the variation in SADI for engine type CFM-56 observed at OAK is shown in Fig. 1.

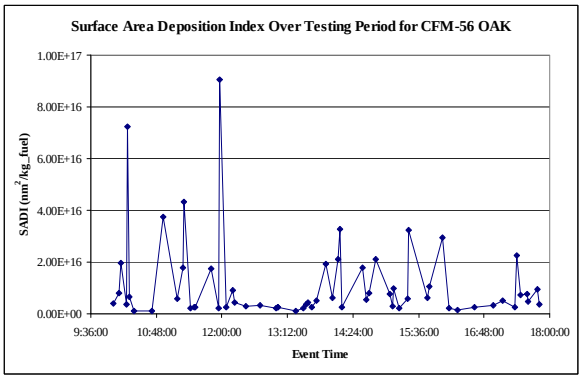

Fig. 1 Surface Area Deposition Index for CFM-56 engine type observed at OAK

Two interesting conclusions to this preliminary study are that statistically significant differences among engine types are not observed in SADI, and variations in SADI are not correlated with temporal changes or changes in meteorological conditions.

EAB was sponsored by the Airport Cooperative Research Program (ACRP 11-04: Graduate Research Award Program on Public-Sector Aviation Issues) administered by the Transportation Research Board of the National Academies (Project Manager: Larry Goldstein). Ultrafine nebuliser for aerosolization of nanoparticles in colloidal suspensions

J.E. Farnsworth[1], D.C. Grant[2], H.G. Van Schooneveld[2], M.R. Litchy[2], B.L. Osmondson[1], and R. Caldow[1]

[1]TSI Incorporated, Shoreview, MN, 55126, USA
[2]CT Associates, Eden Prairie, MN, 55344, USA

Keywords: nebuliser, SMPS, PSL, generation of nanoparticles, surfactants
Presenting author email: jim.farnsworth@tsi.com

Nebulisers are used to aerosolize a variety of particles present in colloidal suspensions, however their usefulness for particles smaller than 100 nm is limited as dissolved residue from the liquid interferes with counting and sizing the particles of interest.

In this paper we present an ultrafine nebuliser capable of generating a small, uniform droplet distribution such that particle formed from dissolved residue when the liquid is evaporated does not interfere with the nanoparticles in the liquid for sizes >10 nm (Grant and Beuscher, 2009). When used with a scanning mobility particle sizer (SMPS), one can measure particle size distributions (Figure 1) and calculate the original number concentration of the liquid sample within ±10%.

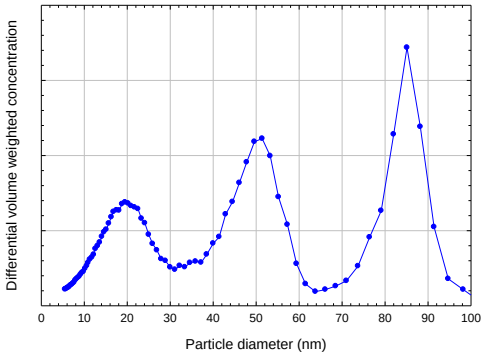

Figure 1. Simultaneous measurement of 20, 50, and 83 nm PSL spheres using the ultrafine nebuliser (Van Schooneveld *et al.*, 2010).

As shown in Figure 2, the liquid sample is fed by a peristaltic pump into the nebuliser system at a flow rate of 0.01-1 ml/min. The sample is diluted with a known ratio of ultrapure water (UPW) to minimize dissolved residue interference. The sample is then aspirated through a micro-orifice and forced around an impactor, generating an aerosol with a narrow droplet size distribution and mean droplet size of 300 nm. The aerosol passes through a heated drying column, combines with dilution air, and exits the instrument at a flow rate around 1.5 L/min.

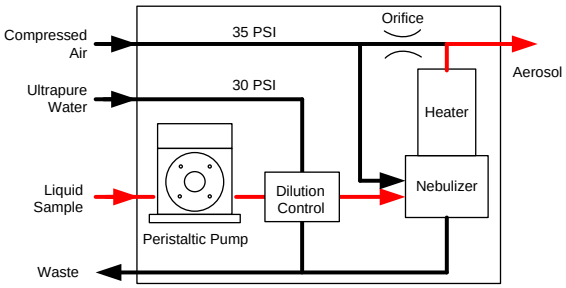

Figure 2. Flow schematic of the ultrafine nebuliser.

The nebuliser has been used to generate nanoparticle-laden aerosols such as gold and alumina, macromolecules such as dextran, PSL in the 20-100 nm range, and colloidal silica (used in semiconductor wafer polishing slurries) in the 10-200 nm range. Coupled with an SMPS the coefficient of variation (CV) of size distributions can be measured directly. Excellent agreement is shown between CV obtained by this approach and CV reported by PSL manufacturers.

The on-line dilution scheme utilized by the nebuliser can be used to differentiate between solid particles and dissolved residue in liquid. For example, by generating PSL at multiple dilution ratios, one can distinguish PSL spheres and surfactant particles from dissolved residue contaminants.

The combination of nebuliser and SMPS (n-SMPS) has been applied as a near real-time characterization tool for industrial liquid systems. The device has been used to characterize polishing slurries used in semiconductor manufacturing, and has been used to measure removal efficiency of liquid filters as a function of particle size, filter pore size, and filter loading. Particle sizing data from these studies are presented.

A Study of Terpenes by Raman Acoustic Levitation

M.V.Ghosh, S.Almabrok, D.J. Stewart, I .Hoare, G. Marston and C. Pfrang

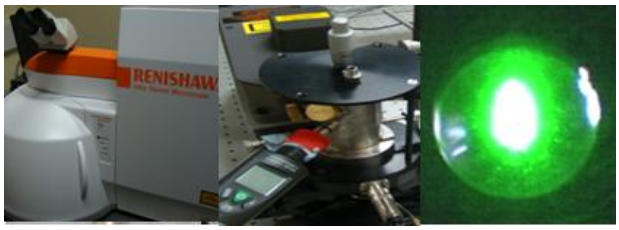
Department of Chemistry, University of Reading, Reading, Berkshire, RG6 6AD, UK
Keywords: acoustic levitation, terpenes, Raman spectroscopy
Presenting author email: m.v.ghosh@reading.ac.uk

Large quantities of volatile organic compounds (VOCs) are emitted into the troposphere from both biogenic and anthropogenic sources. Almost half of the mass of biogenic volatile organic compounds (BVOC) emitted is isoprene and about 11% are monoterpenes of which the highest fractions are α-pinene (25%) and limonene (16%). The oxidation of terpenes leads to ozone formation, and they are known cause the formation of secondary organic aerosol (SOA).[1]

In this study, a novel acoustic levitation set up is being developed to improve the understanding of evaporation kinetics and of changes in chemical composition of acoustically levitated droplets of terpenes such as α-and β-pinene, limonene and Δ-carene.

Acoustic levitation is an elegant method that allows contact-less reaction monitoring and spectroscopy of single particles. It is, however, only recently that acoustic levitation has been considered for atmospheric science.[2,3] Acoustic levitation is generally achieved by an ultrasonic transducer producing a standing sound wave. Alteration of the distance between transducer and (in most cases concave) reflector allows varying the number of the pressure nodes that allow stable particle levitation.[4]

In this study Raman spectroscopy has been successfully combined with acoustic levitation to allow a time resolved contactless monitoring of chemical reactions and physical processes in a single droplet suspended in a controlled gaseous environment.



(a) (b) (c)

Figure 1. Images of the Raman acoustic levitation set up.

Fig. 1 shows from (left to right):

(a) Commercial Raman microscope in the Chemical Analysis Facility, CAF, in the Department of Chemistry at Reading University; (b) Experimental set up with the levitation chamber coupled to the Raman spectrometer; (c) Image of the laser beam focused in the centre of the levitated droplet.

During the evaporation of acoustically levitated droplets of α-pinene the changes in droplet size were measured by a CCD camera and the intensity of the C=C stretching band at 1662 cm^{-1} was monitored by Raman spectroscopy as a function of time.

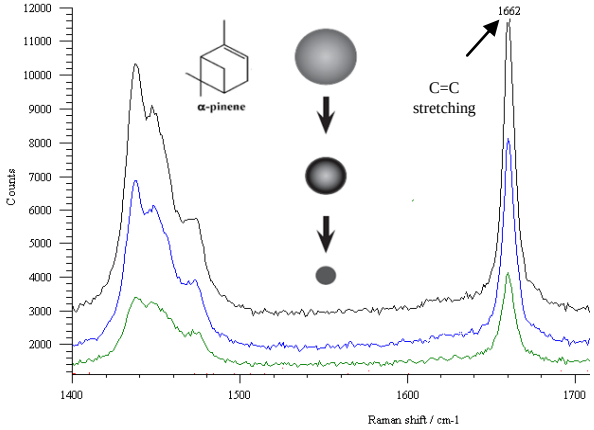


Figure 2. An example of evaporation of a levitated α-pinene droplet in nitrogen at a relative humidity, RH, of 50% and T = 25 °C recorded by Raman spectroscopy as a function of time (acquisition time of 60 s).

Raman acoustic levitation allows monitoring of changes in physicochemical properties of small organic droplets. Following systematic tests to probe the sensitivity of the technique to droplet size and environmental conditions, Raman acoustic levitation has been successfully applied to monitoring the evaporation kinetics and chemical composition of acoustically levitated droplets of terpenes. Being able to suspend a single particle while its chemical composition is being monitored by Raman spectroscopy will be exploited in future studies of the ageing of atmospheric aerosols.

This work was supported by the Royal Society (RG2007/R2; PI Dr Pfrang) and the NERC (NE/G000883/1, PI Dr Pfrang; NE/G019231/1, PI Prof. Marston and Co-I Dr Pfrang). It benefitted from instruments available within the Chemical Analysis Facility, CAF, and is a result of joint research efforts within the newly formed Reading Atmospheric Chemistry and Environmental Research, RACER, team (www.chem.rdg.ac.uk/research/chem-racer.aspx).

Keywords: nanoparticle, exposure, monitor, handheld

Monitoring of exposure to airborne nanoparticles is crucial, e.g. in view of worker protection, as inhalation is seen as the major uptake route for nanomaterials. A number of intensive measurement campaigns have been carried out in the past to very thoroughly study particles and aerosols in workplaces. These campaigns are very time and cost intensive. In some cases, e.g. as a first step in a tiered approach, only a quick check of the exposure concentration or a permanent surveillance is required. Such simplified measurements can be conducted with portable monitoring devices, such as handheld condensation particle counters (CPC) or diffusion charger (DC) based instruments. Five different models of portable nanoparticle monitors were subject to an intensive intercomparison experiment. All these devices have in common that they are small, light weight, battery operated and deliver a size-integrated concentration measure; number concentration in case of CPCs and most DCs and lung deposited surface area concentration in case of some DCs. Time resolutions are between 1 s and 16 s. Both types of devices, CPCs and DCs have their advantages and disadvantages. CPCs are known to be very accurate and particle size, shape and material independent. On the other hand they always have to be maintained in a horizontal position and require a working fluid that needs to be refilled every 5-8 hours in case of the handheld version. DCs can be operated in any orientation and don't require auxiliary materials, but rely on several assumptions and are thus usually less accurate.

During the intercomparison measurements, three different types of test aerosols were generated: NaCl, DEHS and soot. NaCl and DEHS particles were generated using an atomizer (Topas, ATM 226), soot particles were produced with a spark generator (Palas, GFG3000). The NaCl aerosol contained solid, cubic particles with a modal diameter of approximately 50 nm, whereas the DEHS aerosol contained liquid droplets with a modal diameter of approximately 250 nm. Soot particles were fractal-like agglomerates with a modal electrical mobility diameter of approximately 35 nm. A Fast Mobility Particle Sizer (FMPS) was used alongside to measure the particle size distribution. All measurement devices sampled the same aerosol simultaneously. A sequence of number concentrations, as exemplarily shown for soot in Figure 1, was produced for all three aerosol types.

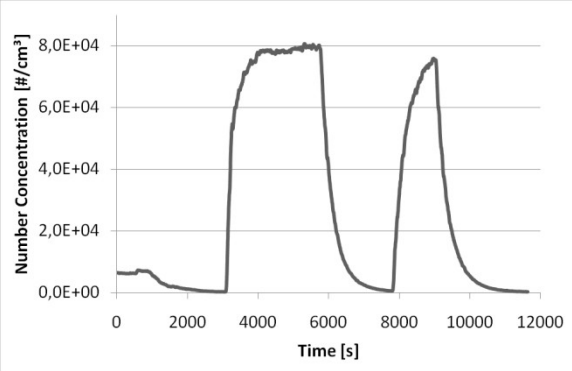

Figure : **Time series of the soot number concentration**

The results show that the devices react differently to the different aerosols and concentration changes. Handheld CPCs generally produced the most accurate results for number concentrations below 10^5 #/cm³ with deviations mostly within ±5%. For higher concentrations, the CPCs reached saturation and became increasingly inaccurate. DCs worked well also for higher concentrations, but expectedly showed a lower overall accuracy, generally within ±30%, which is sufficient for most monitoring applications. Only the DEHS aerosol produced significantly higher errors of some diffusion chargers, most likely caused by the presence of large particles.

The experimantal design will be presented along with intercomparison of the different devices. Results will be discussed in view of simplified and improved monitoring of airborne nanoparticle concentrations.

Evaluation of PEGASOR PPS™ response time for real time aerosol concentration measurements

Gensdarmes F.[1] Roynette A.[1] Maro D.[1] Laguionie P.[1] Boulaud D.[1] and Tikanen J.[2]

[1] Institut de Radioprotection et de Sûreté Nucléaire IRSN, BP 68, 91192, Gif-sur-Yvette Cedex, France.
[2] Navaro Oy, Rautapellonkatu 37, FIN-33700 Tampere, Finland. juha.tikkanen@pegasor.fi

Keywords: real-time detection, eddy covariance fluxes, nanoparticle, electrometer
Presenting author email: francois.gensdarmes@irsn.fr

Nowadays real time measurement is mandatory in many aerosol studies (combustion aerosol, process control…). In the field of atmospheric research, the determination of aerosol fluxes and deposition velocity by eddy covariance techniques is limited due to the lack of aerosol instrumentation having sufficiently low response time. Its full application requires measurement of actual aerosol concentration fluctuation at 10 Hz (Held *et al.*, 2007; Damay *et al.*, 2009). Although some electrical aerosol instruments are now available with 10 Hz data acquisition (EEPS™, ELPI™) their response times shows values between 0.4 s and 14 s.

The aim of this study is to measure the response time of the Pegasor Particle Sensor PPS™ aerosol monitor with the classical concentration step changes method, and to assess the effect of a sampling line on the results for further application in dry deposition aerosol measurement by eddy correlation technique.

The PPS operates by measuring the image current caused by a cloud of corona charged particles passing through a faraday cup. A specific design of the sensor makes it possible to be freed from the collection of particles on a filter as in the traditional aerosol electrometers. The PPS was operated with 50 psi inlet pressure which corresponds to a sampling flow rate of the "ejector pump" equal to 7.8 l/min.

The experimental set-up used to measure the response time is shown in figure 1. It is composed of a spark discharge generator (PALAS GFG 1000) with carbon electrodes and a dilution volume in order to obtain constant output aerosols with different concentration levels and size distributions The concentration step changing system is composed of two synchronized electromagnetic valves switching between the GFG aerosol and filtered air.

The response time is determined by fitting the data with the classical exponential relationship:

$$C(t)/C_0 = 1 - \exp[-(t - t_0)/\tau],$$

where C_0 is the initial concentration (p.cm^{-3}), t_0 the time of the concentration step (s) and τ the response time (s).

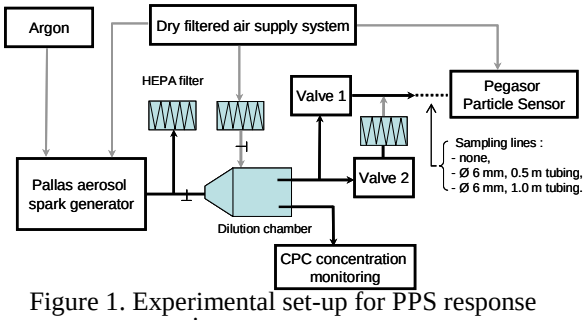

Figure 1. Experimental set-up for PPS response time measurement

Results on response time and sensitivity of the PPS are obtained for aerosol concentrations ranging between 10^3 p.cm^{-3} and 10^7 p.cm^{-3} and particle diameters spanning from 20 nm to 100 nm.

Figure 2 presents the response times for an increase step in concentration measured by the PPS at 10 Hz for different lengths of sampling lines. The results presented are normalized with the same t_0 to take into account different initial time lags in data, according to the tubing lengths. The tested aerosol has a median diameter of 60 nm and a nominal concentration of 3.2×10^5 p.cm^{-3}.

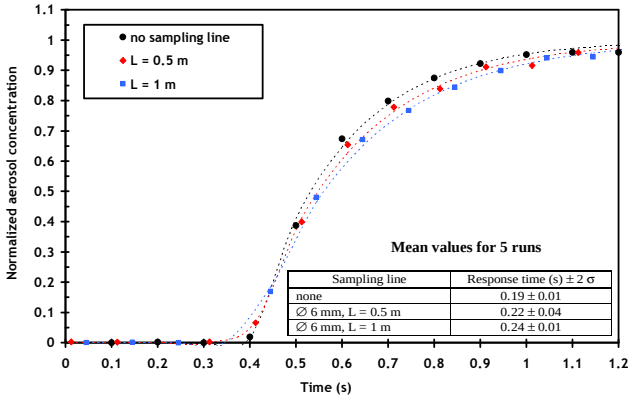

Figure 2. Response times for different sampling lines

Results show very short response times around 0.2 s and logical small increases with sampling line lengths due to laminar flow profile. Further investigations will be made with modified PPS allowing higher sampling flowrate.

A new versatile condensation particle counter for research and environmental monitoring

J. Spielvogel, M. Weiss

Palas® GmbH, Greschbachstr. 3b, 76229 Karlsruhe, Germany
Keywords: aerosol instrumentation, nanoparticles, CPC, number concentration, ultrafine particles
Presenting author email: spielvogel@palas.de

Presented will be a recently developed condensation particle counter in which the unique, patented way of providing the working fluid for condensation allows the user to change the working fluid from e. g. butanol to isopropanol or water. For the first time the user can select a working fluid based on suitability or considerations like adverse health effects or environmental-friendliness.

Working principle

The aerosol with nanoparticles first enters a heated saturator. Within the saturator the working fluid is moved helically around the flow area of the aerosol leading to a homogeneous contact area. Downstream, the aerosol and saturated carrier gas enter a cooled condenser in which the working fluid condenses onto the nanoparticles forming droplets of sizes typically larger than 1 µm.

The counting is performed by an optical aerosol spectrometer (sensor) that also measures the size of the droplets (Figures 1 & 2). A researcher can easily monitor changes in this droplet distribution due to different temperature settings, different working fluid or different particle composition in the analysed aerosol.

The modular design of this instrument further allows adapting the sensor to different concentration levels up to single particle counting of concentrations of 1,000,000 particles/cm^3. This eliminates the need to dilute the aerosol in many cases.

Data

Figures 1 and 2 present data that were obtained by changing the temperatures of the saturator and condenser, then varying the working fluid from butanol to water and repeating the experiment.

In figure 1 the saturator temperature is kept constant at 40°C but the condenser temperature changed from 12°C (dark blue) to 10°C (red). The resulting marginal change in the size distribution of the resulting droplets can be explained that by keeping the saturator temperature constant no change in working fluid vapour is introduced and a change in cooling has little effect on droplet size and number.

However, keeping the condenser temperature constant at 10°C but changing the saturator temperature from 40°C (dark blue) to 44°C (green) and to 47°C (blue) leads to a considerable shift in droplet size distribution. Here, the available amount of working fluid vapour is influenced by the temperature change in the saturator and visible in the increasing size of the forming droplets. At the same time a larger ΔT between saturator and condenser increases the sensitivity of the UF-CPC.

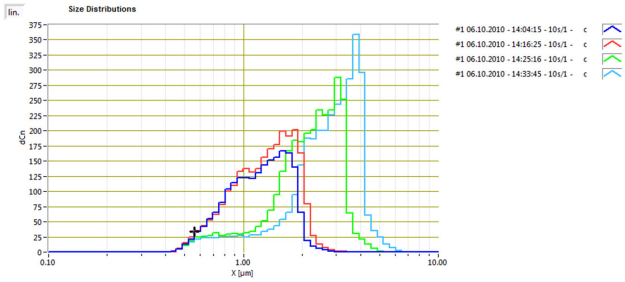

Figure 1. Working fluid butanol. Particle size distributions of droplets resulting from changed saturator and condensor temperatures.

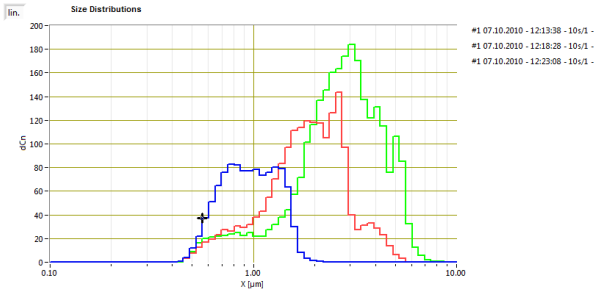

Figure 2. Working fluid water. Particle size distributions of droplets resulting from changed saturator and condensor temperatures.

In figure 2, the butanol was replaced with water and the experiment repeated with three different settings for the saturator temperature (65°C, 70°C, 75°C). Similar to the experiment with butanol, an increase in saturator temperature resulted in a shift in droplet size distribution to larger particles.

Summary

Since butanol can cause skin irritation and other adverse health effects it is desirable to use other working fluids when possible. This condensation particle counter provides a platform to analyse suitable replacements.

Also by changing the working fluid but with the same hardware it is for example possible to conclude on hydrophilic and hydrophobic particles or to study how these properties change during aging of the aerosol.

Measurements using this feature were made at a mail distribution center and will be presented.

Two New Fast Response Laminar-Flow Water-based CPCs

Kathleen A. Erickson[1], Fred R. Quant[1], Sean Morell[1], Susanne Hering[2], Robert Caldow[1]

[1]TSI Incorporated, 500 Cardigan Road, Shoreview, MN, 55126
[2]2Aerosol Dynamics, 935 Grayson Street, Berkeley, CA, 94710
Keywords: particle counter, condensation particle counter, CPC, WCPC.
Presenting author email: kerickson@tsi.com

Two new laminar-flow, water-based condensation particle counters (WCPCs) will be presented. These instruments are based on the Hering design of a differentially diffusive, laminar-flow WCPC (Hering, 2005). Water as a working fluid has significant benefits in terms of elimination of VOC butanol vapours which can interfere with gas monitoring instruments, create difficulties for electronic device or pharmaceutical manufacturing clean environments, and be a nuisance for indoor air monitoring applications. Water also has the added benefit of being easy to procure and transport.

The Model 3788 Nano Water-based Condensation Particle Counter (N-WCPC) has 2.5nm minimum particle detection and the fastest response of any condensation particle counter to date. The concept of using a time constant to characterize the response time of CPC was introduced by Wang et al in 2002. The time constant of the 3788 N-WCPC is ~43 milliseconds which corresponds to a traditional rise time (10-90%) of <100 milliseconds. This fast response makes the instrument well suited for particle formation studies and fast scanning electrical mobility based sizing. The N-WCPC also has the highest activation energy of any WCPC with a temperature differential of 60ºC.

The 3787 General Purpose Water-based Condensation Particle Counter (GP-WCPC) has 5 nanometer minimum particle detection, a time constant of ~130 milliseconds, and a temperature differential of 40ºC.

Both instruments incorporate optimization of the wick geometry to achieve more uniform droplet growth as a function of concentration (Lewis and Hering, 2010). By kinetically limiting droplet growth, it is possible to prevent particles from growing to different sizes at different particle concentrations. This reduces variations in the minimum particle detection at high concentrations due to vapour depletion. More uniform droplet growth, paired with changes to the optical design and electronics signal detection enable the N-WCPC and GP-WCPC to measure concentrations up to $4x10^5$ particles/cm^3 and $2.5x10^5$ particles/cm^3 respectively in single-particle count mode.

The minimum detectable particle diameter of particle counters is typically defined as the diameter at which 50% of the particles are detected by the counter (D_{50}). The particle detection efficiency for a variety of particle types for each instrument is presented in Table 1. NaCl, a hydrophilic material has the lowest D_{50}. Silver (Ag) is a hydrophobic material and has a slightly higher 50% detection point. Sucrose is a neutral material on which the instrument specifications are based. It is interesting to note that the N-WCPC, which has the highest temperature differential (i.e. vapour pressure), exhibits the smallest degree of material dependence. This is similar to the results found by Wang et al 2010 for butanol CPCs.

Table 1. Minimum Particle Detection (D_{50})

Model	NaCl	Sucrose	Ag	ΔAg-NaCl
N-WCPC	2	2.5	4	2
GP-WCPC	3.5	5	7	3.5

Water as a working fluid poses a unique set of engineering challenges. Building from the successful first generation laminar-flow WCPCs, the 3788 and 3787 incorporate substantial engineering changes designed to ensure robust field performance. The air flow scheme is based on protected critical orifices to provide stable flow rates which are critical to concentration accuracy. The water handling system incorporates optimized wicking and active water removal. Remote accessible instrument diagnostics are also enhanced. A unique pulse height analyzer tracks the amplitude of the analogue pulses to monitor the instrument health and supersaturation rate as a safeguard for measurement accuracy.

The basic design of the instruments will be detailed, and several key performance parameters will be presented for each WCPC including concentration linearity versus a traditional butanol-based CPC, particle detection efficiency and instrument response time.

Session 12F: Atmospheric Applications of Aerosol Modelling

Model comparison between global and regional climate-aerosol models ECHAM5-HAM and REMO-HAM: European aerosols

J.-P. Pietikäinen[1,2,3], D. O'Donnell[1], M. Kulmala[4], D. Jacob[2,3] and A. Laaksonen[1]
[1]Finnish Meteorological Institute, P.O. Box 503, 00101 Helsinki, Finland
[2]Max Planck Institute for Meteorology, Bundesstraße 53, 20146 Hamburg, Germany
[3]Climate Service Center, Bundesstraße 45 a 20146 Hamburg, Germany
[4]Department of Physics, University of Helsinki, P.O.Box 44, 00014, Helsinki, Finland
Keywords: aerosols, climate modelling, sulfur dioxide, nucleation
Presenting author email: joni-pekka.pietikainen@zmaw.de

REMO-HAM is a regional climate-aerosol model, which can be used to investigate aerosol-cloud-climate interactions starting from 10 km grid resolution. The model is a hydrostatic, three-dimensional atmospheric model, that has been developed at the Max-Planck-Institute for Meteorology in Hamburg (Jacob, 2001). The aerosol model in REMO is based on the HAM-M7 aerosol module (Stier *et al*, 2005).

We have done simulations with REMO-HAM and global climate-aerosol model ECHAM5-HAM. The data from ECHAM5-HAM has been used as driving field on the boundaries of REMO-HAM. The meteorological fields, as well as the nudging fields for ECHAM5-HAM, are from the European Centre for Medium-Range Weather Forecasts (ECMWF) operational data. So far, the simulation have been done for the year 2005, taking into account the spin-up times of the models. The resolution for ECHAM5-HAM was T63L31 (horizontally ∼210 km), and for REMO-HAM we used two different resolutions: 0.44° (50 km) and 0.088° (10 km).

The physics and chemistry part of the aerosols is similar in both models. The main differences are coming from the dynamical core of the models (for example the advection of tracers). The main switches of the models are chosen to be as close to each other as possible. Moreover, both of the models are using the AEROCOM (http://nansen.ipsl.jussieu.fr/AEROCOM/) vertically dependent emission data.

The Fig. 1 shows the measured and modelled sulfur dioxide (SO_2) gas phase concentrations and the total number concentrations from Hyytiälä for the year 2005. We can clearly see that ECHAM5-HAM overestimates the SO_2 concentrations, whereas REMO-HAM follows the measurements throughout the year. From the total number concentrations, we can see that REMO-HAM seems to underestimate the concentrations, whereas ECHAM5-HAM does not differ significantly during the year 2005. Nevertheless, based on our analysis, the high SO_2 concentration leads to an overestimation of nucleation mode particles due to the used binary sulfate/water based nucleation.

The models have only an emissions based proxy for the secondary organic aerosols. Moreover, the boundary layer nucleation was not used during the simulations. These both would only increase the total number concentrations, and thus we believe that the results from REMO-HAM are actually more realistic than the ones from ECHAM5-HAM.

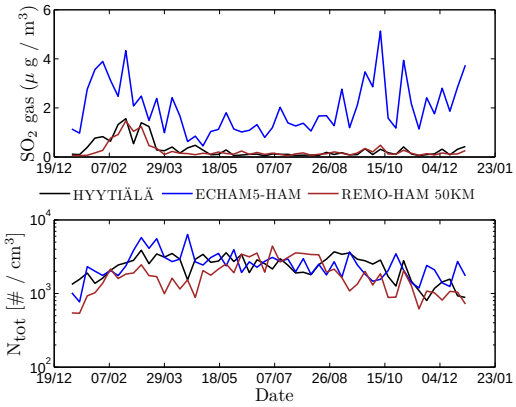

Figure 1: Measured and modelled gas phase sulfur dioxide (SO_2) concentrations as well as aerosol total number concentrations from Hyytiälä for the year 2005.

We have also done analysis for other measurement sites than Hyytiälä. The results from Melpitz, Mace Head and Jungfraujoch measurement sites show similar patterns as seen from the Fig. 1. Moreover, at the European scale, the spatial concentrations of nucleation mode particles seem to be too high in ECHAM5-HAM, especially in Northern Europe during the spring. Too high SO_2 concentrations increase the sulfuric acid (H_2SO_4) concentrations, which affects the nucleation rates directly.

In the future, we will concentrate on investigating the differences between the two models. The main focus will be in the gas phase SO_2 concentrations, H_2SO_4 formation, and in the nucleation. More detailed analysis and the main findings will be presented during the conference.

Development and Application of Two-Product Secondary Organic Aerosol Model Parameters Based on Volatility Basis Set Fits

K.C. Barsanti[1], A.G. Carlton[2] and S.H. Chung[3]

[1]Department of Civil & Environmental Engineering, Portland State University, Portland, OR, 97201, USA
[2]Department of Environmental Sciences, Rutgers University, New Brunswick, NJ, 08901, USA
[3]Department of Civil & Environmental Engineering, Washington State University, Pullman, WA, 99164, USA
Keywords: SOA, regional modeling, terpenes, volatility basis set.
Presenting author email: barsanti@cecs.pdx.edu

Historically, ambient mass concentrations of particulate matter (PM) have been underpredicted, presumably due to underprediction of the secondary organic component, secondary organic aerosol (SOA). A wealth of experimental and modeling studies have ensued in efforts to better understand the mechanisms of SOA formation and to develop accurate, yet computationally efficient SOA parameterization schemes. Most commonly, SOA formation is parameterized using the two-product (2p) approach of Odum et al. (1996), in which up to two lumped products are assumed to represent the condensable oxidation products of each VOC+oxidant system. Laboratory data from oxidation studies of individual VOC precursors are used to assign non-unique, empirically-derived partitioning parameters (K_p or C^*) and stoichiometric product yields (α) using a least-squares fitting approach. Partitioning parameter values obtained from studies conducted with very high initial VOC concentrations, which lead to very high SOA mass loadings relative to ambient conditions, may not represent lower volatility products, though such products may explain all SOA formation in low SOA mass loading experiments and in the atmosphere. Nonetheless, such parameters still are widely used to simulate ambient SOA formation in regional and global chemical transport models. In this work an effort is made to derive 2p parameters that better represent the current state of knowledge regarding SOA modeling by taking advantage of the fitting approach and data pooling of the more recently developed volatility basis set (VBS) parameterization (Donahue et al., 2006).

Two-product parameters based on VBS fits (2p-VBS) were obtained for ten SOA precursors, under low and high NOx conditions where appropriate, and for primary organic aerosol emissions. For the SOA precursors treated in CMAQ (Community Multiscale Air Quality model), simulations were performed using the 2p-VBS parameters and compared with simulations performed using the CMAQv4.7 parameters from Carlton et al. (2010). For some SOA precursors there are significant differences between the 2p-VBS and CMAQv4.7 parameters. To illustrate, predicted SOA mass concentrations as a function of amount of reacted hydrocarbon (ΔHC) are shown for monoterpenes under low NOx conditions using the 2p-VBS, default CMAQv4.7, and revised CMAQv4.7 parameters (for the revised parameters, a density correction was applied to α values). Perhaps the most important difference is the ΔHC level at which SOA formation is predicted to occur. To reach a level of 1 $\mu g\ m^{-3}$ of SOA, ΔHC = 3 (2p-VBS), 10 (CMAQ default), and 15 (CMAQ revised) ppb are required; the 2p-VBS predictions are more consistent with chamber data (e.g., Shilling et al., 2008), capturing SOA formation at low ΔHC. The method for obtaining 2p-VBS parameters and the results of their implementation in CMAQ will be presented, as well as a discussion on the linkages between experimental conditions, parameter optimization, and model output. Acknowledgement of the latter is critical to ongoing discussions of SOA model approaches and $PM_{2.5}$ measurements versus model simulations.

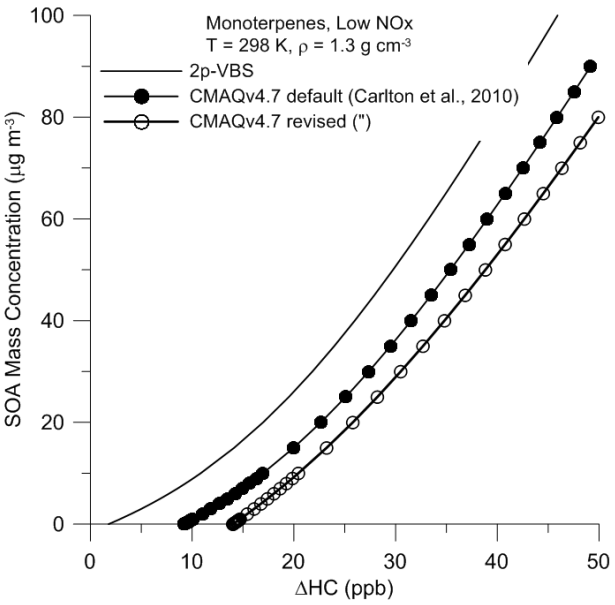

Figure 1. SOA mass concentration as a function of amount of reacted hydrocarbon (ΔHC) as predicted using 2p-VBS, default CMAQv4.7 and revised CMAQv4.7 parameters.

Models are being extensively used for diferent purposes in air quality management. Normally, the evaluation of model performance is carried out using information obtained at monitoring sites, and thus all the physical and chemical procesess involved in air pollutant concentration are evaluated in a global way. This means that errors in a certain process can be compensated with errors in another one, making difficult to decide on how the model is suceeding to represent individual procesess. Moreover, secondary organic aerosols have an additional uncertainty, as normally measurements at monitoring sites are not directly measured, but obtained from OC/EC relations.

Six experiments with biogenic organic precursors were carried out in the EUPHORE facility located in CEAM (Valencia, Spain) (Becker, 1996). Figure 1 illustrates de chamber when it is closed (left), being opened (center) and opened to sunlight (right).

Figure 1. EUPHORE facility: closed (left side of the figure), while opening (middle of the figure), and opened to sunlight (right side of the figure).

Experimental conditions are summarized in Table 1. Different mixtures of volatile organic compounds and HONO were introduced into the chamber at different relative-humidity values. Other experiments with anthropogenic precursors were also performed in 2008 (Vivanco and Santiago, 2010, Vivanco et al., 2011)

NO2	40		0/128	26.1		
HR	20%	20%	0%	20%	20%	35%

Multiple measurement techniques, such as Gas Chromatography coupled with Mass Spectrometer (GC-MS), Fourier Transform Infrared Spectrometry (FTIR), High Pressure Liquid Chromatography (HPLC), Gas Chromatography (GC-ECD and GC-FID/PID), Absorptive Sampling Solid Phase Microextraction (SPME) were used to monitor the gas concentration of reactants and products. Regarding the particle phase, aerosol concentration was monitored in an on-line way with a TEOM (Tappered Element Oscillating Monitor) and a SMPS (Scanning Mobility Particle Sizer).

Two models (CMAQ and CHIMERE) were applied in order to simulate the six experiments. Both models were modified to reproduce EUPHORE conditions. SOA formation is described in both models by the gas-particle partitioning theory, by which the formation of these aerosols is governed by the formation of a group of semivolatile compounds from the photochemical oxidation of certain biogenic and anthropogenic volatile organic compounds. Modeling results indicate that a general overestimation is found for both models. An example of how CMAQ and CHIMERE overestimates SOA recorded in the chamber is shown in Figure 2.

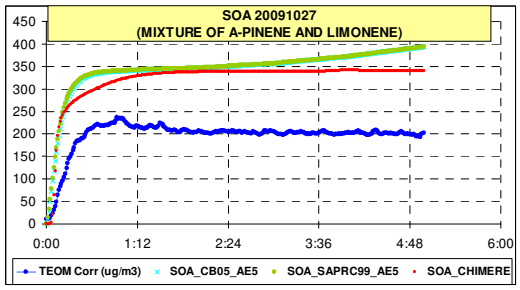

Figure 2. Observed and modelled SOA concentration for the experiment on 27102009. No isoprene was introduced that day into the chamber. CMAQ and CHIMERE results are presented in green and red, respectively. Blue line shows TEOM SOA concentration

We usually define as " nanoparticles ", those particles which present at least one dimension less than 100 nm. Several studies have measured different emission sources of nanoparticles, for indoor and outdoor air. It is also known that these particles are likely to have multiple effects on human health (Oberdörster *et al* (2005)).

INERIS, the french national institute for risk assessment, in collaboration with the Atmospheric Research Center (CEREA) of École des Ponts ParisTech, University Paris-Est of has begun the development of a numerical model for simulating nanoparticles dynamics in both confined and free atmospheres, in order to answer to forthcoming impact study requests.

Unlike existing models, a model of nanoparticles requires to follow the time evolution of both number and mass concentrations, as the number concentration is much more relevant for nanoparticles than mass concentration.

Nanoparticle dynamics mainly consists in coagulation, condensation/evaporation and nucleation, this latter process being a direct source of these particles. The former processes have to be corrected by the Van der Walls forces and the Kelvin effect.

This study focuses on these 0D processes which are usually solved in each cell of a host 3D chemical transport or CFD model. The particle size distribution, from 1 nanometer to 10 micrometers, is discretized into sections characterized by a fixed mean geometric diameter, particle properties are kept constant within each section. The main issue of this study is to find suitable algorithms to solve nanoparticle dynamics with the limited number of sections allowed in 3D models, while still remaining competitive for larger particles.

In this communication, we present the algorithms developed. Coagulation and condensation/evaporation are split in order to use well fitted algorithms for each process. In particular, condensation/evaporation is solved with a semi-lagrangian approach. We show that this approach involves a redistribution step which has to be carefully undertaken.

The abilities of the developed algorithms are tested with two different initial particle distributions, one representative of regional pollution (in hazy conditions) and another one representative of diesel engine emissions.

The results of five algorithms for condensationnal growth and evaporation taking Kelvin effect into account are compared to a reference in the next figures.

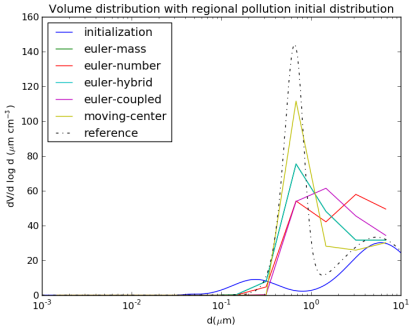

Figure 1: Volume concentration after three hours of simulation of condensationnal growth and evaporation with 12 sections, using the distribution from regional pollution.

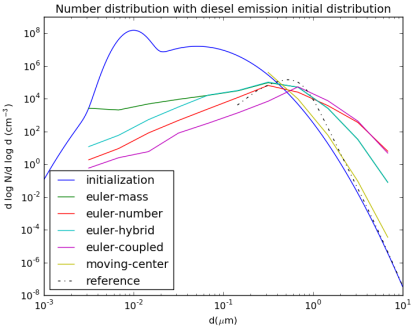

Figure 2: Number concentration (in logarithme scale) after three hours of simulation of condensationnal growth and evaporation with 12 sections, using the distribution from engine diesel emissions.

Chemical-transport-models provide an essential tool used for air quality forecasting and in performing emission control scenarios. However, their predictive power is limited by inaccuracies in the emission inventories, as well as by model process parameters. Receptor models provide a complementary means of constraining pollution sources and other factors influencing air quality. Positive matrix factorization has become popular because it does not require *a priori* information regarding source profiles.

In the study, the primary organic aerosol predictions from a chemical-transport-model were evaluated for air masses pre-classified based on high-resolution back trajectories and factor analysis. The high resolution chemical-transport-model domain (157x211, 2.5km grid spacing) corresponded to the Border Air Quality and Meteorology (BAQS-Met) study region in southern Ontario, Canada. Figure 1 and 2 illustrates the non-mobile and mobile PM_1 primary organic aerosol emissions in southern Ontario and the mid-west United States. The overarching goal of BAQS-Met was to understand the determinants affecting air quality in the Canadian-U.S. border region, particularly with respect to source emissions, chemical processing and transport. The study area experiences complex meteorology induced by the presence of the Great Lakes (e.g. lake breezes), thus, particular attention was paid to understanding the influence of local scale meteorology.

Aerosol mass spectrometer data were available at two rural sites and one urban site. The base model simulation assumed no evaporative PM2.5 POA combustion emissions. At the urban site (Windsor-Detroit air shed), the daytime model average value was 1.1 $\mu g/m^3$, which was very similar to the HOA factor mass concentration (Table 1). The similar values provides little support to the POA evaporation hypothesis presented in *Robinson et al. 2006*, at least to the extent as published.

At the rural sites, the model showed a negative bias for times sorted by influence from the Detroit-Windsor air shed. For times of regional scale pollution from mid-West U.S., the model showed a negative bias. The model showed largest POA biases at rural sites for light wind conditions, where the weight-of-evidence suggested stagnant conditions were over-emphasizing the importance of weak vertical mixing and over-estimated local emissions (area sources such as charcoal meat cooking and POA-incorporated into dust particle emissions and vehicle emissions allocated to near-by small towns). The model also under-predicted POA for a time period when factor analysis identified biomass burning emissions as important. However, this could be explained as forest fire emissions were not in the chemical-transport-model emission inventory.

Aqueous-phase chemistry and its interactions with gases and aerosols in COSMO-ART

C. Knote[1,2], D. Brunner[1,2] and U. Lohmann[2,3]

Wet scavenging and in-cloud chemistry are key processes affecting the lifetime and concentrations of soluble gases and aerosols in the atmosphere. In order to represent these processes in a regional chemistry-climate model, we have coupled a modified version of the comprehensive MESSy submodel SCAV (Tost *et al.*, 2006), originally developed for global models, to the model system COSMO-ART (Vogel *et al.*, 2009).

The submodel parameterizes wet scavenging of gases via simple Henry-constant equilibria or via a kinetic description of the transfer processes. Aerosol scavenging includes nucleation and impaction scavenging. Both gases and aerosols are scavenged by cloud droplets as well as by falling rain. The classical distinction between in-cloud and below-cloud scavenging in other models is therefore not applicable in SCAV, which in turn enables a more accurate description of "seeder-feeder"-type situations. Cloud droplet chemistry employs the MECCA mechanism (Sander *et al.*, 2005) with some additions from CAPRAM (Ervens *et al.*, 2003). The direct coupling to the aerosol module enables soluble aerosol components to dissolve into cloud droplets, where they can chemically interact with other components from the gas-phase. On evaporation of the cloud the dissolved components are released back to the aerosol phase into the accumulation mode. This essentially represents a "cloud-processing" of aerosols, transferring smaller Aitken-mode particle mass entering the cloud to the accumulation mode when leaving the cloud.

The SCAV scheme was developed for models on the global scale. Scavenging and aqueous-phase chemistry were carried out at each timestep. After that the cloud was artificially evaporated to prevent the need to introduce additional species to be transported within the cloud phase. This approach was reasonable for steps on the order of hours long enough for the species to reach equilibrium between the different phases. Regional-scale models like COSMO with horizontal resolutions of several kilometers, however, employ time steps on the order of seconds. Therefore we adapted SCAV for regional-scale modeling, including the prognostic transport of chemical species in cloud droplets and the partial evaporation of clouds according to the COSMO microphysics scheme.

The coupling of gas- and aerosol-phase species within SCAV distinguishes it from most other implementations of wet scavenging in regional chemistry transport models. The liquid-phase chemistry mechanism is implemented via KPP (Damian *et al.*, 2002) and therefore allows for facile extension to other reactions and species. Our coupling method provides this flexibility also in the combination with COSMO-ART.

Evaluating the original model version revealed a persistent underestimation of ammonium-sulfate aerosol mass, which we expect to disappear in the new version. Overestimations of gas-phase species concentrations found in the original version should also be decreased. Finally, by improving the representation of the aerosol size distribution through “cloud-processing”, the modeling system will be better suitable for climate-aerosol-cloud interaction studies.

In our presentation we will briefly review the scheme and the adaptations we made. We will then show results of idealized 0D and 2D simulations assessing correctness of the implementation and the impact on gas and aerosol concentrations. Finally, results of a 3D simulation including the new scheme highlight the effects of our modifications to the model system on the representation of ambient aerosol composition under realistic circumstances.
